DEDICATION

We dedicate the second edition of Nitrogen in the Marine Environment to our spouses, Linda Duguay, Bill Norton, Skip Stiles, and Gerdi Weidner, for their constructive input to this volume and to our children (Jennifer and Rebecca Capone, Zach, Zane and Zoë Norton, Maeve and Patrick Mulholland Stiles, Daniel Carpenter and Rachel Poccia) for enduring our endless conversations revolving around nitrogen and the oceans.

Foreword

A Timely Book for Interesting Times

Since the first edition of this book in 1983, several revolutions have occurred vis à vis scientific studies of the marine nitrogen cycle. Just consider some of the words and phrases, that appear in this edition but were unknown or seldom-used by marine scientists in 1983. Here are just a few: anammox, archaea, polymerase chain reaction, isotopomer, trace metal limitation. In 1983, we were in the early stages of just being able to properly enumerate the bacteria occurring in sea water. Now we talk about their inherent genetic capabilities of bacteria and archaea, and we are beginning to understand that viruses also play an important role. With respect to the oceanic fixed-N budget several source and sink terms have been increased several-fold, suggesting much more rapid turnover than envisioned in 1983. Thus this book appears at an ''interesting time'' vis à vis changes in our understanding of nitrogen in the marine environment.

While these massive changes in understanding would be more than sufficient to justify an update of the first edition, the articles in this book have perhaps a more important raison d'etre, because of the crucial role that nitrogen cycling plays in atmospheric chemistry and in aquatic productivity. In 1983, we were well aware that anthropogenic greenhouse gas emissions were likely to cause global warming, but it is probably fair to say that the prevailing view was of a process that involved gradual change. Now, we have ice-core data suggesting the possibility of massive climate change on sub-decadal time scales, and we are witnessing great perturbations in the marine ecosystem. In my view, the time is not far off when every scrap of understanding about marine ecosystems will be needed to help adapt to and mitigate global change. Because nitrogen plays such a key role, the chapters in this book are timely as a vehicle for accelerating understanding.

The editors and authors are to be commended for taking on the difficult task of providing a comprehensive update of the deliciously complex subject of nitrogen in the marine environment, and producing a timely book for interesting times!

Preface to Second Edition

The debut of the first edition of Nitrogen in the Marine Environment in 1983 chronicled the tremendous growth in knowledge concerning the cycling of nitrogen in the sea to that point and heralded the explosive expansion in work on oceanic nitrogen cycling that quickly followed (Fig. 1). Nitrogen in the Marine Environment, second Edition (long overdue!) is the natural witness to that growth. The page count alone has doubled relative to the original edition, and this edition is still insufficient to cover all the threads of ongoing research on nitrogen in the sea.

Unprecedented discoveries over the last decade have changed the way we view the marine nitrogen cycle. These include the recognition that phytoplankton in the sea are not uniformly limited by nitrogen, and that the critical limiting nutrient or nutrients (we now recognize co-limitation) vary within and among systems as a result of differences in external forcings and the biogeochemically important functional groups present and consequently selected. The critical role of picoplankton in marine ecosystems and biogeochemical cycles (including nitrogen dynamics) is now well established.

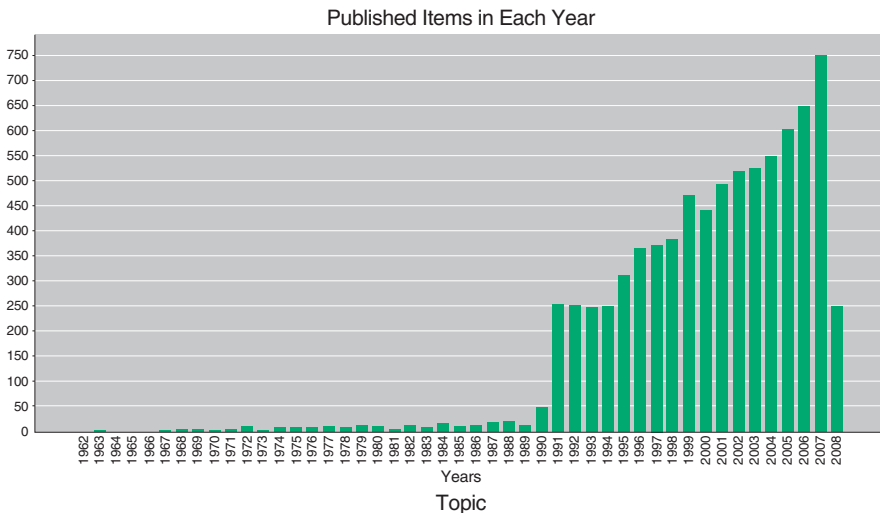
Published Items in Each Year


Figure 1. Number of papers by year with topics including "nitrogen and marine or nitrogen and ocean" from the Web of Science database. We assume the jump in citation rate from 1989 to 1991 represents changes in the data base itself (e.g., new journals included) rather than being a result of publication of the first edition of Nitrogen in the Marine Environment. The steady growth from 1992 is evident, and the number of papers doubled from 1993 to 2003.

We have gained a new appreciation of the diversity and the quantitative importance of marine nitrogen fixers. We now recognize the significance of Archaea and the processes they mediate (e.g., nitrification) and the importance of anammox bacteria in some marine ecosystems. In addition, our traditional view of just who does what in the marine nitrogen cycle is shifting as we discover that taxonomic groups often don't fit squarely into the functional group they've been assigned and furthermore that the biogeochemical roles of bacteria and phytoplankton often overlap. Even our understanding of what constitutes the labile fraction of the dissolved nitrogen pool has changed. We have identified and begun to quantify how many previously unrecognized biotic and abiotic processes affect the marine nitrogen cycle (e.g., extracellular enzymes, use of novel dissolved organic nitrogen compounds, photochemical processes, etc.). This illustrates just how much we have learned and are still discovering about the marine N cycle. We could go on—that's why the book is so long!

Numerous factors have fueled this revolution. Perhaps first and foremost is the appreciable growth of practitioners in this field bringing new tools and unique perspectives. This growth has occurred in tandem with the arrival of new technologies enabling us to address questions we couldn't even imagine or articulate two decades ago. Advances in molecular biology, analytical techniques, remote sensing, sensor technology, and computational methods and power have all had an impact. Moreover, with the burgeoning availability of time-series data sets, these diverse factors have synergistically led to the steady expansion of data collection and synthesis over the last twenty plus years. We have developed the capacity and infrastructure to measure more things in greater numbers and at lower cost.

The pace of discovery continues to accelerate. So what does the future hold? We believe we can safely predict that our resolution of the temporal and spatial scales of variability of the populations and processes relevant to understanding the nitrogen cycle will steadily increase with the improvement and deployment of moored arrays and remote observation systems with novel nutrient and biological sensors. Numerous metagenomic surveys are underway and the prospect that novel organisms and pathways will be revealed is practically a given. Such novel observations will inform and stimulate a new generation of experimentalists as well.

Alarmingly, the sea itself is changing at an unprecedented rate, in large part due to human influences. Increasing CO_2 concentrations, temperatures, coastal eutrophication, atmospheric nitrogen deposition, and decreasing pH will continue or even accelerate over the upcoming decades. What does this portend for the marine nitrogen cycle? What feedbacks within the system may minimize or aggravate the nature and rate of changes in marine ecosystems? Can, and should, the marine nitrogen cycle be manipulated to mitigate these changes? These are all questions on the table to be addressed by current and future cohorts of marine "azotonauts."

We expect the third edition will necessarily follow soon!

THE MARINE NITROGEN CYCLE: OVERVIEW AND CHALLENGES

Nicolas Gruber

Contents

1. INTRODUCTION

The marine nitrogen cycle is perhaps the most complex and therefore the most fascinating among all biogeochemical cycles in the sea. As a limiting element for biological productivity, nitrogen occupies a central role in ocean biogeochemistry, exerting a significant influence on cycles of many other elements, in particular carbon
Figure 1.1 Schematic representation of the marine nitrogen cycle and its coupling to the marine cycles of oxygen, phosphorus, and carbon. Of particular importance are the processes of nitrogen fixation and denitrification, which make the fixed nitrogen content of the ocean open to biologically mediated changes.

and phosphorus (see Fig. 1.1). Nitrogen exists in more chemical forms than most other elements, with a myriad of chemical transformations that are unique to this element. Nearly all these transformations are undertaken by marine organisms as part of their metabolism, either to obtain nitrogen to synthesize structural components, or to gain energy for growth. Although most chemical forms of nitrogen in the ocean are bioavailable, the most abundant chemical form, dissolved nitrogen gas (N_2), is generally not. To emphasize this distinction, one often refers to all forms of nitrogen, except N_2, as *fixed* nitrogen. The general unavailability of N_2 for marine organisms gives the two biological processes of N_2-fixation, i.e. the conversion of N_2 to organic nitrogen, and denitrification, i.e. the conversion of nitrate to N_2, a particular importance. The balance of these two processes determines to first order the size of the oceanic inventory of bioavailable nitrogen, and consequently marine productivity. Marine biological processes in interaction with ocean transport and mixing control also the spatio-temporal variations of the various forms of fixed nitrogen within the ocean.

The primary engine that drives these ocean interior variations is the photosynthetic fixation of carbon into organic matter by marine phytoplankton in the light-illuminated upper ocean (euphotic zone) (see Fig. 1.1). Along with carbon, nutrient elements such as nitrogen, phosphorus, iron and many others are taken up and assimilated. Most of the resulting organic matter is either respired or remineralized

in the euphotic zone, but a fraction of it escapes remineralization and is exported into the dark interior ocean (aphotic zone). There, it is remineralized back to its inorganic forms. Finally, these inorganic forms are transported back to the euphotic zone by ocean circulation and mixing, where they can fuel new growth. This coupling between biological and physical processes thus forms a large-scale biogeochemical loop that controls the distribution of nearly all biogeochemically active chemicals in the ocean. I use the expression ''loop'' here instead of the more commonly used term ''biological pump,'' as ''loop'' emphasizes the coupling between the biologically driven downward transport of organic matter and the physically controlled upward transport of inorganic constituents. As a result of this loop, surface concentrations of the inorganic forms of chemicals, particularly limiting nutrients, are low, while the deep ocean is enriched in these inorganic forms. Concomitantly, the concentrations of organic forms, both particulate and dissolved, are high in the near-surface ocean and tend to decrease rapidly with depth.

This biologically driven biogeochemical loop is fundamental for Earth's climate, as it is one of the processes that determines the concentration of CO_2 in the atmosphere. If this biogeochemical loop were eliminated today, atmospheric CO_2 would raise by more than 200 parts per million (ppm) (Gruber and Sarmiento, 2002). Conversely, if biology became completely efficient in drawing down surface nutrients and exporting the fixed nutrients and carbon to depth, atmospheric CO_2 would fall by more than 100 ppm. Therefore, not surprisingly, changes in the strength of this loop have been invoked from the very beginning as a possible explanation of the large swings in atmospheric CO_2 that occurred over the past million years in association with the glacial–interglacial cycles (e.g., Brzezinski *et al.* (2002); Martin (1990); Sarmiento and Toggweiler (1984); Siegenthaler and Wenk (1984)). Given the key role of nitrogen as a nutrient that limits biological productivity, the hypothesis that alterations of the total amount of fixed nitrogen in the ocean have caused changes in productivity and consequently atmospheric CO_2 is tantalizing (Altabet *et al.*, 1995, 2002; Broecker and Henderson, 1998; Falkowski, 1997; Ganeshram *et al.*, 1995; McElroy, 1983). However, as will be discussed later in this chapter, there are several arguments casting doubts on this hypothesis (see also Gruber (2004) and Chapter 34 by Galbraith *et al*, this volume).

Interest in the marine nitrogen cycle has soared in the last decade, owing to several converging factors. First is the growing recognition that the immense acceleration of the global nitrogen cycle by humans, largely driven by the fabrication of nitrogen fertilizers from atmospheric N_2 and its subsequent application on agricultural soils (Galloway *et al.*, 2004), is changing not only terrestrial ecosystems and freshwater systems, but increasingly also coastal ecosystems (e.g., Beman *et al.* (2005)). The magnitude of this acceleration becomes evident when one considers that the amount of N_2 fixed each year by industrial processes is of similar magnitude as the amount of nitrogen fixed biologically (Falkowski *et al.*, 2000; Galloway *et al.*, 1995, 2004).

A second factor that has furthered interest in the marine nitrogen cycle is the solidifying evidence that the magnitude of marine N_2 fixation is much larger than was thought 20 years ago when the first *Nitrogen in the marine environment* book was published (see e.g., Capone (2001), Capone *et al.* (2005), Gruber (2005), and Mahaffey *et al.* (2005)). The most recent estimates for global N_2 fixation imply a mean residence

time of fixed nitrogen in the ocean of a few thousand years only (Gruber, 2004), an order of magnitude shorter than that of phosphorus, whose residence time is of the order of several tens of thousands years (Delaney, 1998). This makes the marine nitrogen cycle very dynamic and at the same time susceptible to substantial changes, unless there exist strong negative feedbacks that prevent the marine nitrogen cycle from undergoing large swings. A second consequence of the high rates of N_2 fixation is the recognition that the supply of new nitrogen by N_2 fixation to nitrogen stressed regions of the surface ocean could rival that supplied from below by physical processes (Karl *et al.*, 1997; Capone *et al.*, 2005). This makes N_2 fixation an important player for structuring marine ecosystems in such regions, with substantial implications for how carbon is cycled through the system and what fraction of it is exported.

The third and last factor is the growing concern over how marine biology and the marine nitrogen cycle may respond to future climate change and by their response either accelerate (positive feedback) or decelerate global change (negative feedback) (see e.g., Gruber *et al.* (2004), Gruber and Galloway (2008) or Chapter 35 by Berman-Frank *et al.,* this volume). Of particular concern is the likely decrease of the ocean interior oxygen concentration, which is bound to increase denitrification, and through the resulting decrease in the oceanic nitrogen inventory will lower marine productivity. This would cause a release of natural CO_2 from the ocean, thereby accelerating the CO_2 increase in the atmosphere and the resulting warming. In addition, a decrease in the ocean interior oxygen content will also likely increase the production and release of nitrous oxide, which is a much more powerful greenhouse gas than CO_2. Therefore, since both these changes would lead to an acceleration of the warming, the marine nitrogen cycle could act as a significant positive feedback factor in a warming world.

This chapter serves as an introduction to the rest of this book, and in many places, the reader is referred to relevant chapters for further details. The focus here is on providing an overview of the most important pools of nitrogen, their transformations, their distribution, and their connection to the cycling of other biogeochemically relevant elements, primarily carbon, oxygen, and phosphorus. The scale is global, as subsequent chapters (Chapters 11–22) cover individual ocean basins and systems. I will also address a series of nitrogen challenges, such as the question of how the marine nitrogen cycle appears to be able to maintain a relatively well established homeostasis, i.e., a balance between gains and losses of fixed nitrogen. Finally, I will discuss the anthropogenic perturbation of the marine nitrogen cycle. As we will see, however, the answers to many of these questions remain elusive, reminding us how little we know about the marine nitrogen cycle, and how much still remains to be discovered.

2. Overview of Forms, Pools, and Reactions

2.1. The electronic diversity of Nitrogen

With 5 relatively stable oxidation states in the marine environment (Fig. 1.2), nitrogen is very distinct from most other nutrient elements. For example, phosphorus, which has the same number of valence electrons, exists in the marine
Figure 1.2 Major chemical forms and transformations of nitrogen in the marine environment. The various chemical forms of nitrogen are plotted versus their oxidation state. Processes shown in grey occur in anoxic environments only. See text and Table 1.1 for further details.

environment almost exclusively as ortho–phosphate, i.e., as PO_4^{3-} with an oxidation state of +V. Silicon also exists in the ocean primarily in the +IV oxidation state, i.e., as $Si(OH)_4$ or SiO_2 (opal). By contrast, nitrogen can be found in the marine environment as nitrate, NO_3^-, with an oxidation state of +V, nitrite, NO_2^- (+III), nitrous oxide, N_2O (+I), molecular nitrogen, N_2 (O), and ammonia, NH_4^+ (-III). In addition, there are a myriad of organic compounds containing nitrogen, most often in the form of amino–groups in the -III oxidation state (see also Chapter 3 by *Aluwihari and Meador*, this volume). Only carbon exhibits a similar range of oxidation states, from -IV in CH_4 to +IV in CO_2. The basis for the large number of stable oxidation states for nitrogen is its electron configuration, with two of its five valence electrons filling up the 2s orbital and each of the remaining three valence electrons occupying one of the three 2p orbitals. This gives a total electron configuration of $1s^2\ 2s^2\ 2p^3$. Stable oxdiation states, i.e., a noble gas-like electron configuration, can therefore be achieved if either all five valence electrons are "removed," giving an oxidation state of +V, or if five electrons are added, giving an oxidation state of -III. The ionization energy for the removal of the five valence electrons is relatively small, so that the gain from forming co–valent bonds can compensate easily for this energy. This provides an explanation for the relative stability of NO_3^-, and NH_4^+, but it does

not explain the stability of species such as NO_2^-, N_2 or N_2O. However, when considering the reactivity of a compound in the natural environment, one also needs to take into account its bonding energy as well as the activation energy needed to overcome an existing covalent bond.

For nitrogen, the basis for forming stable covalent bonds with other atoms is in most cases the hybridization of its outer s and p orbitals to form either four sp^3 hybrid orbitals or three sp^2 orbitals. In the sp^3 case, the 5 electrons are distributed such that a pair of electrons occupy an unshared sp^3 orbital, while the other three are shared with another atom through covalent bonds. In the case of the sp^2 orbitals, the third p orbital can be used to form π orbitals, which then permits the atom to form double and triple bonds. It is this flexibility, plus the much higher strength of the covalent bonds in the compounds that have double or triple bonds, such as occurs in NO_2^-, N_2 and N_2O, that make so many species of nitrogen stable in the marine environment. Phosphorus shares many of the same characteristics as nitrogen, but because it has 10 more electrons, which occupy the lower orbitals, the energy of many covalent bonds is much lower. Furthermore, these lower orbitals strongly restrict the formation of π orbitals, so that neither silicon nor phosphorus can easily form double or triple bonds. As a result, silicon and phosphorus exist in the marine environment primarily in just one oxidation state.

In summary, the presence of a large number of stable oxidation states for nitrogen in the environment is a result of nitrogen having five valence electrons as well as it being small, giving its electron orbitals a lot of flexibility to rearrange themselves. It is interesting to point out that when comparing carbon, silicon, nitrogen, and phosphorus, the spatial flexibility of the electron orbitals in the smaller elements (carbon, nitrogen) is more important than the number of valence electrons. As a result, nitrogen behaves more like carbon, which has one valence electron less, and less like phosphorus that has the same number of valence electrons.

2.2. The major reactions

The many oxidation states of nitrogen in the marine environment and the resulting large number of nitrogen species give rise to many redox reactions that transform one species to another (Fig. 1.2). In today's ocean, all of the major reactions are mediated by biology, either in association with assimilatory or dissimilatory functions of the involved marine organisms. As discussed in more detail by Berman-Frank *et al.* (Chapter 35, this volume), this was not always the case in Earth's history. For example, biological N_2 fixation evolved much earlier on Earth than biologically driven denitrification (Falkowski 1997).

The most important biologically mediated reactions are summarized in Table 1.1 together with information about the redox environment these reactions take place in, the organisms that are usually conducting these processes, and what biochemical role these processes play for these organisms. I briefly discuss these reactions, but refer to the following chapters for details (see also Table 1.1). For a discussion of a series of additional reactions (e.g. Oxygen-Limited Autotrophic Nitrification-

Table 1.1 Summary of the most important biologically mediated processes transforming nitrogen in the ocean

Process	Organisms	Redox environment	Trophic status	Biochemical role	Chapter
NO_3^- assimilation	Phytoplankton	Aerob	Photo–autotrophic	Source of N	7
NO_2^- assimilation	Phytoplankton	Aerob	Photo–autotrophic	Source of N	7

Denitrification, OLAND), the interested reader is referred to the review by Brandes et al. (2007).

The *assimilation of nitrate or ammonium* into organic nitrogen by marine phytoplankton in order to satisfy their nitrogen demand for growth is the process that quantitatively dominates the marine nitrogen cycle. NH_4^+ is thought to be the preferred source of fixed nitrogen for phytoplankton, because its assimilation does not involve a redox reaction and therefore requires little energy (Zehr and Ward, 2002). It is therefore not surprising that all phytoplankton can grow on NH_4^+ as the only nitrogen source. By contrast, the assimilation of NO_3^- involves the reduction of nitrogen from an oxidation state of $+V$ to $-III$, i.e., the transfer of eight electrons, which requires the investment of a substantial amount of energy. Since NO_3^- in the ocean is generally much more abundant that NH_4^+ (see below), most phytoplankton have the enzymes necessary to undertake this reduction (nitrate reductase), with a few notable exceptions. The best studied organisms lacking the ability to use NO_3^- as a nitrogen source are Prochlorococcus and certain strains of Synechococcus (Moore *et al.*, 2002). All phytoplankton that can use NO_3^- can also use NO_2^- as a source of nitrogen. This is because NO_2^- is an intermediary product during the assimilation of NO_3^-. However, NO_2^- is usually only a very minor source of nitrogen for phytoplankton, as its concentration is often an order of magnitude lower than that of NO_3^- or NH_4^+ (see below).

The assimilation of nitrogen by phytoplankton is strongly linked to the photosynthetic fixation of carbon, because both elements are needed in order to build living organic tissue. The same applies to the assimilation of phosphate. Since most phytoplankton appear to have a relatively fixed cell quota for protein, lipids, carbohydrates, and DNA/RNA (see e.g., Hedges *et al.* (2002)), they tend to take up these different elements with a relatively fixed ratio, permitting us to write the synthesis of organic matter by the coupled assimilation of CO_2, NO_3^-, and PO_4^{3-} as:

$$106CO_2 + 16NO_3^- + HPO_4^{2-} + 78H_2O + 18H^+ \Rightarrow$$
$$C_{106}H_{175}O_{42}N_{16}P + 150O_2 \quad (1.1)$$
and in the case when NH_4^+ is used as nitrogen source:

$$106CO_2 + 16NH_4^+ + HPO_4^{2-} + 48H_2O + 14OH^- \Rightarrow$$
$$C_{106}H_{175}O_{42}N_{16}P + 118O_2 \quad (1.2)$$
where $C_{106}H_{175}O_{42}N_{16}P$ denotes the average composition of organic matter in phytoplankton, and where I used the stoichiometric ratios of Anderson (1995). Note that these ratios differ from those originally proposed by Redfield *et al.* (1963), in particular with regard to the production of O_2. The uptake of NO_3^- and NH_4^+ has a notable impact on the photosynthetic quotient (PQ), i.e., the stoichiometric ratio between the uptake of CO_2 and the release of O_2, with the uptake of NO_3^- having a PQ of 1.4 and the uptake of NH_4^+ having a PQ of 1.1 (*cf.* Laws (1991)).

It is important to recognize that the stoichiometric ratios used in Eqs. (1.1) and (1.2) are averages, and that any given phytoplankton sample may deviate substantially

from these mean ratios (see e.g., Klausmeier *et al.* (2004) and discussion in Chapters 37 and 38). However, water column data suggest that when averaged sufficiently over space and time, these ratios hold up remarkably well (e.g., Takahashi *et al.* (1985)). As I will demonstrate below, the concept of constant stoichiometric ratios, often termed *Redfield ratio concept*, is very powerful to investigate and understand the large-scale distribution of nitrogen species in the ocean, and how their distribution is linked to that of other elements, in particular carbon and phosphorus.

Most of the fixed organic nitrogen in the ocean is returned back to nitrate by remineralization processes. This occurs in three distinct steps: *ammonification, ammonium oxidation, and nitrite oxidation*, where the latter two processes in combination are often referred to as *nitrification* (see Fig. 1.2 and Chapter 5 by Ward, this volume). Ammonification is the reverse process of the NH_4^+ assimilation reaction (1.2), i.e., the transformation of organic nitrogen to NH_4^+. Most of this process is done by heterotrophic bacteria, which use the oxidation of organic carbon to CO_2 as a source of energy, but release the organic nitrogen then as NH_4^+ as they lack the ability to oxidize it to NH_4^+ or NO_3^-. This latter step is undertaken by a specialized group of bacteria, which are using the oxidation of NH_4^+ to NO_3^- as a source of energy, i.e., they are chemo–autotrophic. The two steps of nitrification, the oxidation of NH_4^+ to NO_2^-, and the oxidation of NO_2^- to NO_3^- are most often done by two distinct groups of organisms. The best known are *Nitrosomonas spp*, an ammonium oxidizer, and *Nitrobacter spp*, a nitrite oxidizer. Nitrification requires the presence of O_2 and tends to be inhibited by light, which has important implications for the upper ocean nitrogen cycle, as I will discuss below. To summarize, the following three distinct reactions remineralize organic nitrogen to nitrate:

The heterotrophic process of ammonification, which is the return pathway of NH_4^+ assimilation (reaction 1.2):

$$C_{106}H_{175}O_{42}N_{16}P + 118\ O_2 \Rightarrow 106CO_2 + 16NH_4^+ \\ + HPO_4^{2-} + 48H_2O + 14OH^- \tag{1.3}$$
and the two processes of aerobic nitrification, i.e., ammonium oxidation, and nitrite oxidation:

$$2NH_4^+ + 3O_2 \Rightarrow 2NO_2^- + 4H^+ + 2H_2O \tag{1.4}$$

$$2NO_2^- + O_2 \Rightarrow 2NO_3^- \tag{1.5}$$

The vast majority of the oxidation of organic matter follows reaction (1.3) involving oxygen as the terminal electron acceptor. Most higher organisms are strict aerobes, i.e., they cannot switch to another oxidant, and therefore cannot live in the absence of free oxygen. In contrast, most bacteria are more flexible and can use a wide range of other electron acceptors, including sulfate, manganese, and iron. However, the first electron acceptor that is generally being used by bacteria in the ocean is NO_3^-, resulting in a process called *denitrification*. The preference of NO_3^- over other electron acceptors is because of the higher energy yield of

denitrification in comparison to the use of the alternative oxidants. Using organic matter with the stoichiometry shown in (1.1), heterotrophic denitrification can be written as:

$$C_{106}H_{175}O_{42}N_{16}P + 104NO_3^- \Rightarrow 106CO_2 + 60N_2 + H_3PO_4 + 138H_2O$$

$$(1.6)$$

Another anaerobic process that removes bio-available nitrogen from the water is the anaerobic oxidation of ammonium (*Anammox*), in which ammonium and nitrite are combined to form N_2, thus

$$NO_2^- + NH_4^+ \Rightarrow 2N_2 + 2H_2O \qquad (1.7)$$
In contrast to denitrification, the Anammox reaction is used as a source of energy, i.e., the Anammox bacteria are chemo-autotrophic (Strous *et al.*, 1999). This process, first uncovered in wastewater bioreactors, has been demonstrated to occur in marine environments only very recently (see e.g., Kuypers *et al.* (2003) and Dalsgaard *et al.* (2003)). Its quantitative significance is not known yet on a global scale, but a recent study suggested that anammox rather than canonical denitrification is the primary process causing the fixed nitrogen loss in the oxygen minimum zone of the Benguela upwelling system (Kuypers *et al.*, 2005). It is unlikely that this conclusion can be easily extrapolated, since the requirement for NO_2^- in an anoxic environment means that another process must supply this reactant. The most likely candidate is the partial denitrification of NO_3^-, which means that the anammox bacteria tend to have to compete with denitrifying bacteria for the same resources. But given how little we know about this process and the associated organisms, there is ample room for surprises.

From a geochemical perspective, denitrification and anammox have the same implication, i.e., they both lead to a loss of fixed nitrogen from the ocean, albeit with a somewhat different stoichiometry. This loss requires a counterbalancing source elsewhere if fixed nitrogen in the ocean is to be maintained at roughly constant levels through time.

The most important source for fixed nitrogen in the ocean is *biological N_2 fixation*, which refers to the conversion of N_2 into organic nitrogen. It is undertaken in the ocean primarily by photoautotrophic organisms in order to obtain nitrogen in environments where fixed nitrogen is usually exhausted. The most conspicuous and best studied N_2 fixing organism (diazotroph) is *Trichodesmium* (Capone *et al.*, 1997), although there are many other organisms known to fix nitrogen, including uni-cellular bacteria (Zehr *et al.*, 2001), and cyanobacteria that live endosymbionti-cally within marine diatoms (e.g., Carpenter *et al.* (1999)). The magnitude of marine N_2 fixation has been a topic of intense research and discussion in the last two decades (see e.g., Capone (2001)). In particular, the extent to which the oceanic fixed nitrogen budget is actually in balance is controversial at present, as I will discuss below (e.g., Codispoti (2006); Codispoti *et al.* (2001); Codispoti and Christensen (1985); Gruber (2004); Gruber and Sarmiento (1997); McElroy (1983)).

Organic nitrogen is seldom completely converted to NO_3^- or N_2 during either nitrification or denitrification. Some small fraction ends up as nitrous oxide, N_2O

(Fig. 1.2), most of which escapes to the atmosphere (see Fig. 1.1 as well as Chapter 2 by Bange, this volume). Nitrous oxide acts as a greenhouse gas that is more than 200 times more potent than CO_2 (Ramaswamy *et al.*, 2001). Therefore variations of this gas in the atmosphere can lead to changes in Earth's temperature and climate. Since the oceanic emission of N_2O constitutes a substantial fraction to the total emission of N_2O into the atmosphere, N_2O provides for a direct potential link between the ocean nitrogen cycle and Earth's climate.

In the case of aerobic remineralization, the formation of N_2O is associated with the oxidation of ammonium during nitrification (see Fig. 1.2). Nitrous oxide is also formed during denitrification, as it represents an intermediary product during the reduction of NO_3^- to N_2 (Fig. 1.2). If some of this N_2O escapes the further reduction to N_2, denitrification can act as a source of N_2O. At the same time, denitrification can act as a sink for N_2O in cases where N_2O produced elsewhere is transported into a region of active denitrification. The overall balance generally is believed to be positive, i.e., denitrification is thought to act as a net source of N_2O (Suntharalingam *et al.*, 2000). The relative importance of the two production pathways is still debated, but it appears as if the majority of the N_2O in the ocean is formed in association with nitrification (Jin and Gruber, 2003; Nevison *et al.*, 2003; Suntharalingam and Sarmiento, 2000). However, given the much higher yield of N_2O at low oxygen concentrations, the production is biased toward the low oxygen regions of the world ocean.

2.3. Inventories and residence times

Table 1.2 shows a summary of the oceanic inventories of the major forms of nitrogen in the ocean and their estimated residence times with regard to key processes or the ocean fixed nitrogen inventory as a whole.

By far the largest amount of nitrogen in the ocean (about 1×10^7 Tg N, or about 94%) exists in the form of biounavailable N_2. The majority of the remaining fixed forms of nitrogen occurs as NO_3^- (about 88%), followed by *DON*, which makes up nearly all of the remaining 12%. The other forms, *PON*, NO_2^-, NH_4^+, and N_2O have similar oceanic inventories, but together represent less than 0.3% of the total fixed nitrogen pool. The dominance of N_2 in the ocean is entirely due to its inertness, as the thermodynamically most stable form would be NO_3^-. This explains its high abundance relative to NO_2^- or NH_4^+, but the high inventory of *DON* is remarkable, since one would expect that organic nitrogen is remineralized relatively rapidly. However, as will be discussed by *Aluwihare and Meador* in Chapter 3, certain constituents of *DON* are very refractory.

The different nitrogen species differ by more than 6 orders of magnitude in terms of their turnover times. Due to its large inventory and its inertness, the turnover time of dissolved N_2 with respect to N_2 fixation and/or denitrification is by far the longest, i.e., more than 50,000 years. By contrast, NO_3^- in the ocean gets turned over two orders of magnitude faster, i.e., once every 400 years. Due to their much smaller inventories and even larger turnover rates, NH_4^+ and *PON* have an even shorter turnover time, amounting to one to two weeks only. The estimated turnover time for *DON* is about 20 years, but this represents a mean turnover time for bulk *DON*. In

Table 1.2 Oceanie Inventory, Turnover Rates, and Residence Times for the Major Fixed Nitrogen Species in the Ocean

Species	Mean conc. euphotic zone (mmol m^{-3})	Mean conc. aphotic zone (mmol m^{-3})	Oceanic inventory (Tg N)	Turnover rate[i] (Tg N yr^{-1})	Turnover time (years)
Nitrate, NO_3^- [a]	7	31	5.8×10^5	1,570	370
Nitrite, NO_2^- [b]	0.1	0.006	160		
Ammonium, NH_4^+ [c]	0.3	0.01	340	7,000	0.05
Dissolved Organic N, DON [d]	6	4	7.7×10^4	3,400	20
Particulate Organic N, PON [e]	0.4	0.01	400	8,580	0.05
Nitrous oxide, N_2O [f]	0.01	0.04	750	6	125
Fixed Nitrogen[g]			6.6×10^5	200	3,300
Nitrogen gas, N_2 [h]	450	575	1×10^7	200	54,000

[c] Average profile from 4 process studies of the Joint Global Ocean Flux Study data, see also Fig. 1.3. Estimated uncertainty about ±20%.
[d] Based on Bronk (2002) with an uncertainty of about ±30%. Turnover rate based on her estimate that about 40% of N uptake by phytoplankton ends up as DON.
[e] Based on Sharp (1983) with an uncertainty of about ±50%.
[f] Based on Nevison *et al.* (2003) with an uncertainty of about ±20%.
[g] Sum of NO_3^-, NO_2^-, NH_4^+, *DON*, *PON*, and N_2O.
[h] Computed from global temperature and salinity distribution (WOA01) assuming 100% saturation. Estimated uncertainty about ±10%.
[i] See Fig. 1.14 for sources of rate estimates.

reality, the different components of *DON* have been estimated to have turnover times from a few minutes to many hundreds of years (Bronk, 2002). N_2O has a remarkably long residence time of about 125 years. This primarily reflects the absence of strong oceanic sinks for N_2O, as only the loss to the atmosphere and reduction to N_2 in anoxic regions can remove N_2O from the ocean once it has been produced.

3. DISTRIBUTIONS AND PROCESSES

3.1. Global mean profiles

Sufficient data for computing global mean profiles for nitrogen species exist only for NO_3^- and NO_2^-. An approximation for a global mean profile for NH_4^+ can be obtained by simply averaging all available data, which are somewhat unevenly
Figure 1.3 Global mean profiles of NO_3^-, NO_2^-, and NH_4^+ (A) for the entire water column (0–6000 m), and (B) for the upper 300 m only. Note that the NH_4^+ and NO_2^- concentrations were multiplied by a factor of 100 to see their variations. The NO_3^- profile is based on data from the World Ocean Atlas 2001 (Conkright *et al.*, 2002). The NO_2^- profile was computed by averaging all data from the World Ocean Circulation Experiment (data taken from whpo.ucsd.edu). The NH_4^+ profile is based primarily on data from the Arabian Sea, the Southern Ocean, the North Atlantic, and the Equatorial Pacific (using data from the Joint Global Ocean Flux Study (JGOFS) available at usjgofs.whoi.edu) and augmented by data from a few sites provided by the GLOBEC program (www.usglobec.org).

distributed, but cover the most important regions of the world's ocean. N_2O will not be discussed here, as it is the main focus of Chapter 2 by Bange, this volume.

The mean vertical profiles of NO_3^-, and NO_2^- show a very different behavior (Fig. 1.3). Nitrate exhibits the expected near-surface depletion and enrichment at depth driven by the biogeochemical loop (biological pump). In contrast, NO_2^- and NH_4^+ show a maximum around 50 to 80 m, i.e., in the lower parts of the euphotic zone, and rapidly decreasing concentrations below that depth. This distribution as well as their much lower mean concentrations reflect their status as intermediary nitrogen species, i.e., species that are both rapidly produced and consumed through-out the water column. These two labile species accumulate only to an appreciable level when their generation rate overwhelms their consumption. For NH_4^+ this occurs generally somewhere in the deeper parts of the euphotic zone, where organic nitrogen is rapidly remineralized, liberating large amounts of NH_4^+, but where NH_4^+ uptake by phytoplankton may be limited already by light. Near the bottom of the euphotic zone or below, where light levels are low enough for nitrification to escape light inhibition, part of this NH_4^+ is oxidized to NO_3^-, creating NO_2^- alongside. NO_2^- is also created as an intermediary product higher up in the euphotic

zone during the assimilation of NO_3^-. In the aphotic zone, neither NO_2^- nor NH_4^+ occur at any appreciable level, as they tend to be rapidly converted to NO_3^- by nitrification. An exception are the low oxygen regions, as discussed below.

3.2. Nitrate

3.2.1. Surface distribution

Over most of the surface ocean, the concentration of NO_3^- is below detection level (Fig. 1.4a). The only exceptions are the low-latitude upwelling regions, and the high latitudes. The coastal upwelling regions are accompanied with high levels of chlorophyll, as expected. In contrast, the high surface nitrate concentrations in the Southern Ocean, the equatorial Pacific, and the North Pacific have long been an enigma for marine biologists (see e.g., Cullen (1991)) as these regions exhibit uncharacteristically low chlorophyll levels. In response, they are often referred to as *High-Nutrient Low-Chlorophyll (HNLC)* regions.

In order to explain the HNLC regions, we first have to consider the processes that control surface nitrate. To first order the surface NO_3^- concentration reflects the balance between vertical NO_3^- supply and biological consumption and export. As a consequence, the residual NO_3^- at the surface is a poor indicator of the production and export of an ocean ecosystem, i.e., the surface NO_3^- concentration is poorly related to the strength of the biological pump (Sarmiento and Gruber, 2006). The residual surface NO_3^- concentration is by definition, however, a good indicator of the efficiency of the biological pump, i.e., a measure of how successful biology is in taking up nutrients and exporting them to depth against the physical resupply of new nutrients. This means that the question of what maintains the HNLC regions is equivalent to asking why the biological pump is so inefficient there.

Physiologically, phytoplankton are usually extremely efficient in taking up NO_3^- and the enzymes operate well down to very low concentrations (see discussion by Mulholland and Lomas in Chapter 7, this volume). Therefore, something else must be limiting phytoplankton growth and/or its biomass. Light-limitation, grazing, and low temperatures were proposed as an explanation (Cullen, 1991), but the current consensus is that iron limitation is the primary reason for the HNLC regions, as impressively demonstrated by a series of open-ocean iron fertilization experiments (Boyd *et al.*, 2000, 2004; Coale *et al.*, 1996, 2004; Martin *et al.*, 1994; Tsuda *et al.*, 2003).

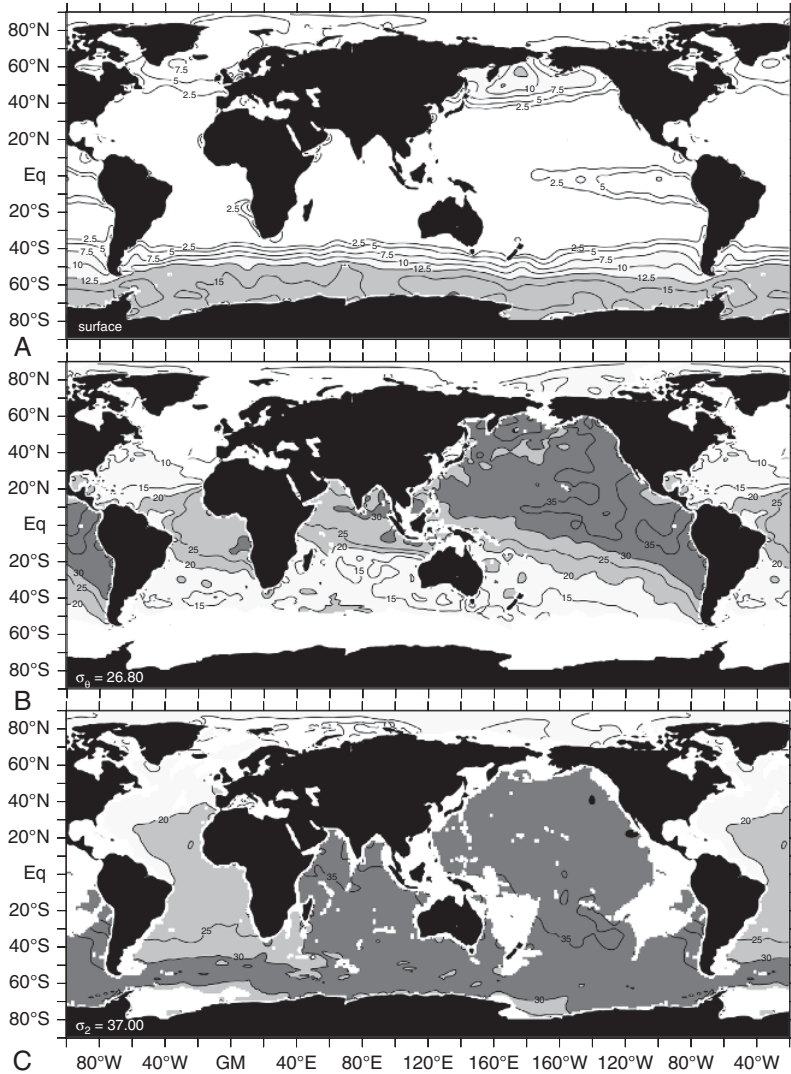
The discussion of the distribution of surface NO_3^- in terms of biological pump efficiency is particularly useful for understanding the impact of the biological pump on the ocean carbon cycle and atmospheric CO_2. This is because surface nutrients are an excellent indicator for the direction of the biologically induced air-sea flux of CO_2. In a case where the biological pump is 100% efficient, all remineralized inorganic carbon that is brought to the surface together with the nutrients is taken up by phytoplankton and mostly exported back down again. As a result, little or no CO_2 can escape to the atmosphere. In contrast, regions where the biological pump is inefficient, much of the inorganic carbon transported upward to the surface remains there along with the unused nutrients, so that a significant fraction of it can escape into the atmosphere. In steady-state, this biologically induced outgassing of CO_2 has to be compensated by uptake in other regions. This occurs in regions of high


Figure 1.4 Maps of annual mean nitrate concentrations at (a) surface, (b) on the isopycnal surface $\sigma_\theta = 26.80$ representing Subantarctic Mode Water in the southern hemisphere, and subpolar mode waters in the northern hemisphere, and (c) on the isopycnal surface $\sigma_2 = 37.00$ representing North Atlantic Deep Water. Based on data from the World Ocean Atlas 2001 (Conkright *et al.*, 2002).

biological efficiency, where part of the fixed and exported organic carbon stems from inorganic carbon taken up from the atmosphere.

In summary, regions with low biological efficiency have high residual NO_3^- and tend to be biologically induced sources of CO_2 to the atmosphere. Regions with high biological efficiency have very low residual NO_3^- and tend to be biologically

induced sinks for atmospheric CO_2. Thus, in order to change atmospheric CO_2, one needs to make the biological pump primarily more efficient and not necessarily stronger. I will come back to this issue in the section on "nitrogen challenges."

3.2.2. Interior ocean distribution

Nitrate at depth exhibits much more spatial variation than revealed in the smooth global mean profile shown in Fig. 1.3. This is illustrated in Fig. 1.5a, which depicts the NO_3^- concentration along a global-scale vertical section that starts in the North Atlantic, goes south along approximately 20°W into the Southern Ocean, wraps around Antarctica at about 60°S, turns north at about 150°W, and ends up in the North Pacific (see map inset). NO_3^- increases very rapidly with depth in the upper 500 m of the tropics, while the vertical gradients are much smaller in the upper 500 m of the mid-latitudes. Below a 1000 m, the NO_3^- distribution follows an entirely different pattern, as the main gradients are horizontal, going from low concentrations in the deep Atlantic to high concentrations in the deep Pacific.

These variations in NO_3^- are highly correlated with variations in PO_4^{3-} and dissolved inorganic carbon (DIC) (Fig. 1.6), with a slope close to the stoichiometric ratio of photosynthesis and respiration, implying that the distribution of these constituents are primarily controlled by the biogeochemical loop. But how are the two main processes of this loop, i.e., biology and ocean circulation interacting with each other to create these spatial variations? For example, are the stronger vertical gradients in the tropics primarily a result of higher export of organic nitrogen and subsequent higher rates of remineralization at depth, or are there other mechanisms at work?

Let us explore the thermocline distribution first. As large-scale oceanic transport occurs primarily along surfaces of equal potential density, it is instructive to inspect variations along such surfaces. Figure 1.4b shows the NO_3^- distribution along the potential density surface $\sigma_\theta = 26.80$, which represents Sub-Polar Mode Water (SPMW) in the northern hemisphere and Sub-Antarctic Mode Water (SAMW) in the southern hemisphere (Hanawa and Talley, 2001). Nitrate concentrations near the outcrops, i.e., where the isopycnal surface intersects the surface of the ocean are near zero, but concentrations increase rapidly as one moves away from the outcrops into the ocean's interior.

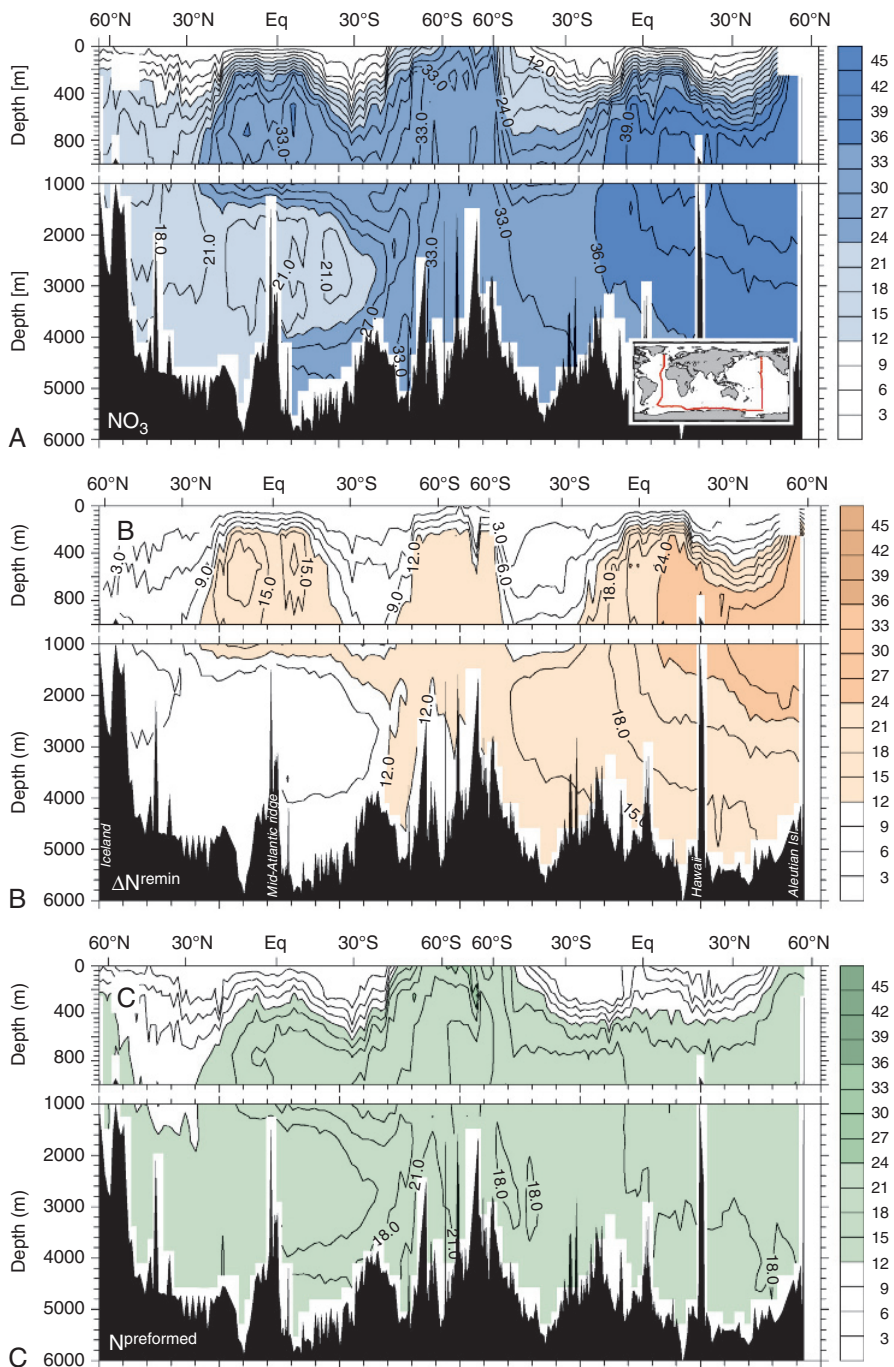
The large-scale circulation on this isopycnal surface consists of a series of anticyclonic gyres that are confined to each hemisphere. Along the anticyclonic path of these gyres, the waters flow near the surface at the poleward outcrops, and descend to depth along the eastern side of the basin, bringing young, recently ventilated water from the surface into the interior. The gyre flow stays generally poleward of 20° on the equatorward side, and then becomes part of the western boundary current along the gyre's western flank. The interaction of this flow pattern with the continuous addition of NO_3^- from remineralization (nitrification) is best seen in the North Atlantic, where the younger waters in the northeastern part of the gyre have the lowest NO_3^- concentrations, and where concentrations gradually increase along the path of the gyre. The time it takes for an average water parcel to make one journey around this basin-scale gyre is on the order of years to decades (Follows *et al.*, 2002; Sarmiento *et al.*, 1982), resulting in a moderate increase in the NO_3^-


Figure 1.5 Vertical sections of (A) nitrate, (B) remineralized nitrate, and (C) preformed nitrate (all in $\mu mol\ kg^{-1}$) along a section that follows the global conveyor belt circulation (see map inset in (A)). Based on WOCE data from the A16, S4, and P16 cruises.
Figure 1.6 Plots of co-variances of (A) phosphate, and (B) dissolved inorganic carbon (*DIC*) with nitrate. DIC has been normalized to a constant salinity of 35 in order to remove the effect of fresh-water fluxes. Based on data from all depth and from selected cruises of the World Ocean Circulation Experiment, i.e., A16, 18NI9S, P16. The lines indicate the expected biologically induced trends.

concentration despite high rates of organic matter remineralization and hence high rates of NO_3^- addition from nitrification.

These basin-scale gyres do not reach the low-latitude regions of these isopycnals, however, resulting in a very poor water renewal in these regions. Consequently, NO_3^- and other nutrients tend to accumulate, while oxygen tends to be consumed. In certain regions, particularly in the eastern parts of the tropical thermocline, this consumption proceeds until all oxygen is consumed, creating conditions conducive for water–column denitrification.

The distribution of NO_3^- on the deep-ocean isopycnal $\sigma_2 = 37.00$ (Fig. 1.4c), representing North Atlantic Deep Water (NADW), illustrates the large-scale increase of NO_3^- from the Atlantic to the Pacific in more detail than the vertical section (Fig. 1.5a). Two observations on this deep isopycnal surface contrast with the NO_3^- distribution on the thermocline surface. First, concentrations near the outcrop regions are not near-zero. In the North Atlantic, the NO_3^- concentration at the outcrop is about 15 µmol kg^{-1}, and in the Southern Ocean, the outcrop concentration of NO_3^- exceeds 30 µmol kg^{-1}. Second, the horizontal gradients are generally smoother, showing no distinction between the tropics and the mid-latitudes. The latter observation reflects the very different flow pattern of the deep ocean, which is dominated by the lower branch of the global overturning circulation (Broecker, 1991). This circulation supplies newly ventilated waters to the deep ocean at two locations only: the high-latitude North Atlantic and the high-latitude Southern Ocean. From the North Atlantic, newly formed NADW is transported southward into the Southern Ocean, where it mixes with waters that are ventilated around Antarctica. This mixture provides then the source waters for the deep Indian and Pacific Oceans. Along this global-scale journey, which starts in the North Atlantic and ends in the North Pacific, water parcels slowly accumulate NO_3^- stemming from the remineralization of organic nitrogen falling through the water column.

Not all of the variations of nitrate on this isopycnal surface are due to remineralization processes, however. We need to consider also the contribution that stems from the mixing of surface source waters that already contain a significant amount of NO_3^-. This *preformed* nitrate is evident in the non-zero outcrop values noted above in Fig. 1.4a. In order to isolate the impact of remineralization on the interior ocean NO_3^- distribution, one therefore needs to separate the observed NO_3^- into a preformed and a *remineralized* component, where the latter refers to the amount of NO_3^- that has been added to a water parcel since it was last in contact with the atmosphere, thus:

$$[NO_3^-]_{observed} = [NO_3^-]_{preformed} + \Delta[NO_3^-]_{remineralized}. \qquad (1.8)$$

We can accomplish this separation for NO_3^- by taking advantage of this separation being relatively straightforward for O_2, since surface O_2 concentrations are often close to saturation. Setting preformed oxygen equal to the O_2 saturation concentration, $[O_2]_{sat}$, and assuming that the stoichiometry of O_2 consumption and NO_3^- release during remineralization is constant with a ratio, $r_{N:O_2}$, we can estimate the remineralized component:

$$\Delta[NO_3^-]_{remineralized} = r_{N:O_2} \cdot \left([O_2]_{sat} - [O_2]_{observed}\right). \qquad (1.9)$$

The preformed component is estimated by difference. This separation is only an approximation, however, as preformed oxygen sometimes deviates substantially from its saturation value (see discussion by Ito *et al.* (2004)). In such cases, one would need to employ an estimate of the true preformed oxygen. For our illustrative purposes here, we neglect this potential limitation.

Figure 1.5c shows that preformed NO_3^- represents a very substantial fraction of the total NO_3^- in the thermocline and deep ocean, and that it is responsible for about half of the surface to deep gradient in NO_3^-. It also shows that much of the NO_3^- increase in the deep Atlantic along the path of NADW is actually caused by mixing of a high preformed NO_3^- end-member from the Southern Ocean while the NO_3^- increase from remineralization is relatively small (Fig. 1.5b). The highest concentrations of remineralized NO_3^- are found in the thermocline, as expected from the fact that about 90% of the organic nitrogen exported from the upper ocean is remineralized above 1000 m (e.g., Martin *et al.* (1987)).

The existence of a significant amount of preformed NO_3^- in the ocean is a direct consequence of the low biological pump efficiency in the surface regions that ventilate the interior ocean. Since the Southern Ocean is a source region for most of the deep waters in the Ocean, the inability of biology to draw down the nutrients there leaves a global-scale imprint on the ocean interior distribution of NO_3^-. This gives biology in the Southern Ocean a uniquely large leverage on global-scale biogeochemistry (Sarmiento *et al.*, 2004). Increasing the biological pump efficiency in this region would not only draw down the (preformed) nutrients locally, but it would also prevent these nutrients from being exported laterally to low-latitude regions by SAMW and Antarctic Intermediate Waters (see elevated preformed NO_3^- concentrations in the mid thermocline of the Southern hemisphere in Fig. 1.5c). These preformed nutrients

eventually end up at the surface of the lower latitudes, fueling productivity there. Therefore, any increase in the biological pump efficiency in the Southern Ocean, such as induced by iron fertilization or Southern Ocean stratification, causes a drop in low-latitude productivity after some delay (Jin and Gruber, 2003; Sarmiento and Orr, 1991; Sarmiento et al., 2004). In a model experiment, Sarmiento et al. (2004) showed that making the biological pump 100% effective in the Southern Ocean would cause, in steady state, low-latitude productivity north of 30°S to decrease 4-fold. Therefore, consideration of such downstream effects is very important when considering past or future changes in the oceanic nitrogen cycle.

3.3. Ammonium

The inventory of NH_4^+ in the ocean is approximately three orders of magnitude smaller than that of NO_3^-. Nevertheless, the cycling of NH_4^+ in the ocean is a crucial component of the upper ocean nitrogen cycle. In fact, the chemical distinction of NO_3^- versus NH_4^+ permits oceanographers to investigate the sources and fate of nitrogen in the upper ocean in a much more detailed way than it would be possible if nitrogen existed just in one major chemical form, such as is the case for PO_4^{3-}, for example.

3.3.1. Distribution

Relative to NO_3^- and NO_2^-, the concentration of NH_4^+ is seldom measured in the open ocean, resulting in a much more patchy understanding of its distribution. This is because standard techniques do not work well at the very low concentrations usually encountered, requiring special high-sensitivity methods (see e.g., Brzezinski (1988), Jones (1991), and Clark et al. (2006)). An exception are the four major process studies undertaken as part of the U.S. component of the Joint Global Ocean Flux Study (JGOFS), i.e., the AESOPS study in the Southern Ocean, the Arabian Sea study, the EqPac program in the Equatorial Pacific, and the NABE experiment in the North Atlantic, as well as a few individual efforts (e.g., Varela et al. (2005)). Average profiles of NH_4^+ for each of the four JGOFS process studies are shown in Fig. 1.7, together with those for NO_3^-, NO_2^-, and PON.

   Several observations stand out. Although the euphotic mean concentration of NH_4^+ averaged from all regions is about 0.3 μmol kg^{-1} (see Fig. 1.3), the concentration varies by almost an order of magnitude between the Southern Ocean and the Arabian Sea. Since the NH_4^+ concentration reflects the balance between production by ammonification and consumption by NH_4^+ assimilation or nitrification, differences in any of these processes could explain this large range. The positive correlation between high concentrations of PON and NH_4^+ (Fig. 1.7C and D) suggests that higher rates of ammonification are the primary cause, but the much colder temperatures in the Southern Ocean and the resulting lower rates of nitrification, as well as strongly differing values of NO_3^-, may also contribute.

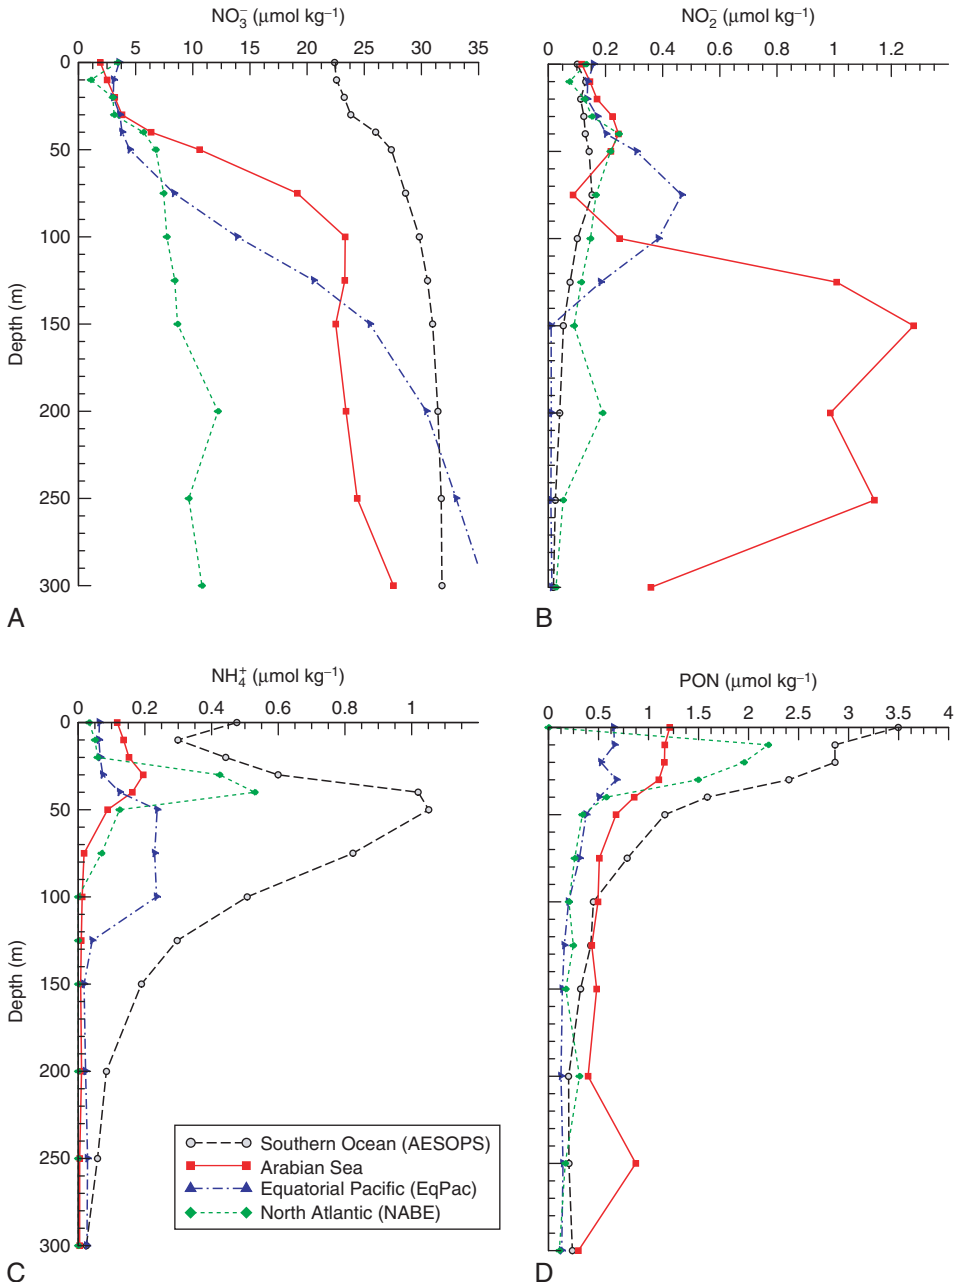
   During these four process studies, the average concentration of NH_4^+ was generally much lower than that of NO_3^-. It is not clear whether this applies globally, but the few available data from the oligotrophic regions suggest that NH_4^+ is extremely low there, and likely lower than NO_3^- (Brzezinski, 1988).


Figure 1.7 Average vertical profiles of (A) NO_3^-, (B) NO_2^-, (C) NH_4^+, and (d) *PON* from the four JGOFS process studies sites, i.e., Southern Ocean in 1996–1998 (80°S–51°S; 160°E–161°W), Arabian Sea in 1995 (8°N–26°N; 54°E–71°E), Equatorial Pacific in 1992 (146°W–135°W; 13°S–12°N), and North Atlantic in 1989 (41°N–59°N; 25°W–17°W). Data were obtained from usjgofs.whoi.edu and were averaged for each study without consideration of exact location or season.

The mid-depth maximum of NH_4^+ observed in the mean profile (Fig. 1.3) exists in all four regions, but occurs with different strengths and at different depths. As was the case above, small differences in production or consumption, such as arising from differences in productivity, depth of the euphotic zone, light, and *PON* availability likely determine the exact shape of the profile.

3.3.2. New versus regenerated production

Arguably, the concept of *new versus regenerated production* has been among the most important paradigms guiding biological and biogeochemical oceanography in the last two decades (Ducklow, 1995; Ducklow *et al.*, 2001; Falkowski *et al.*, 2003; Karl *et al.*, in Chapter 16, this volume). As introduced by Dugdale and Goering (1967), new production refers to that part of primary production that is fueled by nutrients inputs from outside the euphotic zone. Regenerated production is the remainder, i.e., that part of production that is based on inorganic nutrients that are recycled from organic matter within the euphotic zone.

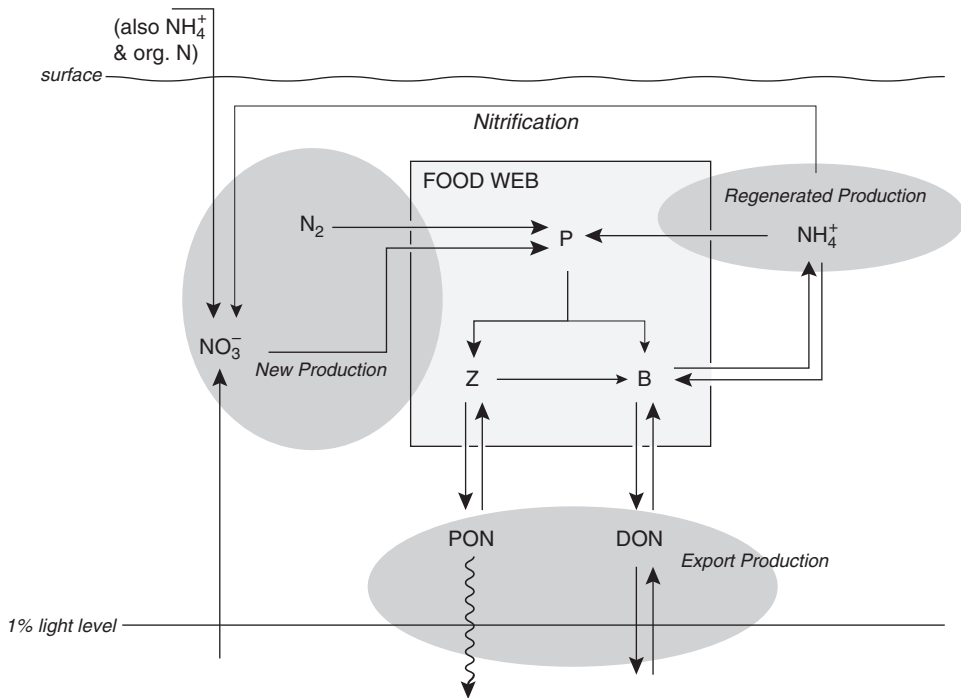
There are two reasons why this paradigm has become so important: First, in steady-state, and if averaged over sufficiently long spatial and temporal scales (see e.g., Williams *et al.* (1989) and Plattner *et al.* (2005)), new production can be equated with export production, i.e., the flux of organic carbon and nutrient elements out of the euphotic zone (Fig. 1.8) (Eppley and Peterson, 1979). Since it is the magnitude


Figure 1.8 Schematic illustration of the nitrogen cycling paradigm in the euphotic zone. Adapted from Sarmiento and Gruber (2006).

of export production and not primary production that determines the efficiency of the biological pump, and it is the latter that determines the impact of biology on atmospheric CO_2, estimating export production has been a primary focus of bio-geochemical research (Ducklow *et al.*, 2001). However, export production is notoriously difficult to measure (see e.g., Buesseler *et al.* (2007) for a discussion of sediment traps), so using estimates of new production as a proxy for export production is attractive (Brix *et al.*, 2006; Neuer *et al.*, 2002).

The second reason for the success of the new production paradigm is that new production is relatively easy to measure. This is because new production in the open ocean is usually associated with the uptake of NO_3^-, while regenerated production is associated with the uptake of NH_4^+. This remarkable fact is a direct consequence of nitrification being inhibited by light. As a result, NH_4^+ that is created by ammonification in the euphotic zone is usually taken up again by phytoplankton rather than nitrified to NO_3^-. In contrast, nearly all NH_4^+ created in the aphotic zone is nitrified to NO_3^-, so that fixed nitrogen that is supplied back to the euphotic zone from the ocean's interior is almost exclusively in the form of NO_3^-. Recognizing the chemical distinction between nitrogen following either the new or the regenerated production pathways, Dugdale and Goering (1967) demonstrated that one can use ^{15}N labeled NO_3^- and NH_4^+ in incubation experiments together with ^{14}C labeled CO_2 to determine the fraction of primary production that is caused by either new or regenerated production.

This method has been widely adopted and has not changed much conceptually since its inception. Due to need to spike the phytoplankton sample with NO_3^-, the method is problematic to use in oligotrophic gyres (Falkowski *et al.*, 2003). As a result, it has been applied primarily in HNLC regions (e.g., Aufdenkampe *et al.* (2001)) and in more productive coastal or high-latitude regions (e.g., Wilkerson *et al.* (1987)). Many insights have been gained from these measurements, permitting to develop models of what controls the ratio of new or export production to primary production (see e.g., Laws *et al.* (2000) for a summary of results and a model of this ratio).

Although recognized from the very beginning that equating NO_3^- uptake with new production is only correct if other processes such as N_2 fixation, atmospheric deposition, or river input are negligible (Dugdale and Goering, 1967), this caveat has been ignored often. This was done because of either experimental limitations or lacking evidence that the other nitrogen supply pathways were substantial. However, research over the last two decades has revealed that atmospheric deposition, river fluxes, or N_2 fixation supplies in many regions a substantial amount of fixed nitrogen to the upper ocean, in some cases equaling or exceeding the classical vertical transport pathway (Capone *et al.*, 2005). Phytoplankton have been identified that can migrate vertically over substantial distances in order to take up excess fixed nitrogen at depth and then float to the surface to undertake photosynthesis (Villareal *et al.*, 1993), providing a novel pathway of introducing new nitrogen into the system. In addition, increasing evidence exists that nitrification occurs within the euphotic zone (Ward *et al.*, 1989; Zehr and Ward, 2002), and that organic nitrogen can be released and taken up by phytoplankton (Bronk *et al.*, 1994), further blurring the association of NH_4^+ uptake with regenerated production and the uptake of NO_3^- with new production. Nevertheless, the paradigm of new versus regenerated production remains a powerful concept to understand upper ocean biogeochemical cycles.

3.4. Nitrite

Since the commonly used colorimetric method to measure NO_3^- involves the reduction to NO_2^-, the latter is usually measured separately as well, so that the $NO_3^- + NO_2^-$ measurements can be corrected for NO_2^-. As a result, there are nearly as many measurements of NO_2^- as there are of NO_3^-. However, many of these samples have NO_2^- concentrations below the relatively high detection level. In addition, the colorimetric method is not very accurate at low concentrations, so that special low-level methods are required to study nitrite dynamics (Brzezinski, 1988; Dore and Karl, 1996; Lipschultz et al., 1996; Zafiriou et al., 1992).

The turnover time of NO_2^- is not well known, but has been estimated to be about 3–7 days (Lipschultz et al., 1996). This makes NO_2^- the shortest lived among the nitrogen species considered here. The main reason for this fast turnover is that NO_2^-, even more so than NH_4^+, represents an intermediary species (Figure 1.2). It is produced during NO_3^- assimilation, nitrification, and denitrification, and then immediately consumed again.

The interaction of these processes explains the ocean mean distribution shown in Fig. 1.3, as well as the distribution observed during the four U.S. led JGOFS process studies (Fig. 1.7). In general, the NO_2^- distribution in the euphotic zone appears to follow roughly that of NH_4^+, except that its mean concentration is slightly smaller, on average. While the correspondence of NH_4^+ and NO_2^- in the euphotic zone suggests that NO_2^- there is mostly controlled by nitrification (Ward et al., 1982), some of the deeper NO_2^- may reflect also its generation during the assimilation of NO_3^-. This is supported by the observation that elevated concentrations of NO_2^- are often associated with the nitracline, i.e., the first appearance of elevated NO_3^- concentrations in the water column (Dore and Karl, 1996; Herbland and Voituriez, 1979) (see e.g., Fig. 1.9).

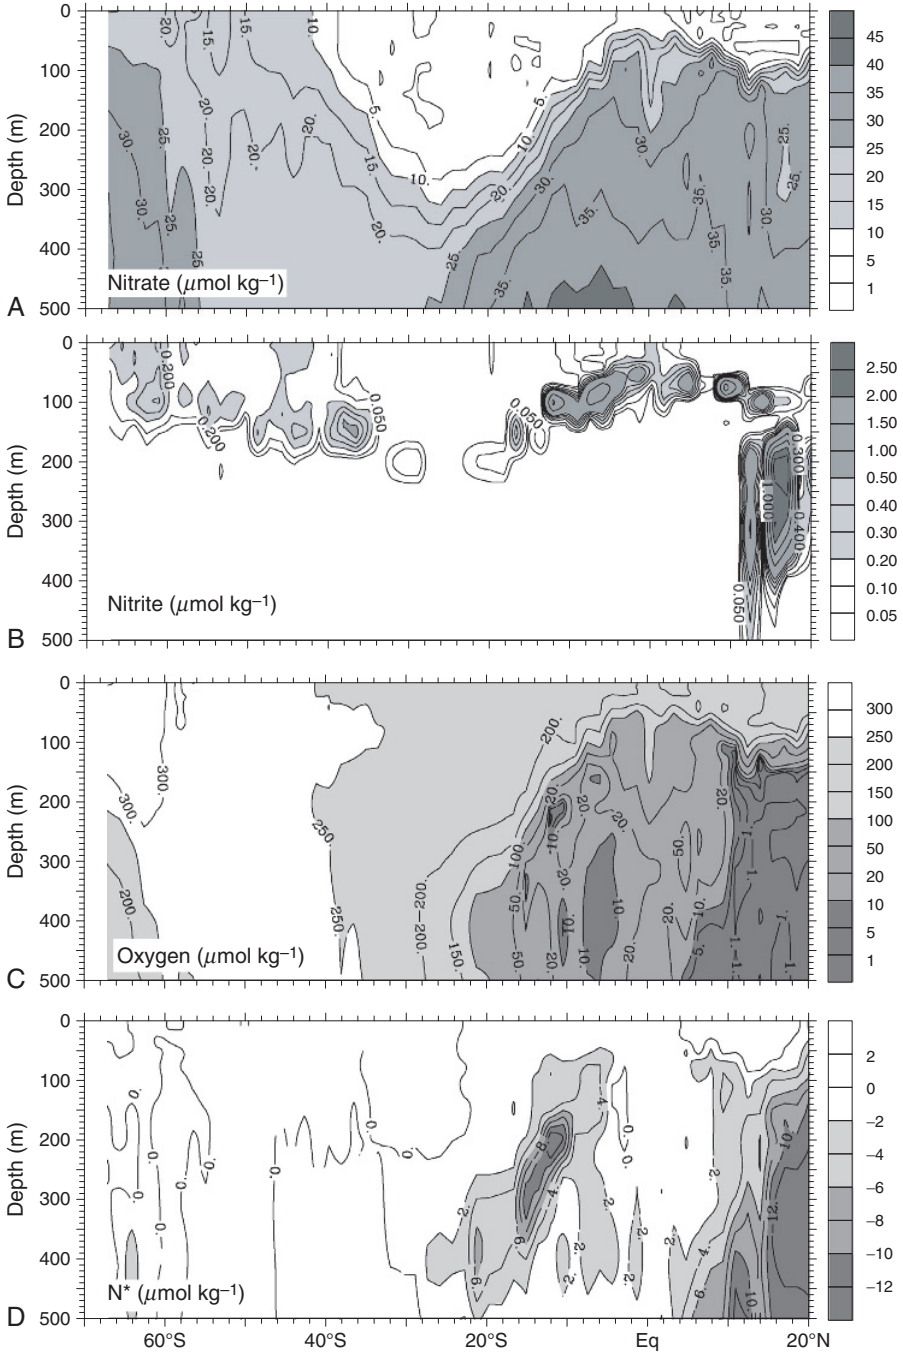
The correlation of NO_2^- and NH_4^+ concentrations often breaks apart below the euphotic zone. This is particularly the case in oxygen minimum zones, where a secondary NO_2^- peak is frequently observed (see Fig. 1.7 and Codispoti and Christensen (1985)). In the Arabian Sea, NO_2^- concentrations exceed 1 µmol kg^{-1} between about 100 m and 500 m (Fig. 1.7). A similar secondary NO_2^- peak can be observed between 250 m and 500 m in the eastern Tropical Pacific (Fig. 1.9b) (Codispoti, 1983; Codispoti and Christensen, 1985; Codispoti and Packard, 1980). This secondary NO_2^- peak can be attributed to denitrification, as it occurs in association with a well developed anoxic region at mid-depths in the eastern tropical North Pacific (see Fig. 1.9c). A closer inspection shows that the NO_2^- maximum often occurs outside the region of strongest anoxia, i.e., at O_2 concentrations between 1 and 5 µmol kg^{-1} (see e.g., Codispoti et al. (1986) and Codispoti and Christensen (1985)). This location of the secondary NO_2^- maximum is usually interpreted as reflecting the superposition of NO_2^- formation by (aerobic) nitrification, and NO_2^- formation by (anaerobic) denitrification (e.g., Yakushev and Neretin (1997)) both of which can co-occur at these very low, but non-zero O_2 concentrations (Morrison et al., 1999). In contrast, inside the oxygen minimum zone, NO_2^- is very efficiently reduced further to N_2, preventing it from accumulating there. There exist more subtle reasons, involving, for example, trace metal limitations of the nitrite oxidizers at these very low oxygen concentrations (Granger and Ward, 2003).


Figure 1.9 Meridional sections of (A) NO_3^-, (B) NO_2^-, (C) oxygen, and (D) N^* along about 100°W in the eastern Pacific. Data are from the WOCE cruise P18 conducted in 1994 (whpo.ucsd. edu).

3.5. Organic nitrogen

More than 99% of the organic nitrogen in the ocean exists in the form of dissolved organic nitrogen, *DON* (see Table 1.2). Only a small fraction of it is chemically characterized, reflecting the large number of organic molecules that contain nitrogen groups. I will not elaborate further on *DON* as it is discussed in detail by *Aluwihare and Meador* in Chapter 3, this volume (see also Bronk (2002)). I therefore limit my discussion to particulate organic nitrogen, *PON*.

   PON represents only about 0.5% of the total organic nitrogen pool, but since some of the *PON* is heavy enough to sink, it represents a crucial component of the marine biological pump. Its mean turnover time is only about 2 weeks (see Table 1.2), reflecting the rapid synthesis and degradation of *PON*. In the euphotic zone, most of the POC is believed to be living matter, although the composition of PON is not well characterized. *PON* exists in size across several orders of magnitude, ranging from very fine suspended particles to large aggregates, such as marine snow or fecal pellets.

   Figure 1.7d shows a summary of *PON* measurements from the four JGOFS process studies. In most cases, *PON* is highest near the surface and decreases quasi-exponentially with depth. There exist large differences in the mean concentrations between the different JGOFS process studies, with *PON* concentrations during the Southern Ocean experiment reaching above 3 μmol kg^{-1}, on average, while *PON* barely exceeds 0.5 μmol kg^{-1} in the Equatorial Pacific. The depth distribution within the euphotic zone as well as the spatial differences largely reflect variations in living biomass (mostly phytoplankton). For example, the Southern Ocean JGOFS program targeted spring blooms in the Southern Ocean, during which very high concentrations of phytoplankton can be reached (Smith *et al.*, 2000).

   Below about 200 m, *PON* concentrations tend to asymptote to similar levels of about 0.1 to 0.3 μmol kg^{-1}, irrespective of the large differences in *PON* in the euphotic zone. Overall, *PON* dynamics in the aphotic zone tends to follow that of particulate organic carbon (*POC*), with a stoichiometric C:N ratio of about 7.1 ± 0.1 (equivalent to 16:114 $\pm$ 2) for the particles sinking out of the euphotic zone (Schneider *et al.*, 2003) (see also Hebel and Karl (2001) for long-term observations of the *POC* and *PON* dynamics in an oligotrophic environment). In their analysis of sediment trap samples and particles collected by *in situ* pumps, Schneider *et al.* (2003) also noticed a slight increase of this ratio with depth of about 0.2 per 1000 m, so that particles sinking across 1000 m have a C:N ratio very close to the 117:16 ratio proposed by Anderson and Sarmiento (1994).

3.6. Nitrogen*: The imprint of N$_2$-fixation and denitrification

A remarkable observation from Fig. 1.6a is not only the strong co-variation of NO_3^- with PO_4^{3-} with a slope of about 16:1, but also the near-zero intercept of the mean trendline. While the existence of a well defined slope is not surprising since it reflects the mean stoichiometry of organic matter synthesis and remineralization (reactions 1.1 through 1.5), the reasons for the existence of a near-zero intercept are less obvious. Generally, this near-zero intercept is interpreted as evidence for the

existence of a stabilizing feedback between N_2 fixation and denitrification, which is controlled by the oceanic ratio of NO_3^- to PO_4^{3-} (Gruber, 2004; Redfield, 1958; Tyrrell, 1999) (see discussion below).

A convenient way to analyze the impact of N_2 fixation and denitrification on the oceanic NO_3^- distribution is to remove the photosynthesis/remineralization trend of 16:1, and focus instead on the anomalies from this trend. This is achieved by defining a linear combination of the two nutrients, i.e.,

$$N^* = \left[NO_3^-\right] - 16\left[PO_4^{3-}\right] + 2.9\mu\text{mol kg}^{-1} \qquad (1.10)$$

where the constant of 2.9 µmol kg^{-1} was added to obtain a global mean $N^\star$ of zero (see Gruber and Sarmiento, (1997, 2002) for an in depth derivation and a discussion of caveats). More recently, Hansell *et al.* (2004) introduced the tracer ''excess DIN'' (DIN_{xs}) based on the same concept. In fact, DIN_{xs} is identical to $N,^\star$ except that Hansell *et al.* (2004) set the constant to zero, i.e,. $DIN_{xs} = N^\star$ - 2.9 µmol kg^{-1}.

As illustrated in Fig. 1.10a, $N^\star$ is constant for any line with a slope of 16:1 and represents a measure of the distance between any NO_3^- and PO_4^{3-} pair and the mean oceanic trend line.
Figure 1.10 (A) Plot of NO_3^- versus PO_4^{3-} from all depths and from selected WOCE cruises in all ocean basins (A16,P16,I8NI9S). The inset shows how the various processes influence the NO_3^- versus PO_4^{3-} distribution. The solid line represents the mean ocean trend with a slope of 16:1, while the thinner lines show trends of constant $N^\star$ (see text for definition). (B) Hypothetical distribution of NO_3^- versus PO_4^{3-} in a situation of excess NO_3^-. (C) as (B), except for a situation of a NO_3^- deficit. It is unclear why the intercept of the mean oceanic trendline in (A) is so close to zero. From Gruber (2004).

The strength of the $N^\star$ concept is that it represents the time and space integrated impact of N_2 fixation and denitrification on the oceanic nutrient fields, which is attractive given the fact that direct rate measurements of N_2 fixation and denitrification are difficult, time-consuming, and generally very sparse (see Chapter 4 by *Carpenter and Capone* and Chapter 6 by *Devol*). A drawback is that $N^\star$ cannot distinguish between N_2 fixation and denitrification as it represents the sum of these two processes. However, the interpretation is greatly aided by the fact that these two processes are often spatially and temporally separated. In addition, concurrent analyses of the isotopic $^{14}N/^{15}N$ ratio can also help to disentangle the various processes that lead to variations in $N^\star$ (Gruber, 2004; Sigman *et al.*, 2003, 2005). Figure 1.11 shows the distribution of $N^\star$ along the same global section used before for NO_3^- (cf Fig. 1.5). $N^\star$ concentrations are highest in the North Atlantic and tend to decrease gradually toward the Pacific. This implies a net transport of fixed nitrogen from the Atlantic into the Pacific, suggesting that, from a global perspective, the North Atlantic acts as a net source of fixed nitrogen for the world ocean, while the Pacific acts as a net sink. This does not imply, however, that N_2 fixation in the Atlantic is higher than in the Pacific. It just implies that the balance of N_2 fixation and denitrification is positive in the Atlantic and negative in the Pacific.

Global maps of $N^\star$ on two isopycnal surfaces ($\sigma_\theta = 26.50$, representing subtropical mode waters (mean depth of about 300 m) and $\sigma_\theta = 27.10$, representing subpolar mode waters) reveal that the $N^\star$ minima seen in the thermocline of the Pacific (Figures 1.9 and 1.11) are part of a large-scale pattern extending over much of the eastern tropical Pacific (Figure 1.12). On the $\sigma_\theta = 26.50$ surface, the $N^\star$ minimum is well separated into an Eastern Tropical South Pacific (ETSP) and into an Eastern Tropical North Pacific (ETNP) part with a local $N^\star$ maximum in between (seen also in the P18 section (Fig. 1.9d)). On the deeper surface ($\sigma_\theta = 27.10$), the $N^\star$ minimum
Figure 1.11 As Fig. 1.5, except for $N^\star$ (μmol kg^{-1}).

in the ETSP has lost much of its characteristics, while the minimum in the ETNP remains well defined. Finally, the maps reveal an additional minimum of $N^\star$ in the Arabian Sea.

A more detailed inspection of the $N^\star$ maximum in the subtropical North Atlantic (Fig. 1.12) reveals that the concentration of $N^\star$ increases as waters move
Figure 1.12 Global plots of objectively analyzed $N^\star$ (μmol kg^{-1}) on isopycnal surfaces. (A) $N^\star$ on the $\sigma_\theta = 26.50$ surface. This surface is characteristic of subtropical mode waters, such as the 18° Water in the North Atlantic, (B) $N^\star$ on the $\sigma_\theta = 27.10$ surface representing Subpolar Mode Waters. Solid circles denote the stations; stippling denotes areas where the waters of this potential density are not present in winter time. Cross-hatched areas are regions where the estimated error in objectively analyzed $N^\star$ is greater than 0.7 μmol kg^{-1}. Data are from the WOCE program augmented by selected pre-WOCE cruises and were adjusted by the GLODAP project.

from the outcrop region in the northeastern part of the gyre toward the southwest. This pattern of ingrowth of $N^\star$ was combined with information about the ventilation rate of different water masses to arrive at geochemically-based estimates of N_2 fixation (Gruber and Sarmiento, 1997; Hansell et al., 2004; Michaels et al., 1996). These studies inferred rather divergent N_2 fixation estimates for the entire North Atlantic (see discussion by Hansell and Follows, Chapter 13, this volume), although a new analysis using nitrogen-15 abundance in organic nitrogen by Capone et al. (2005) suggests an intermediate value close to that proposed by Gruber and Sarmiento (1997). This suggestion is also supported by the uncovering of a much larger abundance of Trichodesmium in the subtropical North Atlantic than previously observed (Davis and McGillicuddy, 2006).

Interpretation of the $N^\star$ distribution in the Pacific and Indian oceans is more difficult because of the existence of strong denitrification sites adjacent to the places where one expects to find the N_2 fixation signals. In the subtropical North Pacific, where N_2 fixation is well documented (Karl et al., 1997), the $N^\star$ maximum exists just near the surface and does not extend into the thermocline as is the case in the subtropical North Atlantic. This is likely a result of the eroding effect by waters that obtain extremely low $N^\star$ values in the eastern Pacific and are then advected westwards in the main thermocline (Fig. 1.12).

The strong $N^\star$ minima in the ETNP and ETSP (Figures 1.11 and 1.12) reflect mostly the intense water column denitrification that occurs in these two oxygen minimum regions (Fig. 1.13) (Codispoti and Packard, 1980; Codispoti and Richards, 1976; Hattori, 1983), although benthic denitrification may contribute as well. The two $N^\star$ minima have long tails that reach far westward into the central Pacific. The shape and position of these tails, together with their O_2 concentrations well above the critical O_2 concentration for the onset of denitrification (Fig. 1.13) suggests that these features are the result of westward advection of the $N^\star$ signals in the North and South Equatorial currents and do not reflect in situ water column denitrification. These waters slowly lose their signature as they mix with eastward moving waters in the equatorial undercurrent system and as they entrain subtropical waters, both having elevated $N^\star$ concentrations. A region of reduced $N^\star$ concentrations extends from the ETNP also northward along the American western margin. While most of this signal is thought to reflect the northward advection of low $N^\star$ waters from the ETNP in the California Undercurrent (Castro et al., 2001), these waters likely incorporate $N^\star$ signals from benthic denitrification (Christensen et al., 1987; Devol and Christensen, 1993) or Anammox (Dalsgaard et al., 2003) along the margin as well. These benthic processes explain also many of the low $N^\star$ values found in the North Pacific and elsewhere along the continental margins.

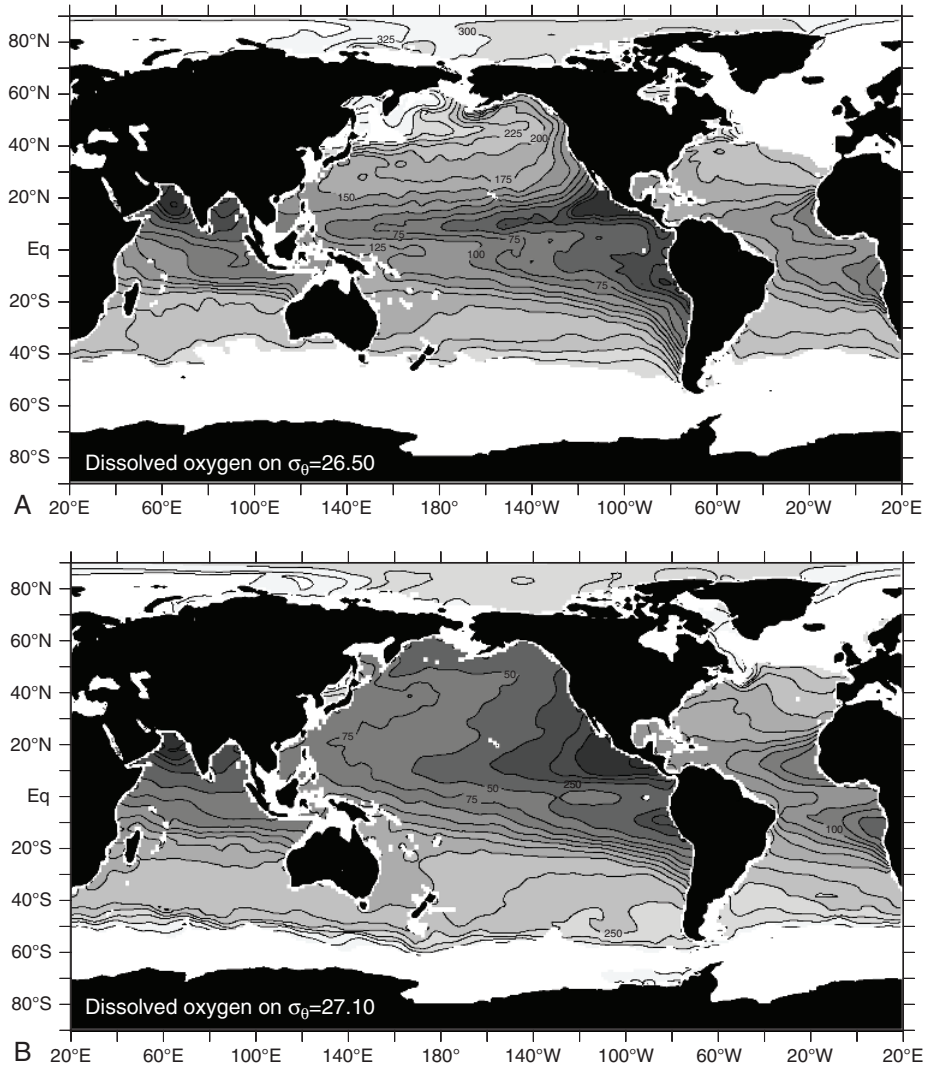
In the Indian Ocean, near surface values of $N^\star$ are slightly elevated (Gruber and Sarmiento, 1997). As these elevated values are located just above some of the lowest $N^\star$ values found anywhere in the world oceans, they suggest rather strong N_2 fixation. Observations of Trichodesmium abundance (Carpenter, 1983) and a few direct rate measurements (reported in Capone et al. (1997)) support this conclusion. The low $N^\star$ concentrations in the thermocline of the Arabian Sea (Fig. 1.12)


Figure 1.13 Global plots of oxygen (μmol kg^{-1}) on (A) the $\sigma_\theta = 26.50$ surface and on (B) the $\sigma_\theta = 27.10$ surface. Based on data from the World Ocean Atlas (Conkright *et al.*, 2002).

coincide with another well known oxygen minimum zone (Fig. 1.13) with high rates of water column denitrification (Mantoura *et al.*, 1993; Naqvi, 1987; Naqvi *et al.*, 1982; Naqvi, Chapter 14, this volume). Low concentrations of $N^\star$ are also found in the Bay of Bengal, but they likely reflect an advective signal from the Arabian Sea and from the shelf sediments rather than water–column denitrification within the Bay of Bengal itself (Gruber and Sarmiento, 1997).

4. BUDGETS

4.1. Oceanic Nitrogen-budget

Figure 1.14 depicts a summary of the current oceanic nitrogen budget, obtained by combining the fixed nitrogen budget of Gruber (2004) with an organic nitrogen budget derived from an organic carbon budget by Sarmiento and Gruber (2006) assuming a constant C:N ratio in organic matter. The budget is shown separately for the coastal/margin and the open ocean environments, where the former is defined as all regions shallower than 1000 m. The numbers shown are central estimates and in most cases contain uncertainties of at least ±30%.

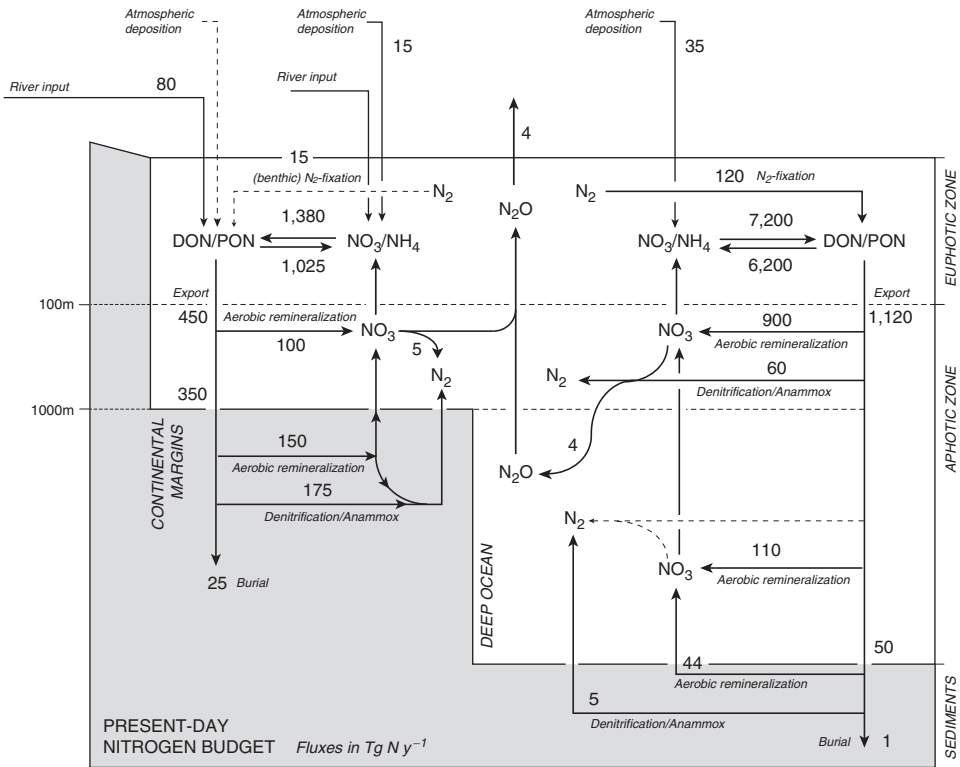
From a quantitative perspective, the most important process of the fixed nitrogen cycle in the ocean is the assimilation of NO_3^- and NH_4^+ into organic nitrogen in the


Figure 1.14 Schematic budget of the present-day (*ca.* AD 1990) marine nitrogen cycle. All fluxes are in units of Tg N year^{-1}. The budget is based on the marine organic carbon budget of Sarmiento and Gruber (2006) (their Fig. 6.5.2) and the fixed marine nitrogen budget of Gruber (2004) given in Table 1.3. A stoichiometric C:N ratio of 7.3 (Anderson and Sarmiento, 1994; Schneider *et al.*, 2003) was assumed when converting the organic carbon fluxes to organic nitrogen fluxes. Ill constrained fluxes were computed by difference, assuming a balanced budget. The level of uncertainty varies strongly between the individual fluxes, but is usually of the order of ±30% (see Table 1.3).

euphotic zone, resulting in the fixation of over $\sim$7000 Tg N year^{-1} in the open ocean, and another $\sim$1400 Tg N year^{-1} in the coastal/margin environments. As is the case for organic carbon, of the order of 20% of the organic nitrogen formed in the euphotic zone is lost to the ocean's interior, resulting in export fluxes of organic nitrogen of the order of $\sim$1100 Tg N year^{-1} in the open ocean, and about $\sim$450 Tg N year^{-1} in the coastal/margin environments. In the open ocean, nearly all of this exported organic nitrogen is nitrified back to NO_3^- in the water column, leading to a very small deposition flux of organic nitrogen to the seafloor (about 50 Tg N year^{-1}). In contrast, the majority of the exported organic nitrogen reaches the seafloor in the margin/coastal environments, leading to a deposition flux of $\sim$350 Tg N year^{-1}.

In the open ocean, the low fluxes of organic matter to the seafloor seldom cause anoxic conditions in the near-surface sediments, so that the majority of the 50 Tg N year^{-1} deposited on the seafloor is nitrified, and only a very small fraction is denitrified ($\sim$5 Tg N year^{-1}). This contrasts dramatically with the coastal/margin environment, where the high flux of organic carbon drives much of the sediments in this region anoxic, favoring denitrification and/or anammox over aerobic reminer-alization of the organic nitrogen. The exact magnitude of benthic denitrification is not well established with estimates reaching values as high as 300 Tg N year^{-1} (Codispoti et al., 2001) (Table 1.3). I adopt here the estimate of Gruber (2004) of 180 Tg N year^{-1}, which is similar to that used by Galloway et al. (2004) and is supported by the recent estimate of 190 Tg N year^{-1} by Deutsch et al. (2004).

Table 1.3 Present-day (ca 1990) Global marine nitrogen budgets of Codispoti et al. (2001), Gruber (2004), and Galloway et al. (2004)

Process	Codispoti et al.[a]	Galloway et al.[a,b]	Gruber[a]
	Sources (Tg N yr^{-1})		
Pelagic N$_2$ fixation	117	106	120 $\pm$ 50
Benthic N$_2$ fixation	15	15	15 $\pm$ 10
River input (DON)	34	18[c]	35 $\pm$ 10
River input (PON)	42	30[c]	45 $\pm$ 10
Atmospheric deposition	86	33	50 $\pm$ 20
Total sources	294	202	265 $\pm$ 55
	Sinks (Tg N yr^{-1})		
Organic N export	1		1
Benthic denitrification	300	206	180 $\pm$ 50
Water column denitrification	150	116	65 $\pm$ 20
Sediment Burial	25	16	25 $\pm$ 10
N$_2$O loss to atmosphere	6	4	4 $\pm$ 2
Total sinks	482	342	275 $\pm$ 55

[a] See the original publications for details, i.e. Galloway et al. (2004), Codispoti et al. (2001), and Gruber (2004).
[b] Listed are the central values reported by Galloway et al. (2004) (see Table 1 and Fig. 1 of their publication).
[c] Galloway et al. (2004) lists only the total river flux. I assumed that about two thirds of the total is PON, and one third is DON.

Subtracting the small amount of benthic denitrification in the open ocean ($\sim$5 Tg N year^{-1}), leads to a coastal/margin benthic denitrification flux estimate of $\sim$175 Tg N year^{-1}. Assuming that the influx of NO_3^- into the sediments from the overlying bottom water is small, this means that about 50% of the organic nitrogen being deposited on the seafloor in the margin/coastal environments is denitrified. 25 Tg N year^{-1} is buried, which implies that about 150 Tg N year^{-1} or about 43% of the deposited organic nitrogen is undergoing aerobic oxidation to nitrate (nitrification). The benthic denitrification estimate of Codispoti *et al.* (2001) of 300 Tg N year^{-1} would mean that nearly 90% of the nitrogen deposited on the seafloor was denitrified, leaving only 25 Tg N year^{-1} for nitrification. Considering that a substantial fraction of the bottom waters overlying the sediments in the margin/coastal environments are oxygenated, such a small role for nitrification is difficult to imagine. However, the presently available data are insufficient to reject either estimate.

Water column denitrification represents the second most important loss process for fixed nitrogen. Current rate estimates diverge quite substantially (see Table 1.3), with estimates as high as 150 Tg N year^{-1}. I adopted here the estimate by Gruber (2004) of 65 Tg N year^{-1}, which is at the low end of the current range of estimates, but satisfies the nitrogen–15 mass balance constraint of an approximately 3:1 ratio between benthic and water-column denitrification (Brandes and Devol, 2002). It is also in good agreement with the recent estimate of 70 Tg N year^{-1} by Deutsch *et al.* (2004). I assume that the majority of the water column denitrification occurs in the open ocean, such as the eastern Tropical Pacific and the Arabian Sea. The formation and subsequent loss of N_2O represents another loss term. Although its magnitude is small (about 4 Tg N year^{-1}), this flux is important when considering the atmospheric N_2O budget, as it represents about a third to half of the estimated pre-industrial N_2O sources to the atmosphere (Prather *et al.*, 2001; see also Chapter 2 by Bange, this volume).

These fixed nitrogen losses add up to more than 300 Tg N year^{-1} (Table 1.3). Without processes supplying fixed nitrogen to the ocean, these losses would lead to a complete exhaustion of all fixed nitrogen in the ocean within about 2000 years. Atmospheric deposition of fixed nitrogen is estimated to be about 50 Tg N year^{-1} (Duce *et al.*, 2008) and rivers add another 80 Tg N year^{-1} the ocean (see Seitzinger and Harrison in Chapter 9, this volume, for a more thorough discussion of nitrogen fluxes by rivers). The largest source of fixed nitrogen to the ocean is N_2 fixation, however. Over the last two decades, estimates of the magnitude of global pelagic N_2 fixation have increased dramatically, but most recent estimates con-verge around 100 to 150 Tg N year^{-1} (Table 1.3) (Gruber, 2004; Gruber and Sarmiento, 1997; Galloway *et al.*, 2004; Deutsch *et al.*, 2007). It is presently not well established how much of this global N_2 fixation occurs in the coastal/margin environment, although the canonical view is that most of it occurs in the open ocean, where conditions are usually more conducive for *Trichodesmium*, i.e., high temperatures, high vertical stability, and low NO_3^- concentrations (Karl *et al.*, 2002). However, recent observations in the Southern California Bight suggest also substantial rates of N_2 fixation in a coastal setting, particularly during the nutrient depleted, well stratified summer period (A. Leinweber and D. Capone, personal communication, 2006). Benthic environments add another $\sim$15 Tg N year^{-1} to the ocean, primarily in very nearshore environments (Capone, 1983).

Adding these numbers together, a nearly balanced marine nitrogen budget emerges, albeit with very large uncertainties. A strongly differing view was recently taken by Codispoti *et al.* (2001), who suggested that the losses of fixed nitrogen were underestimated in the past by nearly a factor of two, leading to a marine nitrogen budget that may be out of balance by nearly 200 Tg N year^{-1}. These authors suggested that this may reflect the substantial alteration of the global nitrogen cycle by humans, and therefore may be a very recent phenomenon. Galloway *et al.* (2004) recently reviewed the global nitrogen budget and arrived at an oceanic fixed nitrogen budget that is in between that of Codispoti *et al.* (2001) and that of Gruber (2004) (see Table 1.3). Galloway *et al.* (2004) also provided direct estimates of the human perturbation fluxes, and identified that these account for about $\sim$45 Tg N year^{-1}. Even when considering the substantial uncertainties with this estimate, this perturbation flux is much smaller than the imbalances in the marine nitrogen budgets of Codispoti *et al.* (2001) and Galloway *et al.* (2004). Therefore the human perturbation is unlikely the cause for the imbalance in the budget. The much more likely cause are uncertainties in the different terms of the budget, in particular the magnitude of benthic and water column denitrification. Therefore, a renewed focus on these two processes with the aim to reduce their uncertainties would provide currently the most efficient way to reduce uncertainties in the oceanic fixed nitrogen budget. However, regardless of these uncertainties, all budgets agree that the marine nitrogen cycle is very dynamic, with a residence time for fixed nitrogen of about 3000 years only (see Table 1.2). This contrasts with the residence time of PO_4^{3-} in the ocean, which is about 30,000 to 50,000 years (Delaney, 1998).

4.2. Global Nitrogen-budget

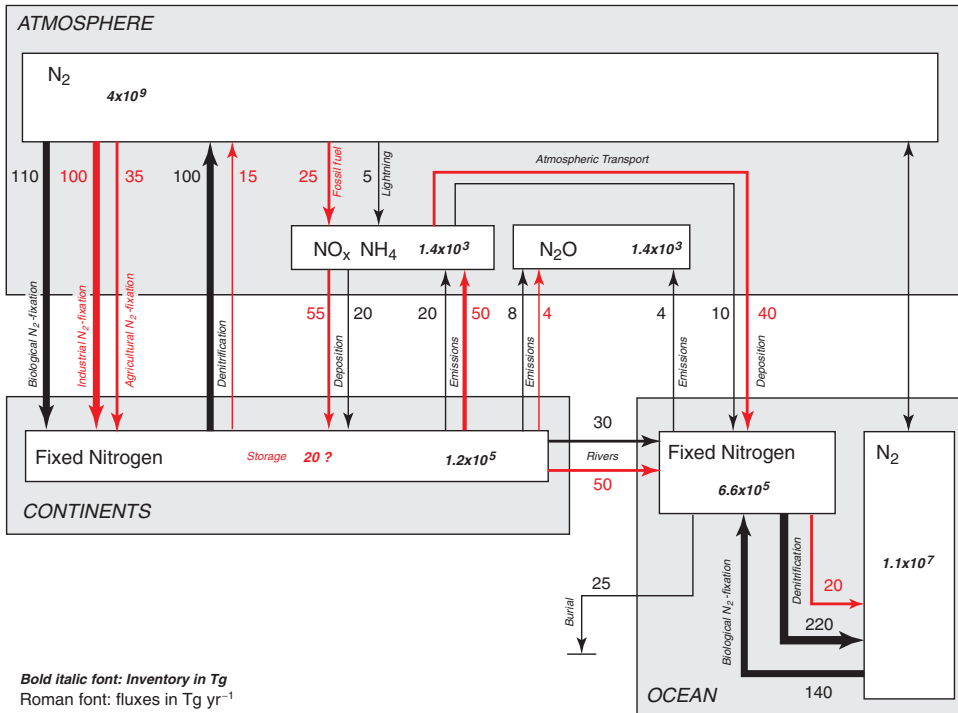
Figure 1.15 shows the marine nitrogen cycle in the context of the global nitrogen cycle in preindustrial times as well as how it has changed since then. A first remarkable observation is that the ocean is the largest reservoir of fixed nitrogen on Earth, containing about 5 times more fixed nitrogen than the land biosphere, where most of it is stored in soils. The amount of fixed nitrogen in the atmosphere is tiny, reflecting the high reactivity of these nitrogen species in the atmosphere and their quick removal. A second remarkable observation is that biological N_2 fixation on land and in the ocean is of similar magnitude. Interestingly, the same is the case for primary production, where photosynthetic organisms in both the ocean and on land fix about the same amount of carbon each year (Field *et al.*, 1998). However, due the lower fixed nitrogen inventory of the land biosphere, the turnover times for fixed nitrogen on land is faster than that in the ocean. Contrasting the land and ocean further, the land acted in preindustrial times as a net source of fixed nitrogen, while the ocean acted as a net sink. On land, preindustrial N_2 fixation exceeds denitrification so that a certain fraction of the fixed nitrogen can be exported laterally by rivers to the ocean, where it permits oceanic denitrification and burial to exceed N_2 fixation. The ocean also receives fixed nitrogen from the atmosphere, some of which has been produced there from N_2 by lightning, and some of which is exported from the land through the atmosphere.


Figure 1.15 Schematic budget of the global nitrogen cycle in preindustrial times (black) and how it changed as a result of human intervention (red). Fluxes are in units of Tg N year^{-1} and inventories (bold italics) in Tg N. The flux estimates are based on Gruber and Galloway (2008).

Over the last 250 years, humans have caused a massive perturbation of the global nitrogen cycle (see Galloway (1998) and below for more discussion), with most impact in terrestrial ecosystems. Industrial N_2 fixation by the Haber–Bosch process now rivals biological N_2 fixation by the land biosphere. Furthermore, the planting of legumes and other plants with endosymbiontic N_2 fixers has led to an additional input of fixed nitrogen to the land. Finally, the burning of fossil fuels leads to the generation of NO_x, most of which gets oxidized in the atmosphere to NO_3^- before being deposited on land. The combined anthropogenic inputs of fixed nitrogen into land ecosystems now exceeds the preindustrial net input by nearly 50%. Most of this anthropogenic nitrogen input into the land ecosystems is either stored there or is denitrified, but a substantial fraction gets exported to the ocean via rivers and atmosphere, leading to more than a doubling of the input of fixed nitrogen into the ocean. The fate of this anthropogenic nitrogen in the ocean is not well understood. It appears as if most of the anthropogenic nitrogen transported by rivers is denitrified in the lower parts of the estuaries and in the coastal ocean (Seitzinger and Kroeze, 1998; Galloway *et al.*, 2004). By contrast, much of the increased atmospheric deposition likely makes it further out into the ocean, possibly stimulat-ing productivity there (Duce, 1986).

5. Nitrogen Challenges

5.1. Controls on the marine fixed Nitrogen-content

On some timescale approaching the turnover time of fixed nitrogen in the ocean (i.e., about 2000 to 3000 years), nitrogen fixation and denitrification in the ocean must be coupled to each other, otherwise the marine fixed nitrogen content of the ocean would have undergone massive swings in the past, with large implications for marine productivity. There is little evidence in the geological record that such massive variations occurred (Sigman and Haug, 2003), suggesting that the coupling must be reasonably tight. This requires the existence of well developed negative feedbacks that prevent the growth of initial perturbations, such as induced, for example, by the large climate variations associated with the glacial–interglacial transitions in the last million years.

Two negative feedback processes have been proposed to stabilize the oceanic nitrogen cycle (see Fig. 1.16 and discussions by e.g., Tyrrell (1999), Deutsch et al. (2004), and Gruber (2004), see also Galbraith et al. in Chapter 34, this volume). The first feedback process is based on denitrification (Broecker and Peng, 1982; Codispoti, 1989). Suppose that denitrification became stronger in response to some environmental change. This would cause the fixed nitrogen content of the ocean to decrease relative to the PO_4^{3-} content, thereby tending to reduce the supply of fixed nitrogen to the surface ocean as well. This would result in a smaller export production, leading to a smaller oxygen demand in the thermocline and a smaller organic nitrogen deposition onto the marine sediments. Since these two processes are thought to control denitrification, their decrease would cause both column and benthic denitrification do decrease as well. This would reduce the initial perturbation, i.e., close the negative feedback loop.

The second feedback builds on N_2 fixation and the assumption that diazotrophic organisms can outcompete "normal" phytoplankton in situations of severe NO_3^- depletion but where PO_4^{3-} is still present (Karl et al., 2002), but that diazotrophic organisms are otherwise at a disadvantage because of their slow growth. Therefore, if fixed nitrogen became scarce relative to PO_4^{3-} in the ocean, these surface regions characterized by residual PO_4^{3-} would expand, increasing the ecological niche for diazotrophic organisms. As a consequence, N_2 fixation would increase and add newly fixed nitrogen to the ocean. After a while, the resulting increase in fixed nitrogen would reduce the regions of PO_4^{3-} residuals, removing the competitive advantage of diazotrophs, and hence lowering N_2 fixation again. An equilibrium is reached when N_2 fixation is back in balance with denitrification. Haug et al. (1998) provided evidence that such a feedback might have operated across glacial–interglacial cycles in the Cariaco Basin.

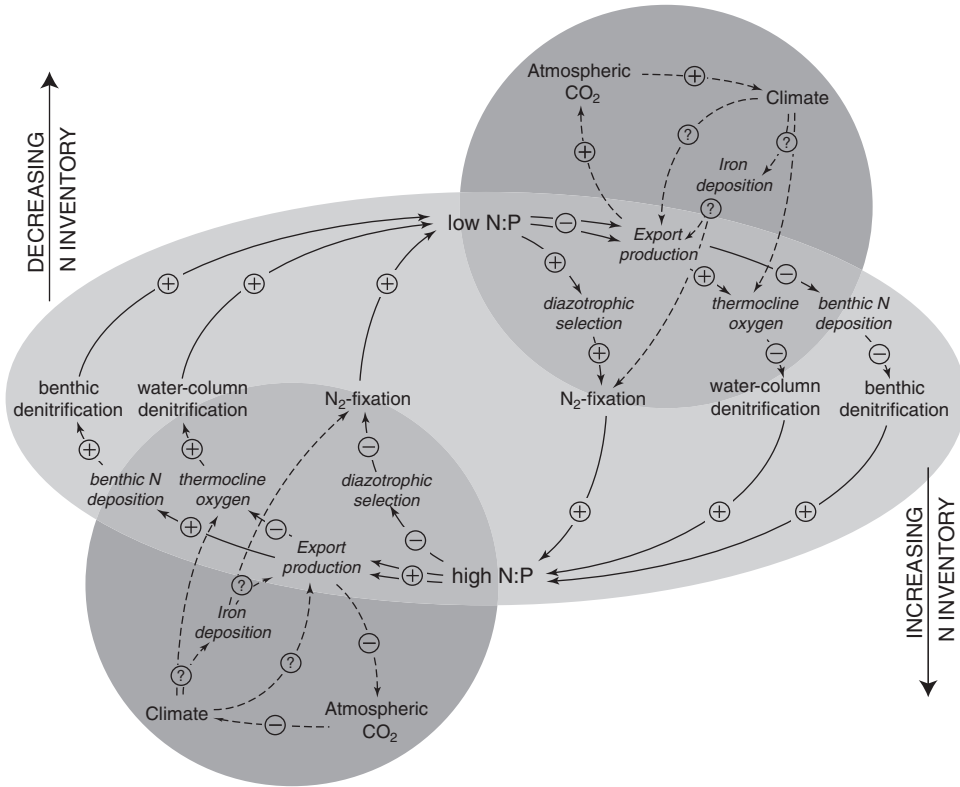
In both proposed feedback mechanisms, the dominant controlling factor is the surface ocean NO_3^- to PO_4^{3-} ratio (see Fig. 1.16). Both feedbacks are expected to operate in situations of excess NO_3^- (i.e., high NO_3^- to PO_4^{3-} ratio, shown at the bottom of the feedback loop in Fig. 1.16), as well as in situations of NO_3^- deficiency (i.e., low NO_3^- to PO_4^{3-} ratio, shown at the top of the feedback loop). If this view is correct, these two feedbacks would provide a rather tight control of the marine nitrogen cycle, creating a well balanced homeostasis. A further consequence is that


Figure 1.16 Schematic representation of feedbacks within the marine nitrogen cycle. The inner light grey ellipse shows the two nitrogen cycle "internal" feedback loops that tend to be stabilizing. These two feedback are proposed to be mainly controlled by the NO_3^- to PO_4^{3-} (N:P) ratio in surface waters. If the surface N:P ratio is low, denitrification tends to get reduced because of lower surface productivity, while N_2 fixation tends to increase because of favorable conditions for diazotrophic organisms. Both processes lead to an increase in the oceanic fixed nitrogen inventory. In contrast, when the surface N:P ratio is high, N_2 fixation tends to decrease, while denitrification increases, leading to a reduction of the oceanic fixed nitrogen inventory. These nitrogen internal feedbacks can be altered significantly by their interaction with the carbon cycle, climate and other processes (dark grey ellipses). The sign of these feedbacks are currently not understood and can be either positive or negative, leading to stabilizing or destabilizing feedbacks. From Gruber (2004).

on time–scales longer than the residence time of phosphorus in the ocean (i.e., about 30,000 to 50,000 years (Delaney, 1998)), the marine nitrogen cycle would be completely slaved to the marine phosphorus cycle, making PO_4^{3-} the ultimate limiting nutrient (Tyrrell, 1999). This view can be traced back to Redfield (1958) and is shared by many geochemists (e.g., Broecker and Peng (1982), see discussion by Codispoti (1989)). This also would move processes that control the marine phosphorus content, such as erosion on land, and burial in marine sediments to the center of attention if one wants to understand past oceanic productivity (Lenton

and Watson, 2000). However, upon closer inspection, the processes and factors controlling marine N_2 fixation and denitrification are more complex than simply the NO_3^- to PO_4^{3-} ratio of surface waters.

A first challenge to the PO_4^{3-} control hypothesis emerges from the observation that the tropical and subtropical North Atlantic are sites of high N_2 fixation (Capone *et al.*, 2005; Carpenter and Romans, 1991), yet these waters have extremely low PO_4^{3-} concentrations (Wu *et al.*, 2000). By contrast, there appear to be vast regions in the South Pacific that have substantial residual PO_4^{3-} concentrations, yet there is little evidence for enhanced N_2 fixation (Carpenter, 1983). Clearly, other factors besides the NO_3^- to PO_4^{3-} ratio must play a role in controlling N_2 fixation. Karl *et al.* (2002) suggested temperature, light, and the ambient concentrations of O_2, NO_3^-, NH_4^+, and essential trace metals. In particular, the availability of iron has been proposed as a major factor controlling N_2 fixation, based on the argument that N_2 fixers have a particularly high iron demand (Falkowski, 1997). If this was correct, there would exist substantial potential for the marine nitrogen cycle to escape the proposed negative feedbacks, and cause major changes in marine productivity and atmospheric CO_2 (Broecker and Henderson, 1998; Falkowski, 1997; Lenton and Watson, 2000; Michaels *et al.*, 2001).

The observed pattern of N_2 fixation, the distribution of $N^\star$ and the fact that the North Atlantic and to some degree the North Pacific receive much more iron from the atmosphere than the South Pacific appear to be consistent with the posit of iron playing an important role for controlling N_2 fixation. However, the evidence for large-scale iron limitation of N_2 fixation is largely circumstantial. Results from iron addition experiments are inconclusive (Hood *et al.*, 2000), or show that the stimulation is small unless PO_4^{3-} is added as well (Mills *et al.*, 2004). Recent analyses of the iron content in natural populations of *Trichodesmium* in the central Atlantic reveal neither a significantly higher iron requirement, nor a geographical pattern in cellular iron content consistent with patterns of iron deposition (Sanudo-Wilhelmy *et al.*, 2001). Rather, these authors assign PO_4^{3-} a key role in explaining the observed variability. More recently, Deutsch *et al.* (2007) pointed out that the global distribution of upper ocean NO_3^- and PO_4^{3-}, when interpreted diagnostically with a simple coupled ecological/physical model, suggest that N_2 fixation is mainly located in the Pacific Ocean and tends to be associated with regions of NO_3^- deficiency, i.e., PO_4^{3-} excess. They interpret these results as an indication that the NO_3^- to PO_4^{3-} ratio re-emerges as the primary factor controlling marine N_2 fixation, lending support to the N_2-fixation-based negative feedback loop in Fig. 1.16.

What about the denitrification-based feedback loops? The primary factor controlling benthic denitrification is thought to be the supply of organic nitrogen to the sediments (Middelburg *et al.*, 1996). As the flux of organic nitrogen to the seafloor is primarily a function of surface export production and bottom depth, these two factors ultimately control benthic denitrification. The former is connected to the surface ocean NO_3^- content, providing support for the negative feedback loop. However, bottom topography can be changed independently, leading to the potential for decoupling benthic denitrification from N_2 fixation. Such a scenario was proposed by McElroy (1983), who suggested that the lowering of sea-level during the last glaciation caused a substantial decrease of benthic denitrification, leading to a higher marine fixed nitrogen inventory, and ultimately lower atmospheric CO_2.

The primary factor controlling water column denitrification is the oxygen concentration. In the interior of the ocean, the condition for the generation of an oxygen depletion zone is given when the supply of O_2 by ocean transport from the surface ocean is smaller than the oxygen demand from the remineralization of organic matter. Therefore both low ventilation of the water column or high rates of remineralization of organic matter can cause oxygen depleted waters and hence water column denitrification. It appears that both processes are important for generating the oxygen depleted conditions in the three regions, where we currently observe such conditions i.e., the ETSP, the ETNP and the Arabian Sea. Therefore, the dependence of water column denitrification on surface ocean productivity and export provides the needed link for creating the proposed negative feedback loop. In contrast, the possibility of altering water column denitrification by changes in ocean circulation provides a potential avenue for undoing the tight control of the marine nitrogen content by the denitrification feedback loop. There is ample evidence in the geological record that water column denitrification indeed varied greatly in the past (Altabet *et al.*, 1995, 2002; Ganeshram *et al.*, 1995, 2000). However, evidence for large changes in glacial productivity are scarce, and in summary suggesting a rather similar biological productivity during those times, but with a different spatial distribution (Kohfeld *et al.*, 2005).

Despite substantial uncertainty, the view that emerges is an oceanic nitrogen cycle that is relatively well stabilized by the two proposed negative feedback loops. Both feedbacks operate on the time-scale of whole ocean overturning, i.e., decades to a few hundred years, thus keeping the system only in an approximate dynamic homeostasis, as on time-scales shorter than this, imbalances between N_2 fixation and denitrification can exist and significantly alter the fixed nitrogen content of the ocean. The internal feedbacks can be perturbed by outside factors, including changes in climate, iron deposition, and sea-level, some of which can form closed feedback loops (Fig. 1.16, see also Michaels *et al.* (2001)). While the basic structure of these controls on the marine nitrogen cycle seem relatively well established, there remain many open questions. For example, what is the role of iron limitation for marine N_2 fixation? For example, Lenton and Watson (2000) demonstrated on the basis of model simulations that the proposed negative feedback loops keep the marine nitrogen cycle indeed closely slaved to the marine phosphorus cycle under iron replete conditions. However, when they reduced the iron availability, N_2 fixation became decoupled from denitrification, leading to a substantial deficit in the marine nitrogen content relative to that of phosphorus.

5.2. The marine Nitrogen-cycle, Carbon-cycle, and climate

Given the importance of the marine nitrogen cycle in controlling marine productivity and the close connection between the marine carbon and nitrogen cycles (see Fig. 1.1), it is not surprising that changes in the marine nitrogen cycle were suggested very early on as a possible explanation of past variations in the global carbon cycle and particularly atmospheric CO_2 (e.g., McElroy (1983), and more recently Altabet *et al.* (1995), Ganeshram *et al.* (1995), Falkowski (1997), Broecker and Henderson (1998), and Michaels *et al.* (2001)) (see Chapter 34 by Galbraith *et al.* and Chapter 35

by Berman-Frank *et al.* for more in depth discussions). Although they vary in their details, the basic premise of all hypotheses is that it is possible to decouple marine N_2 fixation and denitrification enough to cause a long-term change in the marine inventory of fixed nitrogen. This change would then alter marine productivity, and consequently the ocean–atmosphere partition of CO_2. However, as discussed above, it appears to be relatively difficult to keep the marine nitrogen cycle out of balance for a long time, as the negative feedbacks seem rather strong. This prevents sizeable variations in marine productivity to occur in response to alterations in the marine nitrogen cycle, limiting the strength of the nitrogen cycle-based hypotheses to explain past changes in atmospheric CO_2.

A second argument against marine nitrogen cycle-based hypotheses is the observation that low- and mid-latitude alterations of the surface ocean CO_2 chemistry are generally much less efficient in changing atmospheric CO_2 than high–latitude changes (Broecker and Peng, 1998; Broecker *et al.*, 1999). This is primarily a result of the high-latitudes providing the "window" to the deep ocean, where most of the combined atmosphere-ocean carbon inventory resides. Since biological productivity in the high-latitudes, and particularly in the Southern Ocean are controlled by factors other than fixed nitrogen, the nitrogen–cycle based hypotheses primarily operate through changes in low- and mid-latitude productivity. This gives these hypotheses much less leverage on atmospheric CO_2 than iron based hypotheses that permit large changes in high–latitude productivity. In summary, despite a possibility for surprises given our limited understanding of the processes that lowered atmospheric CO_2 during the ice-ages, it appears as if changes in the marine nitrogen cycle have had relatively little influence on atmospheric CO_2 (Gruber, 2004).

Nevertheless, past changes in the marine nitrogen cycle were likely quite substantial. This is evidenced, for example, by the considerable changes in atmospheric N_2O associated with the glacial/interglacial transitions (Flückiger *et al.*, 1999), and the large changes in the extent of denitrification (Altabet *et al.*, 1995; Ganeshram *et al.*, 1995) and their possible connection with atmospheric CO_2 variations (Altabet *et al.*, 2002). However, our quantitative understanding of the past changes in the marine nitrogen cycle is only poorly developed, representing another major challenge of the marine nitrogen cycle. The development of a better quantitative understanding of these past changes is particularly important if we want to have some confidence in projecting the impact of future climate changes on the oceanic nitrogen cycle.

5.3. The anthropogenic perturbation

The direct anthropogenic perturbation of the global nitrogen cycle has been massive, leading to an enormous acceleration of this cycle (see Fig. 1.15 and Galloway *et al.* (1995), Vitousek *et al.* (1997), Galloway *et al.* (2002), and Gruber and Galloway (2008)). Although the widespread application of nitrogen-based fertilizers has been an important contributor to the ability of humans to grow enough despite a rapidly growing population, the negative environmental effects of this fertilizer use are widespread (Galloway *et al.*, 2002). In addition, the creation of reactive forms of nitrogen (mostly NO_x) during the combustion of fossil fuels has also increased dramatically over the last few decades, leading to problems as diverse as enhanced

tropospheric ozone formation, acid rain, and eutrophication in aquatic ecosystems. Galloway and Cowling (2002) introduced the term *nitrogen cascade* to emphasize that a fixed nitrogen molecule introduced into the environment by humans often leads to a whole series of impacts, some of which occur much later and far away from where the molecule was introduced first. For example, the application of nitrogen fertilizer on some agricultural patch may first lead to the loss of biodiversity. As some of this fertilizer gets washed into nearby streams, it leads to eutrophication there, and later, perhaps, in a lake downstream. If this fixed nitrogen escapes denitrification, it may end up in the coastal ocean, causing another episode of eutrophication.

On the global scale, there is little evidence so far that the acceleration of the global nitrogen cycle by humans has led to detectable changes in the marine nitrogen cycle (Duce *et al.*, 2008). This is not the case in many coastal regions, however, as there exist several well documented examples of coastal eutrophication in direct response to the input of anthropogenically derived nitrogen, mainly by rivers (see e.g., Beman *et al.* (2005), Rabalais (2002), and Chapter 11 by Paerl and Piehler, this volume for a discussion). The impact of these changes can be multi-faceted, ranging from the loss of habitat for fish due to reduced oxygen concentrations to the increased occurrence of blooms of harmful algae. Global creation of fixed nitrogen by humans is expected to increase severalfold in the next 100 years, perhaps going as high as 900 Tg N year^{-1} (Galloway *et al.*, 2002). We therefore have to expect a substantial worsening of the coastal eutrophication problem, as well as to consider the possibility of sizeable direct changes in the nitrogen cycle of the open ocean.

In addition, humans will affect the nitrogen cycle likely also indirectly through anthropogenically induced climate change. Climate projections for the 21st century are inherently uncertain due to uncertainties in the nature and magnitude of future energy use as well as uncertainties in the global carbon cycle and the physical climate system, but it is likely that Earth will warm another few degrees Celsius in this century (see Houghton *et al.* (2001)). This could cause a number of feedbacks within the Earth system involving the marine nitrogen cycle (see Chapter 35 by Berman-Frank *et al.* and Gruber and Galloway (2008)).

For example, nearly all climate projections for the 21st century suggest that oceanic stratification will increase (Sarmiento *et al.*, 1998), primarily as a result of the input of heat into the surface ocean, but in part also by a freshening of the upper ocean. This will likely cause a decrease in export production in the low latitudes, as it will restrict the upward transport of nutrients (Bopp *et al.*, 2001; Matear and Hirst, 1999; Sarmiento *et al.*, 1998;). On the other hand, export production in the mid-to high-latitudes may actually increase due to lower light stress in a shallower mixed layer (Bopp *et al.*, 2001).

The details of these productivity changes vary from model to model, but the future warming acting in concert with increased stratification and reduced ventilation of the thermocline will almost certainly decrease the oxygen content of the ocean's interior (Bopp *et al.*, 2002; Deutsch *et al.*, 2005; Matear *et al.*, 2000; Plattner *et al.*, 2002). This would enhance denitrification and the production of nitrous oxide. Unless this increased loss of nitrogen is compensated by increased N$_2$ fixation, the resulting decrease in the inventory of fixed nitrogen and biological productivity

would result in a net loss of CO_2 from the ocean, causing a positive feedback. The increased production of nitrous oxide would constitute a second positive feedback, leading to an overall acceleration of climate change due to the interaction of the climate system with the marine nitrogen cycle.

6. CONCLUSIONS

Although the marine nitrogen cycle occupies a central role within the biogeochemical cycles of the sea, we have just barely begun to understand its major processes and the factors that regulate them. This occurs at a time when human interventions in the Earth system has risen to unprecedented levels, with a particularly strong impact on the global nitrogen cycle. Although the nitrogen cycle in the open ocean appears to have remained largely unscathed from human influence, many coastal systems have already been seriously impacted. Projections of the future suggest that this may change soon, either directly by the continued addition of anthropogenically created fixed nitrogen to the Earth system and its cascading effects, or indirectly through anthropogenically induced climate change. Some of these alterations have the potential to cause positive feedbacks in the climate system, but they are neither well understood nor quantified. It behooves us well to address these difficult, but exciting challenges.

Gaseous Nitrogen Compounds (NO, N$_2$O, N$_2$, NH$_3$) in the Ocean

Hermann W. Bange

Contents

1. INTRODUCTION

Nitric oxide (NO), nitrous oxide (N_2O), dinitrogen (N_2), and ammonia (NH_3) are constituents of the Earth's atmosphere. They play important roles in the chemistry and climate of the present-day Earth. Moreover, they are intermediates of the oceanic nitrogen cycle. In contrast to most of the other components of the oceanic nitrogen cycle, they exist as dissolved gaseous molecules. Being gases they can be transferred across the seasurface–troposphere interface.

In this chapter, I intent to give an overview about the current knowledge on the oceanic distribution and pathways of NO, N_2O, N_2, and NH_3, which has increased considerably since the publication of ''Gaseous nitrogen compounds in the sea'' by Scranton (1983).

Fundamental physical processes such as gas diffusivities in seawater and air–sea gas exchange as well as details of measurement techniques for dissolved gases in seawater are not discussed in the context of this chapter.

Because of the heavily increasing number of publications (especially for N_2O) it is not possible to give a comprehensive overview on all aspects of the gases discussed in this chapter. Therefore, it was necessary to focus the review on one particular topic—the water-column distribution. However, to cover emerging new developments, sedimentary and atmospheric measurements/processes are introduced when necessary. I tried to document the most actual developments, however, especially for N_2O, it was not possible to consider all relevant publications.

To have a high degree of transparency, I predominately used publications in international journals or books. ''Grey'' literature such as PhD thesis or submitted articles etc. is cited only when unavoidable.

In the literature, dissolved gases are generally expressed either in concentrations ($nmol\ L^{-1}$ or $nmol\ kg^{-1}$ or $mL\ mL^{-1}$) or are expressed as a saturation ratio, which is the ratio of the measured dissolved gas concentration to the expected equilibrium concentration. Saturation ratios <1 indicate undersaturation whereas saturation ratios >1 stand for supersaturation. Saturations are also expressed in percentage, which is equal to the saturation ratio times 100. For example, a supersaturation of 3% is equal to a total saturation of 103%, which in turn is equal to a saturation ratio of 1.03.

2. NITRIC OXIDE

2.1. Climatic and biogeochemical relevance

Nitric oxide or nitrogen monoxide (NO) is a colorless gas. It has a boiling point (bp) of $-151.8°C$ (at 1 atm) and molecular weight of $30.0\ g\ mol^{-1}$. Because it has an odd number of electrons, NO is a very reactive molecule (a so-called radical) (Greenwood and Earnshaw, 1984). It is rapidly oxidized within a few minutes to nitrogen dioxide (NO_2), thus NO and NO_2 are usually referred to as

NO_x (= $NO + NO_2$). NO is a short-lived intermediate in a variety of chemical reactions in both the troposphere and the stratosphere (Warneck, 2000). In the stratosphere NO is derived from the photochemical decomposition of nitrous oxide (N_2O, see Section 3) and is involved in one of the main catalytic ozone (O_3) reaction cycles (Crutzen, 1970, 1996). In the troposphere, NO is rapidly oxidized either to nitrous acid (HNO_2) by reacting with hydroxyl radicals (OH) or to nitrogen dioxide (NO_2) by reacting with O_3 or hydroperoxyl radicals (HO_2). NO_x is involved in the catalytic O_3 formation in the troposphere. The atmospheric lifetime of NO_x ranges from <1 day to several days. In regions with high NO emissions from fossil-fuel combustion (e.g., in urban areas), complex photochemical processes involving NO_x and hydrocarbons result in photochemical smog with enhanced O_3 concentrations. One of the final oxidation products of NO, nitric acid (HNO_3), forms NO_3^- aerosol particles or is washed out by rain. Enhanced NO emissions result in enhanced HNO_3 formation, which in turn lowers the pH of rain ("acid rain"). Photochemical smog and stratospheric O_3 depletion can only indirectly influence the marine nitrogen cycle, whereas acid rain and the dry and wet deposition of NO_3^- aerosol and NO_x can directly impact the marine nitrogen cycle and thus marine productivity in coastal areas (De Leeuw *et al.*, 2003; Jickells, 2006; Kouvarakis *et al.*, 2001) and to a lesser extent in remote open ocean areas (Bange *et al.* (2000); Jickells (2006)) (see Chapters 9 and 11).

NO_x atmospheric mixing ratios range from about 100 ppb (10^{-9}) in polluted urban areas to a few ppt (10^{-12}) in remote marine air masses, indicating that in remote marine locations pristine conditions prevail (Warneck, 2000). In past years, NO_x emissions from ship engines have been recognized as a significant pollution of the marine atmosphere with a profound impact on the atmospheric nitrogen chemistry of the marine boundary layer in ship plumes (Corbett and Fischbeck, 1997; Lawrence and Crutzen, 1999; Von Glasow *et al.*, 2003). However, the effects of NO_x emissions from ships (e.g., via deposition as HNO_3 and NO_3^- aerosols) on the marine nitrogen cycle are yet unknown.

2.2. NO in the ocean

The solubility of NO in water is low; Henry's law constants for NO in water are listed in the literature compilation by Sander (1999). Dissolved NO in seawater can be determined with a purge system, which is connected to a chemoluminescence detector for NO (Ward and Zafiriou, 1988; Zafiriou and McFarland, 1980, 1981).

In aquatic systems NO reacts rapidly with O_2, O_2^-, and NO_2 (Zafiriou *et al.*, 1990). Because of its reactivity, NO has been used as molecular probe to determine production rates of long-lived radicals in seawater (Zafiriou *et al.*, 1990). This method has been applied in various regions of the western North Atlantic Ocean (Dister and Zafiriou, 1993; Zafiriou and Dister, 1991).

In nitrite rich surface waters, NO is photochemically produced via the reduction of nitrite (NO_2^-) (Zafiriou and True, 1979):

$$NO_2^- + H_2O + hv \rightarrow NO + OH + OH^- (295 < \lambda < 410\,nm)$$

Indeed, Zafiriou and coworkers (Zafiriou et al., 1980; Zafiriou and McFarland, 1981) found a diurnal cycle of NO in the NO_2^--rich surface waters of the central equatorial Pacific Ocean. The photochemical induced build-up of NO during the day was found to be balanced by degradation during the night (Zafiriou and McFarland, 1981). During the same study, a mean daytime NO surface concentration of 46 pmol L^{-1} was calculated which translates into a 10,000-fold supersaturation when compared with the atmospheric NO concentration measured during the same cruise. Thus, the NO_2^- rich equatorial Pacific Ocean was a net source of NO to the atmosphere. NO surface concentrations determined during a cruise in the eastern tropical North Pacific (ETNP) were close to or below the detection limit (<1.5 pmol L^{-1}) (Ward and Zafiriou, 1988). This is in line with the assumption that detectable NO surface concentrations occur only in NO_2^--rich surface waters such as upwelling regions.In major parts of the ocean surface layer, NO_2^- concentrations are negligible, which implies that the global ocean is a net sink for atmospheric NO.

Five depth profiles of NO and the corresponding NO production rates have been measured in the ETNP (Ward and Zafiriou, 1988): NO concentrations were in the range from 0 up to 65 pmol L^{-1}. At four stations located in the open ocean, maximum NO concentrations were observed at the upper boundary of the oxygen minimum zone (OMZ, O_2<10 μmol L^{-1}), whereas one coastal station showed an increase of NO from 0 pmol L^{-1} at the surface to about 20 pmol L^{-1} at the bottom in about 250m. Maximum NO production rates were found at the upper boundary of the OMZ at the open ocean stations. However, Ward and Zafiriou (1988) could not unambiguously identify the NO formation process because NO production rates and nitrification rates (i.e., NH_4^+ oxidation rates) were not correlated. NO accumulation appeared when O_2 concentrations were lower than 100 μmol L^{-1}, whereas in the core of the OMZ with O_2 concentrations close to 0 μmol L^{-1}, denitrification seemed to cause a rapid turnover of NO. Highest ever-reported concentrations of dissolved NO were found off Peru ranging from 0 up to 400 pmol L^{-1} (Zafiriou, personal communication in Ward and Zafiriou (1988)).

2.3. The role of the ocean for the global budget of atmospheric NO_x

The major source of tropospheric NO_x is fossil–fuel combustion (33.0 Tg N yr^{-1}). Minor sources (values in parenthesis are given in Tg N yr^{-1}) are biomass burning (7.1), lightning (5.0), soil emissions (5.6), inputs from the stratosphere (<0.5), and exhausts from aircrafts (0.7) (Prather et al., 2001). As stated above, NO_x emissions from ships have gained increasing attention during the last years. The total annual NO_x emissions from ships was estimated to be 6.9 Tg N (Corbett and Koehler, 2003) and only recently, Eyring et al. (2005) estimated that the annual NO_x ships' emissions have increased from 2.2 Tg N in 1950 to 9.4 Tg N in 2001. These new assessments are especially important in view of the fact that NO_x has a very short lifetime and thus NO_x and/or its reaction products will be more-or-less immediately deposited to the ocean surface. This additional nitrogen source should be considered in future studies of the upper ocean nitrogen cycle.

The ocean as a source of atmospheric NO_x is negligible: Based on the data by Zafiriou and McFarland (1981), Logan (1983) estimated an annual source of 0.5 Tg N. Moreover, the ocean can act as a sink for tropospheric NO_x via wet and dry deposition. Duce *et al.* (1991) estimated that a total of 0.04 Tg N yr^{-1} is deposited, however, their estimate did not include ships' emissions (see above).

3. Nitrous Oxide

3.1. Climatic and biogeochemical relevance

Nitrous oxide (N_2O, dinitrogen monoxide, colloquial called laughing gas) is a colorless gas with an asymmetrical linear structure ($N = N = O$). It has a boiling point of $-88.5°C$ and a molecular weight of 44.01 g mol^{-1}. Its physical properties are comparable to the isoelectronic carbon dioxide (CO_2). For example, both gases show similar solubilities and diffusivities in water (King *et al.*, 1995; Wilhelm *et al.*, 1977). Like CO_2, N_2O is a radiatively active atmospheric trace gas, however, its global warming potential is, on a 100 years time horizon, about 296–340 times higher than that of CO_2 (Jain *et al.*, 2000; Ramaswamy *et al.*, 2001). Formation or decomposition reactions of N_2O in the troposphere are negligible resulting in an inert behavior of atmospheric N_2O. The atmospheric lifetime of N_2O is estimated to be about 114–120 years (Prather *et al.*, 2001). Due to its relatively long atmospheric lifetime, N_2O is mixed into the stratosphere where it is photochemically decomposed. Moreover, by reaction with $O(^1D)$ in the stratosphere, it forms nitric oxide (NO) radicals, which are involved in one of the major catalytic ozone (O_3) reaction cycles (Crutzen, 1970, 1996).

Atmospheric N_2O concentrations, depicted from Antarctic and Arctic ice cores as well as from Antarctic firn, show relatively uniform tropospheric N_2O mixing ratios in the range from 260 to 275 ppb (10^{-9}) in the period from 1000 to 1900 AD and an increase to the present values during the last 100 years (Khalil *et al.*, 2002; Prather *et al.*, 2001; Sowers, 2001). The global mean N_2O mole fraction in 1998 was about 313–314 ppb associated with a mean interhemispheric gradient of about 0.7–0.8 ppb (Khalil *et al.*, 2002; Prather *et al.*, 2001; Prinn *et al.*, 2000). Higher N_2O values are measured in the northern hemisphere because the majority of sources of atmospheric N_2O are located the northern hemisphere (Khalil *et al.*, 2002; Prather *et al.*, 2001; Prinn *et al.*, 2000). Due to the lack of significant atmospheric sink and source reactions, almost no vertical tropospheric N_2O gradient is observed, whereas stratospheric N_2O mixing ratios decrease due its photochemical decomposition (e.g. down to 120 ppb by 30 km in the mid-latitudes) (Prather *et al.*, 2001).

3.2. N₂O in the ocean

The Bunsen solubility of N_2O (C_{N_2O} in mol L^{-1}) in seawater in equilibrium with moist air at $P = 1$ atm can be calculated with the polynomial given by Weiss and Price (1980):

$$C_{N_2O} = Fx'P$$

and

$$\ln F = A_1 + A_2 \left(\frac{100}{T}\right) + A_3 \ln \left(\frac{T}{100}\right) + A_4 \left(\frac{T}{100}\right)^2$$
$$+ S \left[B_1 + B_2 \left(\frac{T}{100}\right) + B_3 \left(\frac{T}{100}\right)^2 \right]$$

with

$$A_1 = -165.8806, A_2 = 222.8743, A_3 = 92.0792, A_4 = -1.48425,$$
$$B_1 = -0.056235, B_2 = 0.031619, B_3 = -0.004847$$

F is in mol L^{-1} atm^{-1}. T stands for temperature in K, S stands for salinity, x' stands for the dry mole fraction of atmospheric N_2O, and P stands for the ambient pressure. The polynomial is valid in a temperature range from 273.15 to 311.15°K (0–40°C) and a salinity range from 0 to 40. A alternative equation for C_{N_2O} in gravimetric units (mol kg^{-1}) can be found as well in Weiss and Price (1980). The N_2O equilibrium concentration, $C_{N_2O, \text{equilibrium}}$, at $T = 298.15$ K (25°C), $S = 35$ and $x' = 318$ ppb is 6.38 nmol L^{-1}. It doubles (12.42 nmol L^{-1}), when the temperature is set to 278.15°K (5°C).

It was not until the advent of the electron capture detector (ECD) and the development an appropriate ECD calibration routine when precise and reliable N_2O measurements were made possible (Cohen, 1977; Elkins, 1980; Rasmussen *et al.*, 1976; Weiss, 1981). Up to now the use of an ECD in connection with equilibration or purge-and-trap techniques followed by gas chromatographic separation is state of the art for the determination of dissolved N_2O (Butler and Elkins, 1991).

3.3. Oceanic pathways

N_2O is in mainly produced by two microbial processes, namely denitrification and nitrification (see Fig. 2.1):

(i) Denitrification results in a loss of bioavailable (fixed) nitrogen in the form of gaseous products such as N_2O and N_2 (for details about denitrification see Chapter 6):

$$NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$$
As can be seen from the denitrification reaction sequence, N_2O is a obligatory intermediate. Thus, N_2O originating from denitrification is resulting from the interplay of its formation and its consumption step to N_2. Denitrification is a
Figure 2.1 Overview of processes, which influence the N$_2$O distribution in the ocean. The dashed arrows indicate N$_2$O reduction during N$_2$ fixation (see e.g. Yamazaki *et al.* (1987)). Please note that NO is not an obligate intermdiate of the nitrification sequence.

well-known feature of many different bacteria species in terrestrial and oceanic environments (Bothe *et al.*, 2000; Tiedje, 1988; Zumft, 1997). Denitrifiers are facultative anaerobic bacteria, which can reduce NO$_3^-$ when oxygen becomes limiting. Thus the occurrence of denitrification is favored under suboxic ($0 < $ O$_2 < 2$–10 μmol L^{-1}, (Codispoti *et al.*, 2005)) conditions. Denitrification does not occur under anoxic conditions (O$_2 = 0$ μmol L^{-1}, hydrogen sulphide present).

(ii) Nitrification is the oxidation of ammonium (NH$_4^+$) to NO$_3^-$ via hydroxyl-amine (NH$_2$OH) and nitrite NO$_2^-$ (for details about nitrification see Chapter 5). Autotrophic nitrification represents the final step of the oceanic reminer-alization and is performed in two steps by ammonia-oxidizing bacteria (AOB, e.g. *Nitrosomonas* and *Nitrosospira*) and nitrite-oxidizing bacteria (NOB, e.g. *Nitrobacter* and *Nitrospira*), respectively (Arp and Stein, 2003; Bothe *et al.*, 2000; Kowalchuk and Stephen, 2001):

$$\text{AOB} : \text{NH}_4^+ \rightarrow \text{NH}_2\text{OH}(\rightarrow \text{NO}) \rightarrow \text{NO}_2^-$$

$$\text{NOB} : \text{NO}_2^- \rightarrow \text{NO}_3^-$$
(NO is not known to be an obligate intermediate during ammonium oxidation. It can be produced by AOB but the mechanism is not well known, see also section ''NO in the ocean'' above). During autotrophic nitrification N$_2$O can be formed by AOB either via the pathways NH$_2$OH $\rightarrow$ N$_2$O and NO $\rightarrow$ N$_2$O (Arp and Stein, 2003; Stein and Yung, 2003) or via the pathway NO$_2^- \rightarrow$ NO $\rightarrow$ N$_2$O (the latter is part of the so-called nitrifier–denitrification process) (Stein and Yung, 2003; Wrage *et al.*, 2001). Nitrification is an aerobic process, however, under low-oxygen conditions, N$_2$O yields are enhanced (De Bie *et al.*, 2002; Goreau *et al.*, 1980). Alternatively, N$_2$O can be formed during heterotrophic nitrification (i.e. nitrification linked to aerobic denitrification) via the reaction NO$_2^- \rightarrow$ NO $\rightarrow$ N$_2$O as well, but, the

enzymes involved in the heterotrophic reaction sequence are different from those involved in the autotrophic pathway. Under oxic conditions, N_2O yields from heterotrophic nitrification are higher than those from autotrophic nitrification. However, the relevance of heterotrophic nitrification in the marine environment is not known yet (Stein and Yung, 2003; Wrage et al., 2001).

Both, nitrification and denitrification as sources and sinks of oceanic N_2O have been described in the water column, in the sediments and in association with suspended particles (e.g. Codispoti et al. (2005); Nevison et al. (2003); Schropp and Schwarz (1983); Seitzinger (1990)). N_2O yields from both water–column nitrification and water–column denitrification are listed in Table 2.1. N_2O yields from nitrification range from 0.004% to 0.4%, whereas the N_2O yield from the denitrifying suboxic zone in the Arabian Sea was estimated to be about 2%. (Please note that the yield from the Arabian Sea is a net yield because it includes both N_2O formation and consumption by denitrification). Culture studies with strains of nitrifiers revealed that the N_2O yield from nitrification is significantly enhanced (up to 10%) under suboxic conditions (Goreau et al., 1980). N_2O yields from sedimentary denitrification range from 0.1% to 0.5% with values up to 6% in nutrient-rich regions (see overview in Seitzinger and Kroeze (1998)).

N_2O depth profiles from regions with oxic water masses such as found in the major parts the Atlantic (Fig. 2.2), Pacific, and Indian Oceans are characterized by a subsurface N_2O maximum which coincidents with the minimum of dissolved O_2 and the maximum of NO_3^- (Butler et al., 1989; Cohen and Gordon, 1979; Oudot et al., 1990, 2002). The N_2O subsurface maximum is less pronounced or even absent

Table 2.1 N_2O yields of water-column nitrification and water-column denitrification

in the northern North Atlantic Ocean in the regions of the deep-water formation (Fig. 2.2). N_2O concentrations in deep waters below 2000m show an increasing trend from the deep North Atlantic Ocean to the deep North Pacific Ocean. This trend correlates well with the water age distribution in the ocean and was attributed to nitrification (Bange and Andreae, 1999). N_2O input to deep waters by hydro-thermal vent systems seem to be of minor importance (Bange and Andreae, 1999; Lilley *et al.*, 1982).

N_2O profiles from oceanic regions with suboxic zones such as the Arabian Sea and the eastern tropical North Pacific Ocean, which are sites of intense denitrifica-tion activities, generally show a two-peak structure (Fig. 2.3): N_2O maxima are found at the upper and lower boundaries of the oxygen minimum zone (OMZ), whereas in the core of the suboxic zone, N_2O concentrations are considerably depleted (Bange *et al.*, 2001b; Cohen and Gordon, 1978). In anoxic water masses such as found in the central Baltic Sea, the Cariaco Basin, and Saanich Inlet, N_2O concentrations are close to the detection limit or not detectable (Brettar and Rheinheimer, 1991; Cohen, 1978; Hashimoto *et al.*, 1983; Rönner, 1983; Walter *et al.*, 2006b).

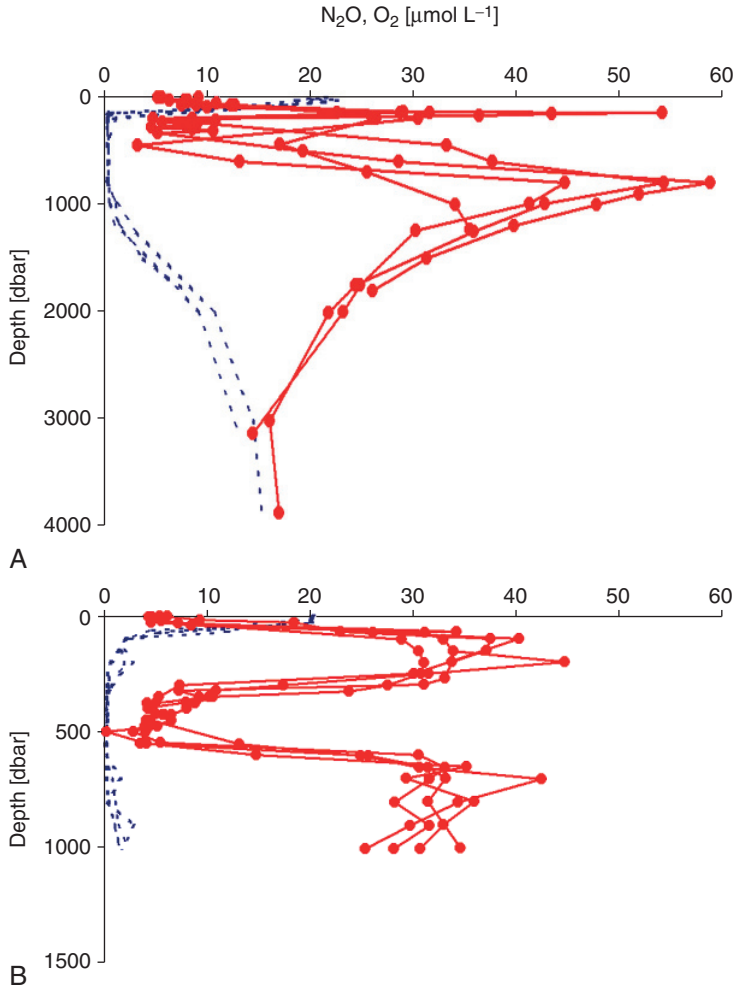
Depth profiles of N_2O (apart from of a exceptions found in suboxic and anoxic waters, see above) show positive concentration anomalies, expressed as $\Delta N_2O(= C_{N_2O, \text{ measured}} - C_{N_2O, \text{ equilibrium}})$. Positive ΔN_2O values are interpreted as an indicator for in-situ N_2O formation. This caused Yoshinari (1976) to coin the term "apparent N_2O production" for ΔN_2O. Because nitrification is directly linked to organic matter remineralization, plots of ΔN_2O vs. apparent oxygen utilization (AOU) or N_2O vs. O_2 have been used to identify prevailing formation and consumption processes of oceanic N_2O. AOU is usually used as a measure of the amount of O_2 consumed during organic matter oxidation in the ocean. Plots of


Figure 2.3 N_2O profiles (in nmol L^{-1}) from oceanic regions with denitrifying intermediate waters: (A) Central Arabian Sea (Bange *et al.*, 2001b) and (B) Eastern tropical North Pacific Ocean (Bange *et al.*, unpublished data). Dashed lines stand for dissolved O_2 (concentration in $\mu mol\,L^{-1}$ divided by 10).

$\triangle N_2O$ vs. AOU from the majority of the oceanic regions show clear positive linear relationships, suggesting that nitrification is the main N_2O formation process. This is supported by the fact that in the most oxic water columns N_2O is positively correlated with NO_3^{-}, the final product of nitrification. The slope of the linear $\triangle N_2O$–AOU relationship varies between 3×10^{-5} and 3×10^{-4} (Bange and Andreae, 1999; Bange *et al.*, 2001b; Nevison *et al.*, 1995; Oudot *et al.*, 2002; Suntharalingam and Sarmiento, 2000) and can be interpreted as the N_2O yield per O_2 molecule consumed indicating that it needs between 33,000 to 3000 molecules O_2 to produce 1 molecule N_2O. Beside the well-documented linear relationships,

non-linear $\triangle N_2O$–AOU 2nd order polynomial fits have been reported from the Arabian Sea (Upstill-Goddard *et al.*, 1999) and the shallow coastal Bedford Basin (Punshon and Moore, 2004). The non-linear relationship have been also attributed to N_2O formation by nitrification. The obvious considerable discrepancies of the $\triangle N_2O$–AOU slopes reported in the literature might result from a variety of reasons:

(i) *Water mass age and history of atmospheric N_2O:* $\triangle N_2O$ is also a function of the atmospheric N_2O mole fraction. This in turn implies that $\triangle N_2O$ should be computed with the atmospheric N_2O mole fraction at the time when a water mass had its last contact with the atmosphere. Using ''historical'' N_2O dry mole fractions would shift $\triangle N_2O$ to higher values. However, it requires the knowledge of the water mass ages and the associated atmospheric N_2O mole fractions, which are not available in most cases.

(ii) *Variability of the N_2O yield:* the N_2O yield from nitrification is not necessarily uniform in the ocean since it depends on the abundance and composition of the bacterial community (i.e., the biological diversity). The O_2-dependence of N_2O formation might be varying for different bacteria species. Moreover, Nevison *et al.* (2003) speculated that the remineralization of nitrogen-enriched organic material (which can be found in regions with high N_2 fixation activities) might lead to an enhancement of the N_2O yield. However, detailed studies on the N_2O yields from marine nitrifiers are lacking.

(iii) *N_2O from denitrification:* signals of N_2O produced in suboxic zones during denitrification can be advected to adjacent oxic, nitrifying zones (Bange *et al.*, 2001b). Moreover, N_2O formation in O_2-depleted microniches such as found in sinking particles, can release additional N_2O (Schropp and Schwarz, 1983).

(iv) *Applicability of AOU:* AOU in deep waters does not represent the true oxygen utilization because surface O_2 concentrations at sites of deep-water mass formation might not be in equilibrium with the atmosphere. This leads to overestimation or underestimation of deep water AOU and raises questions concerning the use of AOU as a measure of respiration (see e.g. Ito *et al.*, 2004). Moreover, uncertainties in the O_2 solubility equations are most pronounced at low temperatures ($<1°C$) and high salinities (i.e. in the typical features of deep ocean water masses of the thermohaline circulation) as pointed out by *Garcia and Gordon* (1992).

There are caveats against a straightforward interpretation of the linear $\triangle N_2O$–AOU relationship as an indicator for N_2O formation via nitrification. In other words, a linear $\triangle N_2O$–AOU relationship may not necessarily result from nitrification. Most recently, based on N_2O isotopomer data (see below), Yamagishi *et al.* (2005) argued that net N_2O formation in the oxygen minimum zone (OMZ) of the western North Pacific Ocean mainly results from denitrification with only a small contribution by nitrification. They showed that this N_2O, when diffusing into deep waters, produces a reasonable linear $\triangle N_2O$–AOU relationship. Moreover, by applying a two end-member mixing model, Nevison *et al.* (2003) showed that isopycnal mixing of water masses with different preformed N_2O and O_2 concentrations can result in a linear $\triangle N_2O$–AOU relationship, which can mask the ''true'' biological N_2O production.

In view of the listed uncertainties, the use of a simple $\triangle N_2O$–AOU relationship in model studies of the global oceanic N_2O distribution (Goldstein et al., 2003; Jin and Gruber, 2003; Suntharalingam and Sarmiento, 2000) might fail to simulate small–scale features of N_2O water–column distributions. A linear relationship between $\triangle N_2O$ (N_2O) and AOU (O_2 or NO_3^-) does not exist in suboxic water masses (eastern tropical Pacific Ocean and Arabian Sea) and in anoxic water masses (e.g., Baltic Sea, Cariaco Basin) indicating a more complex interplay between N_2O formation and consumption during denitrification: The characteristic N_2O double peak structures found in the central Arabian Sea were explained with a coupling of denitrification and nitrification in about 150 m at upper boundary of the OMZ, followed by N_2O consumption due to denitrification in the core of the OMZ in about 400 m. The second, broad N_2O peak in about 800–1000 m was attributed to nitrification (with a signal of denitrification still visible) (Bange et al., 2001b). Incubation experiments with water samples from the denitrifying oxygen minimum zone off northern Chile are in line with the observations from the Arabian Sea: Denitrification was the main N_2O formation process but also the main consumption process resulting in a net depletion of N_2O in the core of the suboxic zone (Castro-González and Fraías, 2004).

Global maps of N_2O in the upper 10 m of the world's oceans have been computed based on the extensive N_2O data set collected by Weiss et al. (1992) since 1977 (see also Nevison et al. (2004) with additional data from two campaigns by Butler et al. (1988) and Lobert et al. (1996). Based on the combined data sets by Weiss et al. (1992) and Butler et al. (1988), Nevison et al. (1995) calculated a global mean N_2O surface saturation of 103.5%. The global distribution of N_2O surface anomalies ($\triangle pN_2O = pN_2O_{measured} - pN_2O_{equilibrium}$, positive anomalies indicate the ocean as a source of N_2O to the atmosphere) is shown in Fig. 2.4. Common features of both maps in Fig. 2.4 are:

- enhanced N_2O anomalies in the equatorial upwelling regions of the eastern Pacific and Atlantic Oceans,
- enhanced N_2O anomalies along coastal upwelling regions such as along the west coasts of North and Central America, off Peru, off Northwest Africa and the northwestern Indian Ocean (Arabian Sea) and
- N_2O anomalies close to zero (i.e. near equilibrium) in the North and South Atlantic Ocean, the South Indian Ocean and the central gyres of the North and South Pacific Ocean.

Differences in the two maps (Fig. 2.4) result mainly from different extrapolation methods (Nevison et al., 1995; Suntharalingam and Sarmiento, 2000).

3.4. N_2O in coastal areas

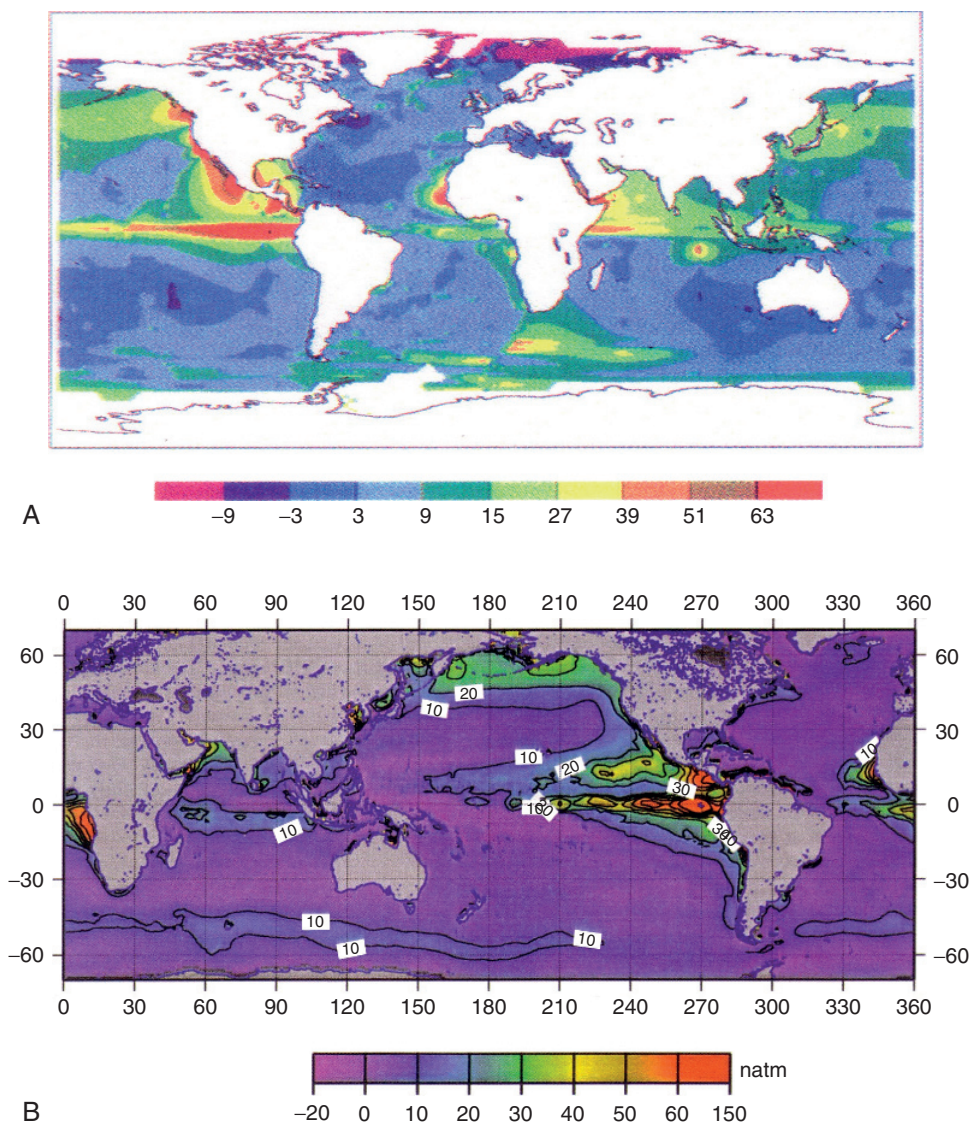
During the last years coastal areas such as estuaries, intertidal areas, upwelling regions and mangrove ecosystems (to name just a few examples) have received increasing attention as sites of intense N_2O formation and release to the atmosphere (see also the sections on eutrophication and N_2O budget). Studies on the biogeochemical cycling of N_2O in coastal regions have been performed to a


Figure 2.4 Maps of $\triangle p$N$_2$O (in natm) in surface layer of the world's oceans: (A) map by Nevison *et al.* (1995) and (B) map by Suntharalingam and Sarmiento (2000). Please note that the color coding is non-linear and different for both maps.

large extent in European and North American coastal regions. A compilation of coastal N$_2$O measurements worldwide is given in Bange *et al.* (1996). More recently, Bange (2006a) compiled and reviewed N$_2$O studies in European coastal regions (Baltic Sea, North Sea, NE Atlantic, Mediterranean Sea, Black Sea). His major conclusions are:

- Maximum N_2O saturations were usually observed in estuaries, whereas in open coastal waters (i.e. shelf waters not influenced by freshwater) N_2O saturations are close to the expected equilibrium saturation indicating that N_2O is exclusively formed in estuarine systems.
- It is obvious that sedimentary denitrification and water-column nitrification seem to be the major N_2O formation processes. However, the yield of N_2O from both processes strongly depends on the local O_2 concentrations, thus dissolved O_2 is the key factor regulating N_2O production (and its subsequent emissions to the atmosphere). Additionally, N_2O distributions in estuaries show a pronounced seasonal variability.
- In anoxic waters, such as the deep basin of the central Baltic Sea or parts of the shallow Po River delta, N_2O is consumed by water-column denitrification.

Bange (2006a) conclusions are in line with a recent seasonal study of N_2O in the water column of the Bedford Basin (Northwest Atlantic Ocean), which showed that water-column nitrification was the dominant N_2O formation pathway (Punshon and Moore, 2004). N_2O consumption was only temporarily observed when dissolved O_2 was considerably depleted (2.5 μmol L^{-1}) shifting the system from oxic to suboxic conditions (Punshon and Moore, 2004).

The narrow band of coastal upwelling such as found along the Arabian peninsula and the coast off Somalia have been identified as "hot spots" for N_2O emissions showing N_2O surface saturations of up to 330% (Bange *et al.*, 2001a; De Wilde and Helder, 1997). The high N_2O saturations result from the upwelling of subsurface water masses where N_2O formation is favored due to suboxic conditions (see e.g., Bange *et al.*, 2001b; Codispoti *et al.*, 1991). Because the coastal upwelling in the western Arabian Sea is triggered by the seasonal occurring monsoon winds, N_2O emissions also show a pronounced seasonality (Bange *et al.*, 2001a).

High precision time series of atmospheric N_2O have been successfully used to quantify N_2O emissions from temporal upwelling events along the coast off California (Lueker *et al.*, 2003) and from the Southern Ocean (Nevison *et al.*, 2005). This seems to be a promising approach, however, it depends on the existence of high-precision N_2O time series, which are at the moment only available at a few coastal sites (Prinn *et al.*, 2000).

The ecosystems of the mangrove forests have a high potential of N_2O formation and release to the atmosphere. N_2O in mangrove sediments from Puerto Rico is mainly produced by nitrification (Bauzá *et al.*, 2002) whereas the results of incubation experiments with mangrove soils from the east coast of Australia revealed that denitrification is the main N_2O formation pathway (Kreuzwieser *et al.*, 2003). The N_2O release from Puerto Rico mangrove sediments was found to be higher than comparable N_2O emissions from intertidal estuarine sediments (Corredor *et al.*, 1999; Middelburg *et al.*, 1995). Actual results from N_2O measurements at three sites in a mangrove forest on the east coast of central China (Jiulongjiang estuary) support this view (Alongi *et al.*, 2005). However, at these sites a pronounced seasonality was observed showing maximal N_2O emissions in summer, whereas in autumn they were close to zero. In a recently published seasonal study of N_2O emissions from a pristine mangrove creek on South Andaman Island (Gulf of

Bengal), Barnes *et al.* (2006) found no seasonality. However, N_2O emissions were negatively correlated with tidal height indicating that N_2O from sediment pore-water was released during hydrostatic pressure drop toward low water. A realistic estimate of the N_2O emissions from mangroves is not possible at the moment because of the very small number of available measurements.

3.5. The effect of coastal eutrophication and Fe fertilization on oceanic N_2O

Coastal eutrophication (i.e., enhanced nutrient input to the coastal areas) can result in a shift from oxic conditions to anoxic conditions (so-called hypoxia). This is especially important in view of the fact that oceanic N_2O formation strongly depends on dissolved O_2. And indeed, Naqvi *et al.* (2000) observed, during a hypoxic event along the West coast of India, N_2O concentrations up to 533 nmol L^{-1}. The accumulation of N_2O was attributed to the onset of denitrification at low O_2 concentrations with the assumption that the activity of the N_2O reductase (which catalyzes the reduction of N_2O to N_2) was not established ("stop and go" denitrification). Based on their results, Naqvi *et al.* (2000) cautioned that N_2O formation and thus its subsequent release to the atmosphere from shallow hypoxic systems might increase due to the fact that the numbers of coastal regions with hypoxia is increasing as well (UNEP, 2004). Eutrophication can also significantly stimulate the sedimentary N_2O formation by denitrification, which was demonstrated by Seitzinger and Nixon (1985) in microcosm experiments.

N_2O release from mangrove ecosystems appear to be very sensitive to eutrophication: N_2O release across the sediment/atmosphere interface was enhanced significantly (up to 2800 times) when adding NH_4^+ to mangrove sediments from Puerto Rico (Bauza *et al.*, 2002; Muñoz-Hincapié *et al.*, 2002). When NO_3^- was added the enhancement was less pronounced. Comparable results were obtained at a Australian mangrove site where N_2O emissions increased by a factor of 50–100 times when nitrogen was added (Kreuzwieser *et al.*, 2003). Therefore, it seems realistic to expect that the contribution of mangrove ecosystems to global coastal emissions of N_2O will increase due to increasing nutrient inputs caused by the ongoing industrialization and intensification of agricultural activities in tropical countries.

Fuhrman and Capone (1991) pointed out that stimulating open ocean productivity by iron (Fe) addition (Martin *et al.*, 1991) might result in an enhanced formation of N_2O. Thus, enhanced N_2O formation by Fe addition might counteract the climatic benefits of a drawdown of atmospheric CO_2. Fuhrman and Capone (1991) argued that enhanced productivity will lead to an enhanced nitrogen export from the euphotic zone, which in turn would result in additional N_2O formation via enhanced nitrification. The idea of a link between Fe fertilization and enhanced N_2O formation was supported by the study of Law and Ling (2001) who found a small but significant N_2O accumulation in the pycnocline during the Southern Ocean Iron Enrichment Experiment (SOIREE) in the Australasian sector of the Southern Ocean (61°S, 140°E) in February 1999. Recently, Jin and Gruber (2003) predicted the long-term effect of Fe fertilization on oceanic N_2O emissions on a global scale with a coupled physical–biogeochemical model. Based on their model

results they concluded that Fe fertilization-induced N_2O emissions could offset the radiative benefits of the CO_2 drawdown (Jin and Gruber, 2003). However, during EIFEX, the European Iron Fertilization experiment in the subpolar South Atlantic Ocean in February/March 2004, no N_2O accumulation was detected within 33 days (Walter *et al.*, 2005). It seems that Fe fertilization does not necessarily trigger additional N_2O formation, which might depend on the prevailing environmental conditions (e.g., the fate of the Fe-induced phytoplankton bloom). The link between Fe addition and enhancement of N_2O formation and the subsequent release of N_2O to the atmosphere remains to be experimentally demonstrated. However, regionally restricted, short-term fertilization experiments such as SOI-REE and EIFEX cannot account for the predicted enhancement of N_2O production due to expansion of suboxic regions as a result of large-scale and long-term (10 yr) Fe fertilization (Jin and Gruber, 2003).

3.6. Isotope studies

The stable isotopic ratio $^{15}N/^{14}N$ of N_2O is expressed as $\delta^{15}N_{atm}$ relative to atmospheric N_2 (for the exact definition equation see N_2 section). In the same way, the isotope ratio of $^{16}O/^{18}O$ of N_2O is usually expressed as $\delta^{18}O_{VSMOW}$ relative to Vienna standard mean ocean water (VSMOW). However, in some cases $\delta^{18}O_{atm}$ relative to O_2 in the atmosphere is reported. $\delta^{18}O_{VSMOW}$ can be converted to $\delta^{18}O_{atm}$ with the equation $\delta^{18}O_{atm} = -23.0 + \delta^{18}O_{VSMOW}/1.0235$ (Kim and Craig, 1990). Mean atmospheric $\delta^{15}N_{atm}$ and $\delta^{18}O_{VSMOW}$ of N_2O in tropospheric air are 6.72‰ $\pm$ 0.12‰ and 44.62‰ $\pm$ 0.21‰, respectively (Kaiser *et al.*, 2003).

Following the early studies of $\delta^{15}N$ and $\delta^{18}O$ of atmospheric N_2O by Moore (1974), Yoshida and Matsuo (1983), and Wahlen and Yoshinari (1985), measurements of the isotopic composition of oceanic N_2O have become a tool to decipher the various biogeochemical pathways of N_2O in the oceanic environment and to quantify the oceanic contribution to the atmospheric N_2O (Kim and Craig, 1993; Stein and Yung, 2003). The isotopic composition of oceanic N_2O is composed of the isotopic signals of biological sources and sinks, its atmospheric imprint, and mixing processes within the ocean. This, in turn, implies that there are characteristic signals of enrichment or depletion (so-called fractionation), which can be attributed to different biological processes as well as physical processes such as the gas exchange across the ocean/atmosphere interface.

The isotope composition of biologically derived N_2O depends on the isotope composition of the substrates such as NO_3^- (denitrification) and NH_4^+ (nitrification) and the isotopic depletion/enrichment during these processes: An overview of the isotopic depletion/enrichment of N_2O in culture experiments with different strains of denitrifying (*Pseudomonas flourescens*, *Pseudomonas aureofaciens*, *Paracoccus denitrificans*), nitrifier-denitrifying (*Nitrosomonas europaea*) and methane oxidizing bacteria (*Methylococcus capsulatus*) is shown in Fig. 2.5. It is obvious that the range of the resulting nitrogen depletion in N_2O during denitrification and nitrification is similar. The isotope signal of oxygen in N_2O produced during nitrification is introduced by the $\delta^{15}O$ value of dissolved O_2 ($\delta^{15}O = 22–37‰$) and
Figure 2.5 Isotopic depletion/enrichment for nitrogen and oxygen in N_2O relative to the substrates NO_3^- and NH_4^+, and the product N_2. Negative values depict isotopic depletion in N_2O and positive values depict isotopic enrichment in N_2O. Data for oxygen depletion/enrichment in N_2O are given in italics. Biological data were taken from Barford *et al.* (1999), Casciotti *et al.* (2003), Sutka *et al.* (2003), (2004), Toyoda *et al.* (2005) and Yoshida (1988). Air–sea gas exchange data are from Inoue and Mook (1994).

H_2O ($\delta^{15}O = \sim 0‰$) as oxidizing agents (Ostrom *et al.* (2000)). The isotopic signal resulting from air–sea exchange is small compared to the biological processes. Therefore, biological N_2O formation should yield a clear isotopic signature in oceanic N_2O. However, the identification of nitrification or denitrification as N_2O producing processes strongly depends on the knowledge of the isotope signatures of the substrates, which can vary temporarily and spatially. An overview of studies of the isotopic signature of oceanic N_2O is given in Table 2.2. The main results are discussed in detail in the following sections.

First measurements of $\delta^{15}N$ of dissolved N_2O in the eastern tropical North Pacific Ocean revealed that N_2O in the suboxic zone was enriched in ^{15}N relative to N_2O in the atmosphere whereas N_2O was slightly depleted in ^{15}N relative to atmospheric N_2O (Yoshida *et al.*, 1984). This in line with the argumentation that N_2O in suboxic waters is consumed during denitrification and that N_2O is formed during nitrification in oxic waters. Surprisingly, Yoshida *et al.* (1989), found ^{15}N-enriched N_2O in the oxic waters of the upper 2000 m of the western North Pacific and concluded that N_2O is mainly produced by denitrification. A conclusion which seems to be counterintuitive, because denitrification in oxic waters should be negligible.

The first N_2O dual isotope ($\delta^{15}N$ and $\delta^{18}O$) measurements were presented by Kim and Craig (1990). At three stations in the North and South Pacific Ocean, N_2O was found to be slightly depleted relative to atmospheric N_2O in ^{15}N and ^{18}O down

Table 2.2 Overview of the suggested N_2O formation pathways based on isotope measurements of N_2O

Oceanic region	Measured isotopic parameters[*]	Suggested main formation pathways	References

[*] SP_{N_2O} stands for the site preference, for a definition see the section about isotopomers.

to about 600 m, whereas in deep and bottom waters N_2O was found to be enriched in ^{15}N and ^{18}O relative to atmospheric N_2O. The reason for the unexpected enrichment of deep water N_2O is unclear. Kim and Craig (1990) speculated about nitrification with subsequent reduction by denitrification (which might take place in the interior of sinking particles) or, alternatively, N_2O formation during nitrification from a ^{15}N enriched intermediate such as hydroxylamine.

With the application of the newly developed continuous–flow isotope–ratio monitoring mass spectrometers, the required seawater sample volume for N_2O dual isotope measurements have been drastically reduced and therefore facilitated the determination high resolution depth profiles of the N_2O dual isotope signature (Brand, 1996; Yoshinari et al., 1997): Repeated measurements of depth profiles at

the Hawaii ocean time series station ALOHA in the subtropical North Pacific Ocean revealed that $\delta^{15}N$ and $\delta^{18}O$ of N_2O were in equilibrium with atmospheric N_2O at the ocean surface and steadily decreased from the ocean surface to minimum values in about 100–300 m at the base of the euphotic zone, followed by an increase to maximum values in 800 m. The depletion of both ^{15}N and ^{18}O was attributed to result from nitrification (Dore *et al.*, 1998; Ostrom *et al.*, 2000; Popp *et al.*, 2002). A more detailed study which included measurements of $\delta^{18}O$ in dissolved O_2 and H_2O, revealed that N_2O might be formed by two different pathways: First, by nitrification via NH_2OH or NO in most depths or, second, by nitrifier-denitrification via reduction of NO_2^- (between 350–500m) (Ostrom *et al.*, 2000).

The situations in the central Arabian Sea and the eastern tropical North Pacific Ocean are complex. N_2O was found to be strongly enriched in both ^{15}N and ^{18}O in the denitrifying oxygen minimum zone, whereas N_2O in the surface layer was depleted in ^{15}N but slightly enriched in ^{18}O compared to atmospheric N_2O (Naqvi *et al.*, 1998a, 1998b; Yoshinari *et al.*, 1997). N_2O in the core of the oxygen minimum zone was obviously formed by denitrification since the final reduction step to N_2 should result in enriched N_2O. However, the ''light'' N_2O found above the OMZ might be explained with a coupled nitrification-denitrification pathway where NO is formed during nitrification which is then reduced to N_2O during denitrification (Naqvi *et al.*, 1998a, 1998b; Yoshinari *et al.*, 1997).

As mentioned in the introductory section, N_2O is an asymmetrical molecule and therefore it is possible to distinguish so-called isotopomers according to the position of ^{15}N within the N_2O molecule (the corresponding δ notation is given in parenthesis: $^{14}N^{15}NO$ ($\delta^{15}N^{\alpha}$) and $^{15}N^{14}NO$ ($\delta^{15}N^{\beta}$) (Toyoda and Yoshida, 1999). The ^{15}N site preference (SP_{N_2O}) in N_2O is given as $\delta^{15}N^{\alpha} - \delta^{15}N^{\beta}$. The mean tropospheric SP_{N_2O} is 18.7‰ $\pm$ 2.2‰ (Yoshida and Toyoda, 2000). Recently Kaiser *et al.* (2004) reported a mean tropospheric SP_{N_2O} of 46.3‰ $\pm$ 1.4‰. The reason for the large discrepancy is unknown, but it was speculated that it might result from the use different primary standards (Kaiser *et al.*, 2003, 2004). Measurements of SP_{N_2O} should allow to identify the mechanisms of N_2O formation according to the different microbial pathways (Sutka *et al.*, 2003, 2006; Toyoda *et al.*, 2005). The SP_{N_2O} strongly depends on both the bacterial strains used and the actual formation pathway. For example, *Nitrosomonas europaea* and *Nitrosospira multiformis*, both nitrifier-denitrifiers, can produce N_2O via both NH_2OH oxidation and NO_2^- reduction. Indeed, the SP_{N_2O} were different for the NH_2OH oxidation pathway (~33‰) and the NO_2^- reduction pathway (~ −0.4‰) (Sutka *et al.*, 2003, 2004). Most recently, based on a study with cultures of AOB, nitrifier-denitrifiers and denitrifiers, Sutka *et al.* (2006) concluded that the characteristic SP_{N_2O} of nitrification and denitrification (incl. nitrifier-denitrification) are generally ~33‰ and ~0‰, respectively. Thus, isotopomers might be used to distinguish between N_2O produced during oxidation (nitrification) and reduction (denitrification and nitrifier-denitrification) processes, however, it seems that isotopomers cannot be used to reveal subtle differences such as nitrifier-denitrification and denitrification (Sutka *et al.*, 2006). The range of SP_{N_2O} (−0.6‰ to −0.5‰) from the denitrifiers *Pseudomonas chlororaphis* and *Pseudomonas aureofaciens* measured by Sutka *et al.* (2006) are in contrast to the results by Toyoda *et al.* (2005) who found a much larger variability for the SP_{N_2O}

produced by two other denitrifiers which showed SP_{N_2O} of 23.3‰ ± 4.2‰ (*Pseudomonas fluorescens*) and −5.1‰ ± 1.8‰ (*Paracoccus denitrificans*) (Toyoda *et al.*, 2005). However, this discrepancy is in line with the theoretical considerations by Schmidt *et al.* (2004), who argued that the observed SP_{N_2O} and the associated $\delta^{18}O$ signatures during NO reduction to N_2O are reflecting the different types of NO reductases used by the different bacteria.

Up to now, the oceanic distribution N_2O isotopomers was determined at station ALOHA in the subtropical North Pacific (Popp *et al.*, 2002), at station KNOT (Kyodo North Pacific Ocean Time series) in the western North Pacific (Toyoda *et al.*, 2002), and in the eastern tropical North Pacific (ETNP) (Yamagishi *et al.*, 2005). The SP_{N_2O} profile at KNOT showed a steady increase from low values at the ocean surface (12‰) to a maximum (up to 36‰) in about 250–750 m (Toyoda *et al.*, 2002). A similar SP_{N_2O} profile was observed at ALOHA, however, the low SP_{N_2O} values were rather uniform in the depth range 0–500 m and then increased to about 25‰ in 600–900 m (Popp *et al.*, 2002). The shape of the SP_{N_2O} profiles at KNOT and ALOHA were explained with N_2O formation during nitrification, however, the exact reaction pathway remained unclear (Popp *et al.*, 2002; Toyoda *et al.*, 2002). In contrast, on the basis of additional isotopomer data from KNOT, Yamagishi *et al.* (2005) suggested net N_2O formation in the oxygen minimum zone which is mainly resulting from both formation and consumption during denitrification with only a minor contribution by nitrification. This revives the debate on whether nitrification or denitrification is the main N_2O formation process in the ocean. A debate, which began with the one of the first publications on oceanic N_2O isotope data (Yoshida *et al.*, 1989).

3.7. The role of the ocean for the global budget of atmospheric N_2O

The 2001 report of the Intergovernmental Panel on Climate Change (IPCC) of the sources and sinks of atmospheric N_2O suggests a reasonably balanced present-day budget of atmospheric N_2O (Prather *et al.*, 2001) (all fluxes in parenthesis are given in Tg N yr^{-1}): Major natural sources of atmospheric N_2O are emissions from the world's oceans (3.0) and soils (6.0). A minor natural source is the N_2O formation by atmospheric ammonia oxidation (0.6). Agricultural soils (4.2) and a bundle of smaller sources such as biomass burning (0.5), various industrial sources (1.3) and cattle farming/feedlots (2.1) have been identified. The only sink for atmospheric N_2O is its photochemical decomposition in the stratosphere (12.3). The IPCC 2001 report indicates an oceanic contribution of about 17% to the overall sources of N_2O and about 31% to the natural sources. Thus, the oceanic N_2O emissions play a major role in the atmospheric N_2O budget. However, the IPCC 2001 estimate does not take into account N_2O emissions from coastal areas such as continental shelves, estuarine and coastal upwelling areas: On the basis of a comprehensive compilation of N_2O measurements in coastal areas, Bange *et al.* (1996) calculated an overall oceanic flux of 7–11 Tg N yr^{-1} and concluded that coastal areas such as estuaries, shelf and coastal upwelling areas contribute significantly (approximately 61%, i.e., 4.2–6.6 Tg N yr^{-1}) to the global oceanic emissions. This is in line with predictions from the model studies by Capone (1991), Seitzinger and Kroeze (1998) and Nevison *et al.*

(2004) who estimated that coastal areas may contribute 7–49% to the overall global oceanic N_2O emissions. Beside different methodological approaches (empirical models vs. extrapolation of measurements) the considerable range of uncertainty is introduced by the fact that the applied classification of coastal areas is not uniform. For example, the overall areal contributions range from 3.3% (Nevison *et al.*, 2004) up to 18.6% (Bange *et al.*, 1996). The results of the global N_2O coastal emissions estimates is supported by the regional study along the West coast of India (Naqvi *et al.*, 2000) which revealed that N_2O emissions were considerably enhanced (up to 0.25 Tg N yr^{-1}) due to the temporarily occurring hypoxia (see above). Based on a compilation of literature data Bange (2006b) recently suggested that the oceanic emissions should be revised upwards by at a factor of two.

4. DINITROGEN

4.1. Climatic and biogeochemical relevance

Dinitrogen (N_2) is a colorless gas at room temperature. It has a boiling point of $-195.8°C$ (at 1 atm) and a molecular weight of 28.01 g mol^{-1}. Because of the very stable N-N triple bond and the symmetric electron distribution in the molecule, which prevents the development of polarity in the N-N bond, N_2 is comparably inert at room temperature (Greenwood and Earnshaw, 1984). The chemically inertness of N-N triple bond results from the high activation energy necessary to break it, thus, it is a kinetic effect and not a thermodynamical issue. Because the formation of NO_3^- is thermodynamically favored, all atmospheric N_2 would react with atmospheric O_2 and H_2O to the form dissolved NO_3^-, however, this is only true for a world without any biological processes (Sillén, 1966). N_2 is the most abundant nitrogen-containing compound in the Earth's atmosphere (78.1% by volume or 75.5% by mass). Nitrogen (N) has two stable isotopes, ^{14}N and ^{15}N, which contribute 99.63% and 0.37%, to its composition (Greenwood and Earnshaw, 1984). The stable isotopic ratio, $^{15}N/^{14}N$, of nitrogen containing compounds is expressed as $\delta^{15}N_{atm}$ relative to atmospheric N_2, thus, $\delta^{15}N_{atm}$ of N_2 in the atmosphere = 0‰:

$$\delta^{15}N_{atm}(sample)[‰] = ((^{15}N/^{14}N)_{sample}/(^{15}N/^{14}N)_{std} - 1) \times 1000$$

Isotopic studies of the oceanic nitrogen cycle are discussed in Chapter 31.

In the lower atmosphere (i.e. the troposphere and stratosphere) N_2 is not radiatively active, whereas in heights above 100 km (i.e. in thermosphere) N_2 absorbs at wavelengths less than 100 nm (Graedel and Crutzen, 1993).

Despite the inertness of N_2, the atmospheric N_2 pool is available for biological productivity by N_2 fixation ($N_2 \rightarrow NH_4^+$), which takes place in both the oceanic and the terrestrial environments. Further details about oceanic N_2 fixation can be found in Chapter 4. The release of nitrogen as N_2 from the fixed inorganic nitrogen pool (i.e. NO_3^-, NO_2^- and NH_4^+) is mediated by two microbial processes:

Denitrification ($NO_3^- \rightarrow N_2$) and anaerobic ammonium oxidation (anammox, $NO_2^- + NH_4^+ \rightarrow N_2$). Details about oceanic denitrification and anammox can be found in Chapter 6.

4.2. N_2 in the ocean

Because N_2 is a non-polar molecule, its solubility in seawater is low. Based on new measurements, Hamme and Emerson (2004) recently presented an improved equation for the Bunsen solubility of N_2 dissolved in seawater in equilibrium with a moist atmosphere at 1 atm (C_{N_2} in µmol kg^{-1}):

$$\ln C_{N_2} = A_0 + A_1 T_S + A_2 T_S^2 + A_3 T_S^3 + S(B_0 + B_1 T_S + B_2 T_S^2)$$

with

$$T_S = \ln\left(\frac{298.12 - t}{273.15 + t}\right)$$

and

$$A_0 = 6.42931, A_1 = 2.92704, A_2 = 4.32531, A_3 = 4.69149$$

and

$$B_0 = -7.44129 \times 10^{-3}, B_1 = -8.02566 \times 10^{-3}, B_2 = -1.46775 \times 10^{-2}$$

S stands for salinity and t stands for water temperature in the range from 1 to 30°C. With $t = 10°C$ and $S = 35$, the equilibrium concentration of N_2 is 500.9 µmol kg^{-1} (Hamme and Emerson, 2004). (The N_2 equilibrium concentration is much higher than the concentration of oceanic nitrate, the most abundant fixed nitrogen compound!) Because of the high equilibrium concentration of oceanic N_2, small deviations from the equilibrium, which can be caused by biological and physical processes (see below), are difficult to detect. The precise knowledge of the solubility function together with high precision measurements are, therefore, a prerequisite to investigate the oceanic distribution of N_2. Early measurements of the oceanic N_2 distribution partly suffer from inadequate analytical precision (for a detailed discussion of the early measurements see Scranton (1983)).

Dissolved N_2 can be determined by measuring the O_2/N_2 ratios by means of seawater/headspace equilibration followed by analysis via a mass spectrometer (Emerson *et al.*, 1999). Absolute N_2 concentrations are derived from O_2/N_2 ratios by using high precision O_2 measurements (e.g. via Winkler titration, see Hansen (1999)). Alternatively, N_2 can be determined with a purge method in combination with gas chromatographic separation and detection with a thermal conductivity detector (Nakayama *et al.*, 2002; Weiss and Craig, 1973). The latter method has the advantage of being suitable for onboard use. Recently, a membrane inlet mass

spectrometry method for shipboard measurement of N_2, among other gases, was introduced (Tortell, 2005). Automated systems for the use on moorings or during continuous underway surface measurements consist of a gas tension device which measures the total pressure of dissolved gases in seawater and sensors for O_2 and/or CO_2 (Anderson and Johnson, 1992; Carignan, 1998; Emerson et $al.$, 2002; McNeil et $al.$, 1995, 2005). The dissolved N_2 concentrations can be calculated as the difference of the total gas pressure and the known or estimated partial pressures of O_2, CO_2, Ar, and H_2O (Emerson et $al.$, 2002; McNeil et $al.$, 1995).

Because dissolved N_2 is assumed to be inert in seawater (at least under the most common condition, see discussion below), it can serve as a tracer of physical processes (Emerson et $al.$, 1995): Measurements of dissolved N_2 in combination with Ar and O_2 measurements were successfully used in mass balance models of the upper ocean in order to quantify the net biological O_2 production and the associated carbon production (Emerson et $al.$, 1991, 1995, 1997).

Recently, a 10 days continuous time series measurements of N_2 at 5 m depth off Massachusetts, provided the possibility to estimate the air–sea transfer coefficient of N_2 and the subsequent computation of the air–sea fluxes of the reactive gases CO_2 and O_2 (McNeil et $al.$, 2006).

The global oceanic distribution of N_2 is mainly controlled by physical processes such as water temperature variability and gas exchange via bubble entrainment and diffusion (Hamme and Emerson, 2002; Nakayama et $al.$, 2002; Schudlich and Emerson, 1996). Exceptions occur only in oceanic regions with denitrifying activities (see below), whereas the influence of N_2 fixation on N_2 surface concentrations is usually ignored. However, under certain conditions N_2 fixation rates are comparable to air–sea gas exchange rates and thus have to take into account when using N_2 as tracer for physical processes: At a wind speed of 4 m s^{-1}, a N_2 supersaturation of 0.5%, and a water temperature of 25°C (N_2 fixation is favored in subtropical and tropical regions with temperatures >20°C (LaRoche and Breitbarth, 2005)), N_2 fixation rates may equal up to 50% of the N_2 air–sea gas exchange (for details of the estimate see caption of Fig. 2.6).

The oceanic distribution of dissolved N_2 is outlined in the following paragraphs. During a transect in the western North Atlantic Ocean (from New York to Puerto Rico), N_2 surface concentrations were monitored continuously and ranged from slightly undersaturated (−1%) to slightly supersaturated (1%). Supersaturation was observed in waters north of 37°N, whereas undersaturations occurred in open ocean waters from 37°N to 18°N. The marked decrease in N_2 saturation at 37°N was associated with the crossing of the Gulf Stream (McNeil et $al.$, 2005). The observed N_2 undersatuation was attributed to rapid solubility changes due to the seasonal cooling of the seasurface layer in connection with low gas exchange rates (McNeil et $al.$, 2005). Based on a simple two-layer box model, McNeil (2006) recently proposed a diurnal thermal pumping mechanism to explain undersaturation of surface N_2 during periods low gas exchange rates (i.e. low wind speeds).

Concentrations of N_2 in non-denitrifying waters are generally close to the equilibrium concentrations. For example, dissolved N_2 concentrations in the upper 200m of the western North Pacific Ocean and eastern Okhotsk Sea were in the range from 500 to 650 µmol kg^{-1} (i.e. 1–4.3% supersaturated) (Nakayama et $al.$,
Figure 2.6 Air–sea flux densities of N_2 (bold lines) calculated as $F = (0.39u_{10}^2)\,(SRC_{air}-C_{air})$ $(Sc_{N2}/660)^{-0.5}$ (Wanninkhof, 1992). SR stands for the N_2 saturation ratio and u_{10} stands for the wind speed in a height of 10m. Water temperature and salinity were set to 25°C and 35, respectively. C_{air} is the equilibrium concentration of atmospheric N_2 and was calculated with the equation given by Hamme and Emerson (2004). The dashed lines represent maximum (3110 µmol N m^{-2} day^{-1}) and minimum (161 µmol N m^{-2} day^{-1}) mean N_2 fixation rates for the North Atlantic Ocean (Capone *et al.*, 2005).

2002). The observed supersaturation was attributed to bubble injection from the overlying atmosphere (Nakayama *et al.*, 2002).

An annual study of N_2 concentrations in the upper ocean at the US JGOFS time series station ALOHA in the suptropical North Pacific Ocean showed a steady increase from 390 µmol kg^{-1} at the surface to 450 µmol kg^{-1} in 200m (Emerson *et al.*, 1995). The corresponding N_2 supersaturations ranged from 0 to 5% but did not show the steady increase with depth (Emerson *et al.*, 1995). No seasonal signal was observed. Depth profiles from the subtropical and the subpolar North Pacific (stations HOT and KNOT, respectively) and subtropical North Atlantic (station BATS) revealed that N_2 was supersaturated by 1–3% in the upper 200 m and slightly undersaturated (−2–0%) in the depth range from 200–4500 m (Hamme and Emerson, 2002). Based on the results from a quasi-steady-state mixed-layer model, Hamme and Emerson (2002) concluded that the N_2 distribution in both surface and deep waters of the North Pacific and North Atlantic Oceans is resulting from only three processes, namely temperature variability, and diffusive and bubble mediated gas exchange.

N$_2$ in the suboxic deep waters (70–440 m) of the western part of the central Baltic Sea was supersaturated up to 8%, whereas in the surface layer N$_2$ was slightly undersaturated (Rönner and Sörensson, 1985). The accumulation of N$_2$ resulted from denitrification. In the suboxic intermediate water masses (150–1000 m) of the central Arabian Sea, N$_2$ concentrations were found to be significantly enhanced with a maximum in 250 m (Codispoti *et al.*, 2001, 2005). This corresponds to a minimum of $\delta^{15}N_{atm}$ of dissolved N$_2$ in the core of the suboxic zone, which drops from 0.6‰ to 0.20‰ (Brandes *et al.*, 1998; Naqvi *et al.*, 1998a). The minimum in $\delta^{15}N_{atm}$ of dissolved N$_2$ is an agreement with a biological formation process. However, the observed N$_2$ excess in the central Arabian Sea exceeds the expected nitrogen loss calculated from the classical denitrification routes. The reason of the extraordinary N$_2$ excess in the central Arabian Sea remains speculative (Codispoti *et al.*, 2001, 2005). See also Chapter 6 about denitrification.

5. AMMONIA

5.1. Climatic and biogeochemical relevance

Ammonia (NH$_3$) is a colorless gas. It has a boiling point of $-33.4°C$ (at 1 atm) and molecular weight of 17.03 g mol^{-1} (Greenwood and Earnshaw, 1984). Gaseous NH$_3$ in the atmosphere dissolves in rain droplets as dissolved ammonium (NH$_4^+$). Moreover, NH$_3$ can form NH$_4^+$ salts (NH$_4^+$ aerosols) by rapid gas-to-particle conversion (Warneck, 2000). Thus, NH$_3$ plays a unique role in the formation of tropospheric aerosols: Because of its basic character it neutralizes acidic sulfuric acid–water aggregates by forming ammonium sulfate aerosols which can act as cloud condensation nuclei (Warneck, 2000; Yu, 2006). Therefore, NH$_3$, as a precursor of aerosols and clouds, is of considerable importance for the Earth atmosphere's composition, chemistry and climate. Additionally, NH$_3$ is a greenhouse gas, but its contribution to the present-day greenhouse effect is negligible. However, during the Archean (4.8–2.2 Gyr ago) oceanic derived atmospheric NH$_3$ might have contributed significantly to the warming of the early Earth, however, this theory is controversially debated (Pavlov *et al.*, 2001; Sagan and Chyba, 1997).

Atmospheric NH$_3$ in the present day marine boundary layer has a short life time ranging from only a few hours to days (Norman and Leck, 2005; Quinn *et al.*, 1988). Atmospheric mixing ratios in pristine remote marine boundary layers can be less than 1 nmol m^{-3} (see e.g. Norman and Leck (2005) and Quinn *et al.* (1990)). Strong gradients of atmospheric NH$_3$ over the ocean are detectable when plumes of biomass burning are influencing the marine boundary layer (Norman and Leck, 2005). NH$_3$ and NH$_4^+$ in the marine boundary layer are mainly removed by dry and wet deposition to the ocean. Oxidation of atmospheric NH$_3$ by OH seems to be of minor importance (Warneck, 2000). Therefore, the distribution of NH$_3$/NH$_4^+$ in both the marine boundary and the oceanic mixed layer is tightly coupled (Fig. 2.7).
Figure 2.7 Simplified scheme of NH_3/NH_4^+ cycling in the marine boundary and ocean surface layers. Exchange processes of NH_4^+ across the ocean/sediment interface are not shown. $(NH_4^+)_p$ stands for particulate NH_4^+ (NH_4^+ aerosol), DON stands for dissolved organic nitrogen, PhyPl and ZooPl stand for Phytoplankton and Zooplankton respectively, and Bac stands for bacteria. Dashed arrows depict uptake/assimilation and release/excretion. Small letters in italics represent physical, chemical, and biological processes: *a*, atmospheric transport processes; *b*, uptake and release in clouds; *c*, gas-to-particle conversion; *d*, gas exchange; *e*, wet and/or dry deposition; *f*, nitrogen fixation; *g*, photochemical decomposition, *h*, nitrification; *j*, decomposition. The scheme is based on publications by Liss and Galloway (1993), Quinn *et al.* (1990), and Bronk *et al.* (1994).

5.2. The NH_3/NH_4^+ equilibrium in water*

When dissolved in water, NH_3 reacts as a base:

$$NH_3 + H_2O \overset{K_b}{\longleftrightarrow} NH_4^+ + OH^-$$
where K_b stands for the equilibrium constant. According to Van Neste and Duce (1987), dissolved NH_3 concentrations, $[NH_3]$, can be calculated as

$$[NH_3] = \frac{[NH_x][OH^-]}{K_b + [OH^-]}$$

where $[NH_x]$ stands for the sum of dissolved NH_3 and NH_4^+. K_b is usually given as pK_b ($= -\log_{10} K_b$, $pK_b = 14 - pK_a$). Gibb et al. (1999a) presented the following equations to calculate pK_b of NH_3:

* See also 'Note added to proof' at the end of the chapter.

$$pK_b = 14 - (pK_a + C)$$

with

$$C = (0.1552 - 0.003142T)I$$

and

$$I = 0.00147 + 0.01988S + 2.08357 \times 10^{-5}S^2$$

where C represents the seawater correction of pK_a ($= -\log_{10} K_a$, dissociation constant of $NH_4^+ \rightarrow NH_3 + H^+$) for temperature ($T$ in K) and salinity (S), I is the ionic strength of seawater. K_a can be calculated according to Bates and Pinching (1950):

$$K_a = 5.67 \times 10^{-10} \exp\left(-6286\left(\frac{1}{T} - \frac{1}{298.15}\right)\right)$$

For $T = 293.15$ K ($20°C$), K_a has the value 9.246.

Whitfield (1974) derived a formula for calculating K_a as a function of temperature, salinity and pressure (P):

$$pK_a = pK_a(T = 298, P = 1atm) + 0.0324(298 - T) + 0.0415P/T$$

with

$$pK_a(T = 298K, P = 1atm) = -0.21428I^2 + 0.40714I + 9.1511$$

for $0.4 < I < 0.8$.

Because the mean pH of the today's ocean surface layer is about 8.08 (with a range from 7.9–8.25) (Raven et al., 2005), oceanic NH_3 can exist as a dissolved, non-protonated gas and, thus, it is available for gas exchange across the ocean/atmosphere interface. For example, for a pH of 8.1, a water temperature of $25°C$, and a salinity of 35, about 6% is available as dissolved NH_3, $[NH_3]$, (Fig. 2.8). The NH_3/NH_4^+ equilibrium is very sensitive to changes of the pH and water temperature. Changes in salinity and pressure are comparably less important (Fig. 2.8).

The theoretical gaseous concentration of NH_3, $(NH_3)_g$ in g L^{-1}, which is in equilibrium with dissolved $[NH_x]$ can be calculated according to Asman et al. (1994) and references therein as

$$(NH_3)_g = \frac{M_{NH_3}[NH_x]}{RTH_{NH_3}\left(\dfrac{1}{\gamma_{NH_3}} + \dfrac{10^{-pH}}{\gamma_{NH_4^+}K_a}\right)}$$

where R is the gas constant ($8.2075 \ 10^{-5}$ atm m^3 mol^{-1} K^{-1}), γ is the activity coefficient of NH_3 and NH_4^+, respectively, M_{NH_3} is the molecular weight of NH_3,
Figure 2.8 Percent dissolved gaseous NH_3 as a function of pH. Dashed and (bold and thin) solid lines were calculated with the equations from Whitfield (1974). Dashed-dotted lines were calculated with the equations from Gibb *et al.* (1999a). Dashed lines, salinity (S) = 0, temperature (T) = 25°C (upper curve) or 15°C (lower curve), pressure (P) = 1 atm; bold solid lines, S = 35, T = 25°C (upper curve) or 15°C (lower curve), P = 1 atm; dashed-dotted lines, salinity, (S) = 35, temperature (T) = 25°C (upper curve) or 15°C (lower curve); thin solid line, S = 35, T = 0°C, P = 1000 atm. The insert shows the possible effect of pH decrease from 8.1 (today) to a predicted 7.9 (for the year 2100), see text for details.

and N_{NH_3} is the Henry's law constant (in mol m^{-3} atm^{-1}). γ_{NH_3} and $\gamma_{NH_4^+}$ can be calculated as follows:

$$\gamma_{NH_3} = 1 + 0.0851 I$$

$$\gamma_{NH_4^+} = 0.883 - 0.0768 \ln(S), \text{ for } 5 < S < 40$$

A frequently used formula for H_{NH_3} is

$$H_{NH_3} = 56 \times 10^{-3} \exp\left(4029\left(\frac{1}{T} - \frac{1}{298.15}\right)\right)$$

(Dasgupta and Dong, 1986). The value for the dimensionless Henry's law constant ($H'_{NH_3} = RT\, H_{NH_3}$) at a temperature of 25°C is 1.37×10^{-3}. Alternative expressions for Henry's law constant of NH_3 in water are listed in the literature compilation by Sander (1999). Recently, a formula for Henry's law constant, corrected for seawater (H'_{sNH_3}), was derived by Gibb *et al.* (1999a):

$$H'_{sNH_3} = \frac{1}{28 \exp\left(\ln H_{298} - 4029\left(\frac{1}{T} - \frac{1}{298.15}\right)\right)}$$

where H_{298} is the value of $H_{\mathrm{NH_3}}$ for a temperature of 298 K. At a temperature of 25°C $H'_{s\mathrm{NH_3}}$ has a value of 0.64×10^{-3} which is considerable lower than the corresponding freshwater value (see above).

5.3. NH$_3$ in the ocean

Maybe not very surprisingly, the distribution of oceanic NH$_3$ is tightly coupled to the distribution of dissolved NH$_4^+$ via the NH$_3$/NH$_4^+$ equilibrium. NH$_4^+$ is one of the essential nutrients in the oceans (Dugdale and Goering, 1967). NH$_4^+$ is the substrate or final product of major biological transformation processes of the oceanic nitrogen cycle such as bacterial nitrification (NH$_4^+ \rightarrow$ NO$_3^-$), assimilation by phytoplankton (NH$_4^+$ $\rightarrow$ nitrogen–containing biomass), and excretion by zooplankton (see Fig. 2.7). See also Chapters 5 and 7. Moreover, NH$_4^+$ can be formed by photochemical decomposition of dissolved organic nitrogen (DON), but, the existing data are partially contradictory, showing also photo-induced losses of NH$_4^+$ (Grzybowski, 2003; Mopper and Kieber, 2002). See also Chapter 10. Because the biological uptake of NH$_4^+$ is rapid, NH$_4^+$ concentrations in the oceans are generally low (e.g., <0.03–2.7 µmol L^{-1} in the North Atlantic Ocean (Quinn *et al.* 1996)). Only in anoxic water masses (e.g., in the Black Sea and the deep basins of the Baltic Sea), NH$_4^+$ concentrations can rise to about 30 µmol L^{-1} (Kuypers *et al.*, 2003; Nausch *et al.*, 2003). Considering the fact that under equilibrium conditions, NH$_3$ contributes only up to 6% of [NH$_x$] (see above), oceanic NH$_3$ concentrations are expected to be low and, thus, difficult to determine: Methods applied in chemical oceanography measure the sum of NH$_3$ + NH$_4^+$ (Hansen and Koroleff, 1999). Dissolved gaseous NH$_3$ can be calculated from [NH$_x$] with the equations given above. Because oceanic NH$_4^+$ concentrations are low and, therefore, are close to or below the detection limit of conventional analytical methods, determination of dissolved NH$_3$ demands a high degree of analytical precision, a low detection limit, and an appropriate contaminant-free working conditions (Genfa *et al.*, 1998; Watson *et al.*, 2005).

Thus, there are only a few data of dissolved oceanic NH$_3$ available. (Reports on oceanic NH$_4^+$ measurements are not considered here because without the knowledge of pH, water temperature, and salinity, the ''true'' concentration of dissolved NH$_3$ remains speculative). Because the NH$_3$/NH$_4^+$ equilibrium strongly depends on the temperature, maximum NH$_3$ concentrations are expected to occur in surface waters and should rapidly decrease with depth in association with temperature profiles in the subsurface and deep ocean. (Exceptions should occur in the few cases where subsurface NH$_4^+$ maxima have been observed (Brzezinski, 1988; Gibb *et al.*, 1999b)). Oceanic NH$_3$ concentrations discussed in the following paragraph are exclusively from the oceanic mixed layer.

Quinn *et al.* (1988) report a mean concentration of 16 ± 7 nmol L^{-1} (ranging from 4.9 to 22 nmol L^{-1}) for NH$_3$ measurements in the coastal area of the northeastern Pacific Ocean. This is agreement with data reported by Genfa *et al.* (1998) from coastal waters of Coconut Island, Hawaii (17.4 ± 6.9 nmol L^{-1}). Comparable concentrations have been found on a transect along 170°W in the central Pacific Ocean: 10 ± 7 nmol L^{-1} (ranging from 2.8 to 21 nmol L^{-1}) (Quinn

et al., 1990). Mean NH_3 concentrations in the Northwest Indian Ocean (i.e., the Arabian Sea) ranged from 8.0 ± 1.9 to 11.9 ± 1.7 nmol L^{-1} (Gibb *et al.*, 1999a).

5.4. The ocean as a source or sink of atmospheric NH_3

The direction of the NH_3 flux cross the ocean/atmosphere interface depends on the concentration difference between NH_3 in the surface ocean $(NH_3)_{g,ocean}$ and $(NH_3)_{g,atmos}$ in the marine boundary layer. In the case of an ocean/atmosphere equilibrium the concentration difference is 0 and no gas exchange is possible. Ideally, both parameters should be measured simultaneously to allow a reasonable flux estimate. Disequilibria, $(NH_3)_{g,ocean} \neq (NH_3)_{g,atmos}$, can develop because the gas exchange across the ocean/atmosphere interface is slow compared to the life times of NH_3 in the marine boundary layer and in the surface ocean (Quinn *et al.*, 1992).

In the pristine marine boundary layer, atmospheric NH_3 concentrations are extremely low (see above) and in this case $(NH_3)_{g,ocean} > (NH_3)_{g,atmos}$ which implies that the ocean can release NH_3 to the atmosphere. In the reverse case of $(NH_3)_{g,ocean} < (NH_3)_{g,atmos}$, the ocean takes up NH_3. Indeed, both cases have been observed: In heavily anthropogenic influenced coastal areas such as the North and Baltic Seas, high atmospheric NH_3 concentrations can lead to a net flux of NH_3 from the atmosphere to the ocean (Asman *et al.*, 1994; Barrett, 1998; Lee *et al.*, 1998). However, in a recently published study, Sørenson *et al.* (2003) pointed out that even at low atmospheric NH_3 concentrations, the coastal North Sea is a sink for atmospheric NH_3. This in line with observations of NH_3 fluxes in the Chesapeake Bay, which varied seasonally. During winter the flux was from the atmosphere into the surface waters, whereas during summer the Chesapeake Bay acted as a source of NH_3 (Larsen *et al.*, 2001). The central Pacific Ocean,the Northwest Indian Ocean (Arabian Sea) and the Northeast Indian Ocean (Bay of Bengal) have been shown to be sources of NH_3 to the atmosphere (Gibb *et al.*, 1999a; Quinn *et al.*, 1990; Schäfer *et al.*, 1993), whereas the Sargasso and Caribbean Seas were found to be a sink for NH_3 (Quinn *et al.*, 1996)

Additionally, micrometeorological methods have been applied to measure NH_3 fluxes in coastal areas. For example, Sørensen Geernaert *et al.* (1998) measured the vertical NH_3 profile above the seasurface in the Kattegat Strait (western Baltic Sea) and found a flux of NH_3 to the seasurface. Recently, Biswas *et al.* (2005) applied a similar technique and could show that the Sundarban mangrove forest (northeastern Bay of Bengal) was a sink of atmospheric NH_3.

Several additional observations based on the distribution and composition of NH_4^+ aerosols over the oceans suggest that large parts of the ocean are, indeed, sources of NH_3 to the atmosphere: During a cruise in the equatorial Pacific Ocean, Clarke and Porter (1993) found a clear relationship between enhanced NH_4^+ aerosols concentrations and enhanced chlorophyll concentrations implying that NH_3 emissions from equatorial upwelling resulted in formation of NH_4^+ aerosols of marine origin. The estimated release of NH_3 from the ocean to the atmosphere (10 ± 10 μmol m^{-2} day^{-1}) needed to form aerosol NH_4HSO_4 was found to be in agreement with a flux estimate by Quinn *et al.* (1990) (1.8–15 μmol m^{-2} day^{-1}) for

the Pacific Ocean. In another study, the concentrations of NH_4^+ aerosols were monitored in an air mass of European origin passing over the North Atlantic Ocean near the Azores (Zhuang and Huebert, 1996). Despite the fact that the plume was diluted with NH_4^+ -free tropospheric air, NH_4^+ aerosol concentrations were relatively constant, thus, an additional, oceanic NH_3 source was suggested to maintain the observed NH_4^+ aerosol concentrations with a mean NH_3 flux of about 26 ± 20 μmol L^{-1} day^{-1}. This flux is in reasonable agreement with the range of sea-to-air fluxes calculated for the Pacific Ocean, the Arabian Sea and the Bay of Bengal by Quinn *et al.* (1990), Gibb *et al.* (1999a), and Schäfer *et al.* (1993) respectively. However, estimates of the NH_3 air–sea exchange for eastern basins of the central Atlantic Ocean (Caribbean and Sargasso Seas) suggested that these basins act as sink for NH_3. This obvious discrepancy might be caused by possible analytical artifacts of the measurements and the fact that the available measurements of dissolved $[NH_x]$ and $(NH_3)_{g,atmos}$ were not simultaneously measured (Quinn *et al.*, 1996). Because NH_3 ocean/atmosphere flux estimates are very sensitive with respect to $[NH_x]$ and $(NH_3)_{g,atmos}$, spatial and temporal differences of non–simultaneous NH_3 measurements in the ocean and in the atmosphere introduce a significant bias (Quinn *et al.*, 1996).

More recently, Jickells *et al.* (2003) measured the isotopic abundance of NH_4^+ aerosols from the North and South Atlantic Ocean. They found a positive correlation between NH_4^+ aerosol concentrations and $\delta^{15}N_{atm}$ of NH_4^+ and concluded that the light NH_4^+ must have originated from oceanic NH_3 emissions (Jickells *et al.*, 2003). Norman and Leck (2005) observed a pronounced diurnal cycle of atmospheric NH_3 in the pristine atmospheric boundary layer of the southeastern Atlantic and attributed this phenomenon to diurnal changes in the oceanic NH_3 source.

5.5. The role of oceanic emissions in the global budget of atmospheric NH$_3$

Based on the fact that only a limited amount of oceanic NH_3 measurements are available and, therefore, the spatial and seasonal variabilities of the NH_3 exchange across the ocean/atmosphere interface are largely unknown, only a few attempts have been made to estimate the global oceanic NH_3 emissions. Schlesinger and Hartley (1992) extrapolated the fluxes from the Pacific Ocean calculated by Quinn *et al.* (1990, 1988) to the global ocean and yielded a mean annual global flux of 13 Tg N with 8 and 18 Tg N as minimum and maximum values, respectively. Dentener and Crutzen (1994) scaled the oceanic NH_3 emissions to the oceanic emissions of dimethyl sulfide (DMS) by assuming equal molar emissions of DMS and NH_3. Their global estimate yielded an annual oceanic NH_3 release of 7.0 Tg N. This estimate is in agreement with the result of a model study, which resulted in a global oceanic NH_3 emission estimate of 8.2 Tg N yr^{-1} (3–16 Tg N yr^{-1}) (Bouwman *et al.*, 1997). Thus, oceanic emissions are a major source of atmospheric NH_3 and contribute about 15% of the total sources (Bouwman *et al.*, 1997). Other major sources are excreta from domesticated animals (21.6 Tg N yr^{-1}) and synthetic fertilizer use (9.0 Tg N yr^{-1}) (Bouwman *et al.*, 1997). Major sinks are dry/wet deposition on land

(40 Tg N yr^{-1}) (Schlesinger and Hartley, 1992) and to the oceans (16.7 Tg N yr^{-1}) (Duce *et al.*, 1991).

Because the NH$_3$/NH$_4^+$ equilibrium and, thus, the concentration of "free" dissolved gaseous NH$_3$ is strongly tightened to the oceanic pH, any changes in the oceanic pH will influence the magnitude and in the extreme case even the direction of the NH$_3$ flux across the ocean/atmosphere interface. This point is especially important since the ongoing increase of atmospheric carbon dioxide results in a significant acidification of the oceans (Caldeira and Wickett, 2005; Orr *et al.*, 2005; Raven *et al.*, 2005). The predicted shift of the pH in the surface ocean from the present-day mean of about 8.1–7.9 in the year 2100 might lead to a reduction of the oceanic NH$_3$ emissions since the fraction of dissolved gaseous NH$_3$ available for gas exchange is further reduced (see Fig. 2.8). This, in turn, implies that the uptake capacity of a more acidic ocean for the atmospheric base NH$_3$ might be enhanced by 7–40% (Jacobson, 2005).

6. Outlook

Despite the fact that our knowledge about the oceanic distribution of NO, N$_2$O, NH$_3$, and N$_2$ has considerably increased during the last decades, we are far from being able to draw a comprehensive picture. Of the four gases discussed above, N$_2$O is the most studied. Increased attention have been paid to NH$_3$ and N$_2$ during the last years. However, because of the analytical difficulties, we still have only a rough idea about the oceanic pathways of NO cycling. In the following section I sketch some major gaps of our knowledge about the gases discussed above:

6.1. Nitrous oxide (N$_2$O)

Future work on oceanic N$_2$O should pay more attention to N$_2$O pathways in coastal areas such as estuaries, mangroves, upwelling areas etc. since it is evident that a significant portion of the oceanic flux to the atmosphere comes from the coastal areas. We still do have only a rough idea how coastal N$_2$O emissions will be altered by ongoing environmental changes such as eutrophication and the development of coastal hypoxia. Another point to be considered for future formation of N$_2$O is that we might expect an expansion of suboxic zones in the world ocean. This, in turn, might lead to enhanced N$_2$O accumulation at the oxic/suboxic boundary layers.

Isotope measurements of N$_2$O have been introduced as a promising tool to decipher the formation pathways of oceanic N$_2$O. However, it turned out that isotopic measurements in some cases are difficult to explain (e.g. in the Arabian Sea) and that they even can lead to contradicting results: For example, from the interpretation of the N$_2$O isotope measurements at station KNOT in the western North Pacific Ocean it is not clear whether nitrification or denitrification is the main N$_2$O formation pathway (see Table 2.2). We need to learn more about the N$_2$O forming pathways and the resulting N$_2$O isotope signatures of the different types of N$_2$O producing organisms. The recently isolated NH$_4^+$ oxidizing archaeon (Könneke *et al.*, 2005) raises the question whether we have overlooked N$_2$O forming organisms other than bacteria. (Especially in view of the fact that NH$_4^+$-oxidizing Archaea have been found to dominate soil ecosystems (Leininger *et al.*, 2006),

which might also be true for the ocean ecosystems.) N_2O isotope studies might help to identify unknown N_2O formation pathways. Moreover, there is an obvious discrepancy in the measured mean tropospheric SP_{N_2O} (19‰ vs. 43‰, Kaiser *et al.* (2004)), which is not resolved yet. Thus, there seems to be an urgent need for interlaboratory calibration of the N_2O isotope methods.

6.2. Dinitrogen (N_2)

In order to quantify the loss of fixed nitrogen via denitrification and anammox we definitely need more N_2 concentration measurements and more formation rate measurements in suboxic zones such as found in the Arabian Sea and the eastern tropical Pacific Ocean.

6.3. Ammonia (NH_3)

More simultaneous measurements of NH_3 in the ocean and in the atmosphere are needed to reduce the considerable uncertainties of the ocean/atmosphere flux esti‐mates. The ongoing acidification of the ocean will shift the NH_3/NH_4^+ equilibrium to NH_4^+. On the one hand this might have implication for the atmospheric distribution of NH_3, since the uptake capacity of the ocean will be increased with unknown consequences for chemistry of the atmosphere (e.g. the aerosol formation) over the ocean. On the other hand this might have severe implications for the nitrification rates in seawater because they are influenced by the *pH*. When the pH drops from 8 to 7, nitrification rates can be reduced by 50% (Huesemann *et al.*, 2002). (One explanation for this is that the ammonia monooxygenase enzyme uses rather NH_3 than NH_4^+ as substrate.) Most recently it was suggested that atmospheric NH_3 serves as a foraging cue for seabirds such as the blue petrel (Nevitt *et al.*, 2006): NH_4^+ is an excretion product of seabird prey. It has been shown that krill swarms release significant amounts of NH_4^+ (Johnson *et al.*, 1984). Shifting the NH_3/NH_4^+ equilibrium to NH_4^+ due to acidifi‐cation reduces the release of NH_3 and might therefore directly influence the ability of seabirds to locate patches of prey in the surface ocean (Nevitt *et al.*, 2006).

ACKNOWLEDGEMENTS

NOTE ADDED TO PROOF

I am very grateful to Tom Bell (School of Environmental Sciences, University of East Anglia, Norwich, UK) to draw my attention to some critical points in the calculations of *[NH₃]* and *H'ₛNH₃* as discussed in detail in Bell *et al.*, (2007) and Johnson *et al.*, (2007), (2008). These publications have been published after the

submission of my manuscript and, therefore, were not available to be included in the main text.

According to Bell *et al.* (2007) there is an alternative way to calculate [NH$_3$]:

$$NH_4^+ \xleftrightarrow{k_a} NH_3 + H^+$$

$$[NH_3] = \frac{[NH_x]K_a}{(K_a + [H^+])}$$

As shown in Bell *et al.* (2007), the calculation proposed by Khoo *et al.* (1977) to correct K_a for salinity and temperature effects is incorrect. Alternative corrections for pK_a (= $-\log_{10}K_a$) are given in Bell *et al.* (2007) and Johansson and Wedborg (1980), respectively:

$$pK_a = 10.0423 - (0.0315536\ t) + (0.14737\ I)$$

$$pK_a = -0.467 + (0.00113S) + \left(\frac{2887.9}{T}\right)$$

where t is the temperature in °C, T is the temperature in K, S is the salinity and I is the ionic strength.

The dimensionless Henry's constant given in Gibb *et al.* (1999a) (see Section 5.2) is erroneous (Johnson *et al.*, 1997; 2008). The correct form is:

$$H'_{sNH_3} = \frac{1}{17.93\left(\frac{T}{273.15}\right)\ \exp\left(\frac{4029}{T} - 9.70\right)}$$

Please note that the two curves in Figure 2.8 (dashed-dotted lines) which were calculated with the equations given in Gibb *et al.* (1999a) are, therefore, erroneous as well.

CHEMICAL COMPOSITION OF MARINE DISSOLVED ORGANIC NITROGEN

Lihini I. Aluwihare *and* Travis Meador

Contents

1. INTRODUCTION

As this collection of papers suggests, Nitrogen plays an important role in maintaining the biogeochemical balance of the marine environment. Many studies have focused on the role and distribution of inorganic forms of nitrogen—primarily, nitrate and ammonia and more recently, dinitrogen (N_2) gas—because of their demonstrated participation in primary production in the ocean and in biological controls on the oceanic distribution. In many parts of the surface ocean, dissolved organic nitrogen (DON) is the most abundant nitrogen species, excluding N_2 (Bates and Hansell, 1999; Cavender-Bares *et al.*, 2001; Wong *et al.*, 2002), and several studies have demonstrated the importance of DON as a currency for N exchange

within the marine ecosystem (see reviews by Antia *et al.*, 1991 and Bronk, 2002). However, the ecological role of marine DON and factors that control its reservoir size remain elusive. Some studies have examined the cycle of model N-containing compounds (urea and amino acids for example), and the presence of these same compounds in seawater has been demonstrated; but much of the DON reservoir remains poorly characterized, leaving its "molecular messages" (Hedges, 2002) unread.

In this chapter we attempt to summarize what is known about the chemical composition of marine DON with a special focus on the fraction that has been isolated by ultrafiltration through a spiral wound membrane of 1 nm pore size. This fraction is identified as high molecular weight (HMW) DON throughout this chapter and is identical to UDON (ultrafiltered DON) as discussed by some investigators (e.g., McCarthy *et al.*, 1998). This review is not meant to be an exhaustive survey of total DON composition but a focused report on more recent analytical advances in the study of complex DON compounds. The compositional information provided by these studies is further interpreted in the context of sources and sinks for particular organic N compounds in the marine environment. We would like to direct the readers to some recent reviews that provide extensive coverage of particular aspects of the DON story that may not have taken center stage in this chapter (Antia *et al.*, 1991; Benner, 2002; Bronk, 2002).

2. DEFINITIONS OF DISSOLVED ORGANIC NITROGEN

Like dissolved organic carbon (DOC), total DON is operationally defined and is differentiated from its particulate counterpart as the fraction of marine organic N passing through a filter having a pore size of either 0.7 μm (typically glass fiber) or 0.2 μm (polycarbonate, polysulfone, or aluminum filters). Note that all DON compounds also contain larger amounts of C, and that DON may be considered a subset of the DOC reservoir. Therefore, it can be useful to make observations of the DOC reservoir (e.g., percent recovery, isotopic composition, etc.) in order to provide a framework for studying the DON pool. Parts of this review employ this strategy.

Unlike DOC, which can be easily differentiated from dissolved inorganic C (DIC), DON is calculated by subtracting the concentrations of nitrate, nitrite, and ammonia from total dissolved N (TDN). This technique introduces several errors to estimates of DON concentration, and robust marine DON concentrations are a relatively recent phenomenon (Sharp *et al.*, 2004). Methods for quantifying each of these N pools are discussed in McCarthy and Bronk (this volume). Contemporary studies often omit the filtration step that differentiates dissolved organic matter (DOM) from particulate organic matter (POM) because DOM is far more abundant even in surface waters. Therefore, reported concentrations often represent *total* organic N (TON) rather than simply the *dissolved* species.

Several separation and isolation methods based primarily on solid phase extraction (SPE) or size fractionation (e.g., ultrafiltration) have been employed to

fractionate the complex DON reservoir (reviewed in McCarthy and Bronk, this volume). In most of these studies seawater was first filtered through a 0.2 μm filter (or at the very least, a 1 μm filter) prior to DON separation. This is important particularly for ultrafiltration, where large volumes of seawater are concentrated to compensate for naturally low concentrations of DOM compounds. Ultrafiltration typically isolates 20–25% of the total DOC (see below) in open ocean environments. This represents <30 μM C (<400 μg C/L). If organisms such as bacteria—whose surface water abundance is approximately 10^9 cells/L—are not removed, they will be included in the ensuing compositional studies. Assuming a C content of 15 fg C/ bacterial cell (Fukuda et al., 1998), one liter of surface water contains approximately 15 μg C as bacterial biomass. Ultrafiltration, as described earlier, concentrates viruses and most studies of HMWDOM characterization will include viruses.

2.1. Methods of isolation

2.1.1. Solid phase extraction

Several non-ionic chromatographic supports have been used for extracting DOM from natural waters on the basis of hydrophobic interactions. The most widely used supports include C_{18} (a silica-based matrix modified by an octadecyl bonded phase) and Amberlite® XAD resins (Aiken, 1985; Ertel et al., 1986; Leenheer, 1981; Mantoura and Riley, 1975; Thurman and Malcolm, 1981; McCarthy and Bronk, this volume). These resins fractionate organic matter based on their chemical composition. The XAD-8 support typically absorbs hydrophobic acids (fulvic acids) and XAD-4 absorbs hydrophilic acids (Aiken et al., 1985). The organic matter commonly absorbed from natural waters in this manner has been referred to as humic substances (i.e., humic or fulvic acids)—terminology adapted from the study of terrestrial organic matter. Commonly employed XAD resins include XAD 2, XAD 4, and XAD 8. The first two are cross-linked styrene-divinylbenzene resins with an average pore size of 50 and 90 Å, respectively and the third is an acrylic ester resin with an average pore size of 250 Å. These resins are often used in series to increase DOM extraction efficiencies (Druffel et al., 1992; Thurman and Malcolm, 1981). Based on $\delta^{13}C$ values, it is clear that most compounds within marine XAD extracts originate from autochthonous marine processes. For example, values of -20.8 ± 0.2‰ were reported for XAD-4 isolates, -22.0 ± 0.1‰ for XAD-2, and -23 ± 0.1‰ for XAD-8 isolates (Druffel et al., 1992).

Typically, seawater samples are acidified prior to extraction (pH 2–4) to protonate organic acids, and the compounds absorbed to resins are eluted with base for XAD resins and with organic solvents for C_{18} resins. Aiken et al. (1992) extracted 30–83% of the DOC in freshwater environments using XAD 8 and XAD 4 in series. For marine environments, Druffel et al. (1992) reported the isolation of 23–39% of the DOC when XAD 4 was used in series with either XAD 8 (30–39% of total DOC) or XAD 2 (23–28% of total DOC). More recently C_{18} resins have been used to isolate about 30% of total DOC from marine systems, and up to 50% from estuarine waters (Amador et al., 1990; Kaiser et al., 2003; Repeta et al., 2004; Simjouw et al., 2005). These resins are purportedly more successful than XAD-2, for example, at removing the colored DOM component from seawater.

The major disadvantage of solid phase extraction is that it provides a chemically biased view of the DOM reservoir, and seems to preferentially extract compounds with relatively low amounts of N. Other problems include sample contamination by various resins and incomplete elution of adsorbed DOM. Solid phase extraction remains, however, the only technique capable of reproducibly isolating DOM compounds within the entire range of MWs. Furthermore, the radiocarbon content (Δ^{14}C) of DOC isolated by XAD resins is depleted relative to the total dissolved inorganic carbon (DIC) reservoir (Δ^{14}C values for XAD isolates are between -300 and -500‰ (>3000 years); Druffel *et al.*, 1992) and so these isolates provide insight into the chemical structure of long-lived C- and N-containing organic compounds.

2.1.2. Tangential flow ultrafiltration

Over the last decade, studies of DOM structure, function, and cycling have relied primarily on the use of ultrafiltration to concentrate dissolved organic compounds and isolate them from the much more abundant inorganic compounds in seawater (reviewed in McCarthy and Bronk, this volume). The value of ultrafiltration was first demonstrated by Ogura (1974) but was not widely used by the oceanographic community until the 1990s. Ultrafiltration separates compounds based on size rather than chemical composition, thus providing a more comprehensive view of the structural diversity present in seawater DOM. In addition, since seawater is not pre-acidified, isolated compounds should retain their "natural" chemical character and conformation. However, following ultrafiltration, samples are often de-salted by diafiltration against Milli-Q water and this process likely affects molecular conformation. Theoretically, the intrinsic contamination from the ultrafiltration membrane is low, but poor cleaning of filters, for example, can result in cross contamination between samples and contamination from bacterial growth.

The most widely used nominal pore size for ultrafiltration is 1 nm, which is estimated to retain compounds with MWs >1000 Da. The 1 nm pore-sized membrane isolates $\sim20\%$ of the total DOC in surface and deep ocean waters and up to 55% of the DOC in coastal and estuarine environments (Benner *et al.*, 1997; Carlson *et al.*, 1985; Guo and Santschi, 1996). Ultrafiltration membranes with a smaller pore size are rare and do not show reproducible retention characteristics; filters with a larger pore size retain only a small fraction of total DOC and they are not widely used. In general, the actual MW retained and the isolation of reproducible quantities of DOC by ultrafiltration depends strongly on the membrane (e.g. construction material, manufacturer), sample type (e.g. river, coastal, open ocean), total DOC concentration, concentration factor, extent of desalting and operating conditions (Buesseler *et al.*, 1996; Guo and Santschi, 1996; Guo *et al.*, 2000). Losses to the ultrafiltration membrane can also be significant (Guo *et al.*, 2000) and depend primarily on the physiochemical characteristics of the particular molecule.

On average, approximately 20–25% of open ocean DOC is found in the >1000 Da or high MW (HMWDOC), fraction (Benner, 2002). In the Middle Atlantic Bight, Guo and Santschi (1997) found that approximately 54% of the C resided in the <1000 Da fraction while 25% of the DOC was found to be between 1000–3000 Da, 14% between 3000–10 000 Da and approximately 7% in the $>10\,000$ Da fraction. Carlson *et al.* (1985) reported that between 0 and

16% of the total DOC (isolated from the North Atlantic Ocean) was retained by a 10 000 Da filter and only 6% was retained by 30 000 Da filters. Together, these data show that most of the organic compounds dissolved in seawater have MWs below 1000 Da. Examples of molecules with weights close to 1000 Da that may be retained and concentrated by ultrafiltration include chlorophyll *a* and *b* (893.49 and 906.51, respectively), $\geq$ pentasaccharide, $\geq$ decapeptide, and large lipids such as the polar tetraether membrane lipids of the *Archaea* (few long chain, free lipids are expected to have MWs above 1000 Da).

The next few sections focus primarily on bulk and molecular level chemical characteristics of DOM isolated by ultrafiltration using membranes with a nominal pore size of 1 nm. This fraction is referred to as HMWDOM, HMWDOC, or HMWDON depending on the context.

3. BULK CHEMICAL COMPOSITION OF HIGH MOLECULAR WEIGHT DISSOLVED ORGANIC NITROGEN

3.1. Elemental composition

Only occasionally has the N content of solid phase extracts been reported. At a site in the Atlantic Ocean the carbon to nitrogen ratio (C:N) of XAD 8 and XAD 2 extracts fell in the range of 40–57 (57 ± 0.9 and 41.1 ± 3.3, respectively; Druffel *et al.*, 1992). In contrast, at the same site XAD 4, when used as the second resin in series with XAD 8 or XAD 2, extracted compounds with lower C:N ratios - 19–24 (21.0 ± 2.4). These values are only slightly higher than ratios reported for total DOM (see below). McKnight and Aiken (1998) reported a C:N value of 37 for DOM extracted by XAD 8 at one site in the Pacific Ocean; at other sites in the N. Pacific Ocean XAD 2 was found to extract DOM with a C:N ratio between 32 and 46.5 (Druffel *et al.*, 1992; Meyers–Schulte and Hedges, 1986). Bronk (2002, Table III) compiled various literature values and arrived at an average C:N ratio of 32.8 ± 19.5 for total ''humic substances'' isolated from a variety of aqueous environments (see McCarthy and Bronk, this volume).

The total DON extracted from the Sargasso Sea when using XAD 4 in series with either XAD 8 or XAD 2 is reported in Fig. 3.1A (Druffel *et al.*, 1992). If we assume a total DON concentration of 5.0 μM N in surface waters and 3.0 μM N in deep waters (estimated from Hansell and Carlson, 2001), the organic N extracted by XAD resins represents approximately 10% of the total DON present throughout the water column. The C/N ratio for DOM isolated by C_{18} resins has not been reported but is probably similar to that for other solid phase extracts (i.e., ≥ 30).

Figure 3.1B shows a vertical profile of the concentration of DON and HMWDON in the eastern North Pacific and Central Pacific, respectively. As is clear from this figure ultrafiltration only isolates a fraction ($<30\%$) of total DON. In the case of HMWDOM isolated from estuarine, coastal and open ocean areas the C:N ratio ranges from 11 to 25. These ratios are lower than those of DOM extracted onto chromatographic supports as discussed above. HMWDOM from marine sites are on the low end of this range with average ratios ($\pm 1\sigma$) of 16.0 (± 1.8; $n = 41$) for surface waters, 16.6 (± 3; $n = 9$) for mesopelagic waters (750–1200 m) and
Figure 3.1 (A) Depth profile of humic DON isolated from the Sargasso Sea using XAD 8 + XAD 4 (diamonds) and XAD 2 + XAD 4 (squares). Adapted from Druffel *et al.* (1992). (B) Profile of total DON (North Pacific Ocean at 34°50′N, 123°0′W; Loh and Bauer, 2000) and HMWDON (Central Pacific Ocean at 12°S, 135°W; McCarthy *et al.*, 1998).

18.6(±0.7; $n = 4$) for bathypelagic waters (>2500 m) (Aluwihare *et al.*, 2002; Benner *et al.*, 1997; Guo *et al.*, 2003 (salinity >30); Meador *et al.*, 2007; Fig. 3.2). As shown in Fig. 3.2 total DOM has an average C:N ratio of approximately 14.6 (±3.3) in the surface ocean, 14.3 (±1.9) in the mesopelagic and 13.7 (±1.8) in the bathypelagic (Bronk, 2002; Hansell and Carlson, 2001; Loh and Bauer, 2000; De Jesus and Aluwihare, unpublished). Based on these data HMWDOM and DOM appear to share similar bulk C:N ratios in surface waters. Hopkinson and Vallino (2005) found that the C:N ratio of deep ocean DOM (primarily at sites in the Atlantic Ocean) was much higher than the ratio measured for surface waters—22 versus 14 (Fig. 3.2). These latter C:N ratios of total DOM are in better agreement with the C:N ratio of HMWDOM in surface and deep waters. Overall, data for both DOM and HMWDOM imply that N is preferentially lost from the dissolved organic reservoir with depth.

Benner (2002) estimated that the C:N:P of HMWDOM was 298:18:1 and 496:28:1 in surface and deep waters, respectively. In contrast, Hopkinson and Vallino (2005) calculated values of 374:27:1 for total DOM in surface waters and 3511:202:1 in deep waters. Both the C:N and C:N:P ratio of DOM and HMWDOM deviate significantly from the Redfield ratio (i.e., 106–132:16:1). However, vertical gradients in the C:N:P of total DOM suggests that the average DOM that is produced in surface waters and degraded at depth must have a ratio close to 199:20:1—similar to the Redfield ratio (Hopkinson and Vallino, 2005). In contrast, Loh and Bauer (2000) found little variation in the C:N:P of DOM with depth. Average values were shown to be 229-682:12-47:1; N:P ratios reported here are significantly lower at depth relative to values reported by Hopkinson and Vallino
Figure 3.2 Vertical profile of C/N ratios in total DOM (closed diamonds) and HMWDOM (isolated via ultrafiltration through a 1000 Da membrane; open squares). Data for total surface (<50 m) DOM were derived from Bronk (2002) and De Jesus and Aluwihare (unpublished). Meso-pelagic (1000–2000 m) and bathypelagic (3000–4000 m) C/N values in total DOM (black, closed diamonds) were derived from Loh and Bauer, (2000) and Hansell and Carlson (2001). Also shown on the figure are more recent estimates of the C/N ratio in total DOM isolated from the deep ocean (from Hopkinson and Vallino, 2005; grey diamond). C/N ratios of HMWDOM were taken from Benner *et al.* (1997), Guo *et al.* (2003), Aluwihare *et al.* (2002), Meador *et al.* (2007) and Meador and Aluwihare (unpublished). Error bars depict the 1σ standard deviation for each data set. The depths at which the C/N values are located on the figure are for the general depiction of surface waters (near 2 m), mesopelagic (750–2000 m), and bathypelagic regions (depths >2500 m) only and do not correspond to the exact depth at which each sample was collected.

(2005). These observed discrepancies may reflect the challenge of accurately deter-mining DON and dissolved organic phosphorus (DOP) concentrations in the deep ocean where the concentration of the corresponding inorganic species is an order of magnitude higher. According to Kolowith *et al.* (2001) the C:N:P ratio of HMWDOM that is lost with depth is approximately 227:14:1 – significantly enriched in C compared to the Redfield ratio, but a similar N:P ratio as the Redfield ratio. In the case of DOM N and P are preferentially remineralized relative to the *accumulating* DOM reservoir. However, in the case of HMWDOM the accumulat-ing component and the component that is removed with depth have a similar C:N ratio, but P is enriched in the remineralized component. In order to balance what is observed for the total DOM reservoir, low molecular weight DOM compounds that are removed with depth must be enriched in N relative to HMWDOM.

Values discussed in the previous section represent an oceanic average and indi-vidual regions and parts of the water column may behave differently. For example, Abell *et al.* (2000, 2005) found that the DOM remineralized along isopycnals outcropping in the subtropical North Pacific Ocean is C-rich (C:N ∼ 30); based on this C:N ratio these authors concluded that DOM contributes between 70 and 90% of the total organic matter remineralized in the upper thermocline. As more data are collected, other sites in the ocean may show similar variability.

3.2. Stable isotope composition

Available stable C and N isotope values (δ^{13}C and δ^{15}N) for HMWDOM are listed in Table 3.1. Average δ^{13}C values for HMWDOM isolated from surface, mid–depth (between 100–1000 m) and deep waters (>2000 m) are −21.2‰ (±1.9), −21.7‰ (±0.3) and −21.7‰ (±0.3), respectively (Guo *et al.*, 2003 ($n = 4$; open ocean); Benner *et al.*, 1997 ($n = 21$); Meador and Aluwihare, unpublished ($n = 49$)). Some surface samples were influenced by local riverine inputs and this explains the greater variance in the surface ocean data set reported in Table 3.1. Reported values for the δ^{15}N signature of HMWDOM vary among studies; average values are 5.3‰ (±1.6) in the surface ocean, 6.4‰ (±2) at intermediate depths and 5.9‰ (±2.2) in the deep ocean. The observed spread in surface water δ^{15}N values (∼3.2–9.5‰) may reflect spatial or temporal (seasonal or longer time scale) changes in the isotopic composition of HMWDON. However, seasonal variations (i.e., temporal variations in primary production) are unlikely to influence the DON reservoir of the deep ocean. In addition, similar locations were sampled by multiple studies, so spatial variations alone cannot explain these differences. In fact, recent data from diverse marine sites show similar δ^{15}N values for HMWDON in the surface ocean despite spatial variations in inorganic N concentrations and N species as well as primary producer assemblages (Meador *et al.*, 2007). There is almost a 10 year lag between samples collected for the Benner *et al.* (1997) study—which reports high δ^{15}N values—and the Meador *et al.* (2007) study (for example). Therefore, decadal-scale variability could drive the observed difference. If the Benner *et al.* (1997) data are excluded, then the remaining surface ocean δ^{15}N values in Table 3.1 compare well with the δ^{15}N signature of the deep ocean nitrate reservoir (∼5‰; Sigman *et al.*, 2000).

There is less known about the δ^{15}N signature of total DON. At Station ALOHA, total DON in very near-surface waters was found to have a relatively low δ^{15}N signature, between 2 and 4‰ (Karl *et al.*, 2002). No such depletion in ^{15}N was recorded for HMWDOM isolated at or near this site (Meador *et al.*, 2007). However, δ^{15}N values for total DON below the euphotic zone at Station ALOHA were between 5 and 7‰ (Karl *et al.*, 2002), similar to values in Table 3.1. A one-year time series study at the Bermuda Atlantic Time Series (BATS) site found that the δ^{15}N signature of DON showed no seasonal variability and had an annually averaged value of 3.9‰ (Knapp *et al.*, 2005). Meador *et al.* (2007) reported a similar average δ^{15}N value for HMWDON isolated from the surface North Atlantic Ocean—4.1±0.64‰ (Table 3.1; $n = 25$). Unlike the relatively stable values reported for DOM and HMWDOM, the δ^{15}N signature of suspended organic particles is more variable and influenced by inorganic N concentrations and N species supporting primary production at specific sites (e.g. Altabet and Francois, 1994; Mino *et al.*, 2002; Rau *et al.*, 1998). These comparisons between PON and DON, and the minimal spatial and temporal (on < annual timescales) variability exhibited by δ^{15}N values of DON and HMWDON led Knapp *et al.* (2005) and Meador *et al.* (2007) to conclude that most of the DON/HMWDON reservoir accumulating in surface waters is refractory on annual timescales.

Table 3.1 Average carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) isotope signature of HMWDOM isolated from several different sites in the Atlantic Ocean, Pacific Ocean, and the Gulf of Mexico

	$\delta^{13}C$ (HMWDOM)				$\delta^{15}N$ (HMWDOM)				Reference
	Atlantic	*Pacific*	*Gulf of Mexico*	*Arctic*	*Atlantic*	*Pacific*	*Gulf of Mexico*	*Arctic*	
Surface	−21.2 ± 1.2	−21.6 ± 0.2			4.1 ± 0.64	5.39 ± 0.75			Meador *et al.*, 2007
	−22.2	−21.6 ± 0.2			6.6	7.8 ± 0.5	9.5		Benner *et al.*, 1997
			−21.36		6.6		4.2		Guo *et al.*, 2003
				−21.1 ± 0.1				4.4 ± 0.3	Benner *et al.*, 2005

Some values include ± 1 σ standard deviation; all values are expressed as ‰. Values reported by Meador *et al.* (2007) are from 2 m and 1000 m depth for surface and mid–depth values, respectively (analytical error on these measurements are ± 0.5‰). The data for Arctic Ocean samples were taken from Table 3.1 of Benner *et al.* (2005) and exclusively represent Nordic sea surface (<250 m), Arctic Ocean mid depth (200–600 m), and Arctic Ocean deep (>1000 m) samples because these were the only samples that were considered to be truly marine.

3.3. Functional groups in HMWDOM

The application of ultrafiltration to concentrate and isolate HMWDOM has allowed the scientific community to apply a variety of analytical tools to elucidate DOM chemical structure. Of particular note is the employment of ^{1}H, ^{13}C, ^{15}N and ^{31}P nuclear magnetic resonance (NMR) spectroscopy to study the chemical structure of DOM (e.g. Aluwihare *et al.*, 1997; Benner *et al.*, 1992; Hedges *et al.*, 1992; Kolowith *et al.*, 2001; McCarthy *et al.*, 1997; McCarthy and Bronk, this volume). Within the context of studying bulk HMWDOM, NMR spectroscopy provides a reproducible, quantitative method for identifying particular chemical functional groups. The *x*-axis of the NMR spectrum (as shown in Fig. 3.3; Eglinton and Repeta, 2004) identifies the chemical environment that surrounds each observed nucleus (e.g., in the case of ^{13}C NMR, various chemical substituents around the rare ^{13}C nucleus are observed) and the integrated area under each peak provides information on the relative abundance of various functional groups in HMWDOM. Based on functional group identification, we can infer (and quantify) the types of biochemicals present in HMWDOM.

Figure 3.3 shows ^{1}H, ^{13}C and ^{15}N NMR spectra of HMWDOM isolated from surface waters near Hawaii (modified from Eglinton and Repeta, 2004). The major functional group identified by both ^{13}C and ^{1}H NMR spectroscopy is HC-OH (between 3 and 4 ppm, ^{1}H-NMR; 50–80 ppm, ^{13}C-NMR), which is interpreted as arising from carbohydrates. Other carbohydrate specific resonances such as O-CH-O at the anomeric position (C-1 of the aldose ring) are also identifiable (between 5–6 ppm, ^{1}H-NMR; centered near 100 ppm, ^{13}C-NMR). Other major NMR resonances include alkyl/lipid functional groups (CH$_x$; 0.5–1.5 ppm, ^{1}H-NMR; 20–40 ppm; ^{13}C-NMR); acetate functional groups identified by ^{1}H-NMR spectroscopy as CH$_3$C $=$ O(O/N) (at 2.0 ppm) and manifested in the ^{13}C-NMR spectrum as carboxylic/amide (O $=$ C(O/N)) and carbonyl (C $=$ O) (between 170 and 180 ppm); and in some cases, aromatic functional groups (C $=$ C; 7–8 ppm, ^{1}H-NMR; 130–150 ppm, ^{13}C-NMR). In most open ocean samples, ^{1}H-NMR spectroscopy detects very little aromatic hydrogen suggesting that any aromatic compounds present in surface HMWDOM must be fully substituted (Aluwihare *et al.*, 1997, 2002). In general, 60–70% of C (O-CH-O+HC-OH) in surface HMWDOM can be attributed to carbohydrates, 10–12% to acetate (CH$_3$C $=$ O), 2–4% as non-acetate carbonyl/carboxylic/amide, and the remaining C to alkyl/lipid compounds which may also be found in compounds such as deoxy and methylated sugars (Fig. 3.4).

Proton and ^{13}C-NMR data compare well with each other and suggest that surface ocean HMWDOM has a H:C ratio of approximately 1.8–1.9 (Aluwihare, 1999; Benner *et al.*, 1992) and an O:C ratio between 1 and 1.1. These H:C and O:C ratios are very close to those of a pure carbohydrate with a general hexose structure (e.g., C$_6$H$_{12}$O$_6$). In comparison, humic substances isolated from seawater have an H:C ratio between 1.2 (direct elemental analyses) and 1.4 (based on NMR estimates) and are therefore, relatively C-rich (Hedges *et al.*, 1992). The H:C and O:C composition of phytoplankton as estimated by NMR spectroscopy is approximately 1.7 and 0.3, respectively (Hedges *et al.*, 2002). In comparison to phytoplankton
Figure 3.3 (A) Proton (^{1}H; 400 MHz, D_2O, δ), (B) carbon (^{13}C; 400 MHz, D_2O, δ), and (C) nitrogen (^{15}N; 400 MHz, solid-state, δ) nuclear magnetic resonances (NMR) spectra for HMWDOM isolated from surface waters of the North Pacific Ocean (after Eglinton and Repeta, 2004).

(where proteins dominate intracellular biochemicals) HMWDOM is rich in oxygen and deficient in hydrogen, consistent with a predominantly carbohydrate-like composition. While this discussion focuses primarily on the assignment of C, H and O in HMWDOM, it is necessary to understand this stoichiometry for the ensuing discussion on N-containing compounds in the marine environment.

At approximately 1000 m depth, sugars comprise 26–38% of HMWDOC while acetate comprises 4–6% of the total C (Fig. 3.4). At these depths, HMWDOM is also significantly enriched in lipid and olefinic C (C = C). Together, the surface and deep data support the existence of a large surface-derived carbohydrate reservoir that is removed with depth. Based on ^{13}C-NMR spectroscopy, the HMWDOM that is lost with depth has H:C and O:C ratios of 1.8 and 1.2, respectively. This component is slightly H poor and O rich relative to glucose (H:C = 2 and O:C = 1). As ^{1}H- and ^{13}C-NMR data cannot distinguish O from N in some functional groups (e.g., C-O-O vs C-O-N), part of the "O" that is lost may be N.

Shown in Fig. 3.3 (C) is the ^{15}N-NMR spectrum of HMWDOM isolated from a depth of 15 m near Hawaii. The one major resonance in the spectrum corresponds to amide N (124 ppm; >90% of the total N). Surface water samples sometimes show a minor resonance near 24 ppm (<10% of the total N), which corresponds to amine N. Amides are commonly present in biological systems within peptide bonds. Other amide containing biochemicals that may be common in oceanic environments include N-acetyl amino sugars such as *N*-acetyl glucosamine, *N*-acetyl muramic
Figure 3.4 The amount of HMWDOM carbon present within various functional groups in surface and deep (1000 m) ocean waters. Functional groups are identified based on ^{1}H and ^{13}C-NMR spectroscopy (see text for details) and the quantification uses areas under each NMR resonance. The range of values (shown as "error" bars) represents direct measurements using the ^{13}C-NMR spectra and indirect calculations based on ^{1}H-NMR spectra and converting to carbon based on average C:H of identified functional groups. (Data are based on spectra in Figure 3.3 and Benner *et al.*, 1992)

acid, chitin (β (1→4)-(*poly*) *N*-acetyl D-glucosamine) and peptidoglycan (which contains a sugar backbone comprised of *N*-acetyl glucosamine and *N*-acetyl muramic acid). Based on the NMR resonance alone, we cannot assign the amide to any particular class of biochemicals. Amines are present in a variety of compounds including amino acids and amino sugars.

At 1000 m depth, the only discernible ^{15}N-NMR resonance corresponds to amide N. However, this amide peak centered near 124 ppm is much broader than the one observed for surface-ocean HMWDON and overlaps with regions in the NMR that correspond to resonances from functional groups such as pyrrole- and indole-N (130–215 ppm; Aluwihare *et al.*, 2005; McCarthy *et al.*, 1997). Results from ^{13}C- and ^{1}H-NMR spectroscopy can be used to indirectly estimate the N contributed by these compounds as they contain characteristic aromatic C and H resonances. According to this estimate, heterocyclic-N compounds represent <15% of the total-N in the deep ocean (Aluwihare and Repeta, unpublished). From the width of the amide peak in the ^{15}N-NMR spectrum, McCarthy *et al.* (1997) estimated that up to 26% of the N in subsurface waters is present in functional groups other than amide-N. The ^{1}H- and ^{13}C-NMR–based compositional analysis suggests that HMWDOM contains a variety of functional groups. However, despite the relatively "high" N content of HMWDOM, only a single type of N—amides (although potentially present in a variety of different biochemicals)—accumulates in this fraction of DOM. Therefore, certain amides (and primarily amides) are either resistant to biological degradation in the marine environment or produced throughout the water column.

As discussed above, NMR spectroscopy has alluded to the presence of many major biochemicals (carbohydrates, proteins and lipids) in HMWDOM. To determine which of these biochemicals are important and how each contributes to the observed NMR spectrum several investigators have performed molecular level analyses of HMWDOM. The discussion below will focus primarily on proteins and related compounds.

4. MOLECULAR LEVEL ANALYSES

4.1. Proteins

In living cells, proteins account for a major fraction of the cellular C and most of the N. We therefore expect that DON released from living organisms will contain proteins. In addition, the prominent amide resonance in the ^{15}N-NMR spectrum of HMWDON could be derived from peptides and therefore, it is reasonable to hypothesize that proteins dominate the DON reservoir. Direct quantification of proteins in DOM has proven to be difficult (as seen later), so to test the above hypothesis many studies have focused on identifying and quantifying total hydrolysable amino acids (THAA) in DOM. Amino acids are released from DOM following hydrolysis of peptides and proteins, and most marine DOM studies have used similar methods of hydrolysis and subsequent quantification (i.e., 6 M HCl hydrolysis with variable temperature and hydrolysis times, followed by HPLC

separation and fluorescence detection of *o*-phthaldialdehyde (OPA) derivatives). Using these techniques only 7–11% of total DON and 1–7% of total DOC can be recovered as THAA (Dittmar *et al.*, 2001; Hubberten *et al.*, 1995; Yamashita and Tanoue, 2003). In the case of HMWDOM, the amino acids quantified represent approximately 16–30% of the total N and 3–6% of the C in surface waters (Aluwihare, 1999; Aluwihare *et al.*, 2005; McCarthy *et al.*, 1996). Thus, either protein-N is not the dominant form of N accumulating in DOM, or current analytical methods underestimate the protein content of DOM. Possible analytical problems that could explain low N recoveries include interference by high salt concentrations, cross-reactions introduced by hydrolysis procedures, or, in the case of HMWDOM, adsorption of proteins to the ultrafiltration membrane. The relative distribution, D/L ratio and isotopic composition of amino acids and the presence of certain membrane proteins in DOM have provided insights into the composition of DON and its potential sources despite the low overall protein-based N yield. Below is a discussion of these studies and their various findings.

4.1.1. Amino acid composition

Early studies looked at both dissolved free and ''combined'' amino acids (DFAA and DCAA, respectively) in total DOM, where HMWDOM proteins are a subset of the DCAA fraction. Lee and Bada (1975) first reported DFAA concentrations in the range of 40–50 nM in surface Pacific waters and total hydrolysable amino acid (THAA = DFAA + DCAA) concentrations that were often 10 times higher. To date, the observed range of THAA is approximately 250–650 nM in surface waters (Dittmar *et al.*, 2001, 2004; Hubberten *et al.*, 1995; Yamashita and Tanoue, 2003). Lee and Bada (1975) observed an approximate three-fold decrease in THAA below the euphotic zone (at these depths DFAA became negligible). This trend was also seen in more recent studies where amino acid concentrations decreased to between 160 and 360 nM in mid-depth waters (Hubberten *et al.*, 1995; Yamashita and Tanoue, 2003). McCarthy *et al.* (1996) found that HMWDOM-DCAA concentrations were 178 and 278 nM in surface waters of the Sargasso Sea and North Pacific Ocean, respectively.

As discussed above DOM contains between 200 and 500 nM of DCAA (Lee and Bada, 1975, 1977) and HMWDOM contains between 178 and 278 nM DCAA (McCarthy *et al.*, 1998). Based on these values, between 30% and 100% of DCAA are in the >1000 Da fraction of DOM. Coffin (1989) found that ∼60% of all amino acids isolated from a Delaware estuary were in the <1 kDa fraction; and Sommerville and Preston (2001) showed that >90% of total DCAA (as analyzed by GC/MS) are released from peptides with MWs <3 kDa. Taken together, these studies suggest that peptides and small proteins (∼500 and 3000 Da) contain most of the amino acids detected in DOM so far. Unfortunately, precise MW information is not currently available for proteins in HMWDOM or DOM.

Amino acids identified in both total DOM (as THAA) and HMWDOM (as DCAA) include aspartic acid, glutamic acid, serine, histidine, glycine, threonine, alanine, arginine, tyrosine, valine, isoleucine, phenylalanine, leucine, and tryptophan (e.g., McCarthy *et al.*, 1996; Yamashita and Tanoue, 2003). Figure 3.5A shows the mole percent distribution of these amino acids in DOM and HMWDOM. All
Figure 3.5 (A) The relative distribution of amino acids in total DOM (Lee and Bada, 1975; Henrichs and Williams, 1985; Hubberten *et al.*, 1994), HMWDOM (McCarthy *et al.*, 1996), phytoplankton, and bacteria (both from Cowie and Hedges, 1992). The data of Lee and Bada are a special case because not all the amino acids shown in this figure were quantified (see text for explanation). (B) The relative distribution on amino acids in total DOM, isolated from a variety of sites in the western North Pacific Ocean (data from Yamashita and Tanoue (2003). S and D represent surface and deep DOM samples, respectively. Distributions in HMWDOM are shown for comparison (McCarthy *et al.*, 1996).

DOM samples were obtained from surface waters and sampling locations include the Greenland Sea (Hubberten *et al.*, 1994), near Baja California (Henrichs and Williams, 1985), and the Eastern Equatorial Pacific (Lee and Bada, 1975). The HMWDOM sample was isolated from Station ALOHA (McCarthy *et al.*, 1996). Figure 3.5A also shows the distribution of amino acids in phytoplankton as represented by a net tow in Dabob Bay, WA (June 1982), a culture of the bacterium *Bacillus subtilis* and POM collected in a sediment trap at 60 m in Dabob Bay (July–August 1981; all data are from Cowie and Hedges, 1992). Similar acid hydrolysis conditions and liquid chromatography methods were used to determine the amino acid content of all samples shown in Fig. 3.5A. However, some differences do exist between methods, for example, Lee and Bada (1975) did not report individual concentrations for glycine, arginine, and phenylalanine, and Hubberten *et al.* (1994) omitted the analysis of threonine. Therefore, relative mole percent values shown in Fig. 3.5A for these studies are an overestimate relative to studies where the entire suite of amino acids was detected. Despite the various locations and times of sample collection and differences between methods identified above, the relative distribution of amino acids in both total DOM and HMWDOM as shown in Fig. 3.5A are similar.

Lee and Bada (1975) reported that DFAA were enriched in serine and alanine, and several studies have noted that THAA are enriched in alanine and glycine (e.g. Hubberten *et al.*, 1995; McCarthy *et al.*, 1996; Yamashita and Tanoue, 2003). In fact, glycine comprises between 20–25% of all amino acids detected in surface THAA by recent studies (Dittmar, 2004; Hubberten *et al.*, 1995; Yamashita and Tanoue, 2003). Glycine was also shown to be the most abundant amino acid in HMWDOM (McCarthy *et al.*, 1996). Therefore, most THAA–glycine is present in HMW dissolved proteins and/or ultrafiltration is isolating a representative fraction of total dissolved proteins. The major difference between HWMDOM and total DOM is the relatively high abundance of glutamic acid in HMWDOM. However, the relative abundance of this amino acid in living organisms (phytoplankton and bacteria; Fig. 3.5A) is similar to its abundance in HMWDOM.

The simple comparison of amino acid distributions in bacteria and phytoplankton reveals no obvious differences between these two possible autochthonous sources of dissolved proteins. Accordingly, the amino acid distribution in HMWDOM is similar to the distribution in phytoplankton, bacteria and sediment traps. The relationship between the amino acid distribution in total DOM and various particulate fractions is more variable. In general, it appears that amino acid distribution alone cannot identify the dominant source of dissolved proteins/peptides. However, assuming that the primary source of dissolved proteins in the ocean is bacteria and phytoplankton, these data support the interpretation that hydrolysable proteins in DOM and HMWDOM maintain a source-like amino acid distribution.

Several studies have suggested that the extent of organic matter degradation may be imprinted on the relative distribution of amino acids. For example, the depth-dependant relative enrichment of certain amino acids in POM has been interpreted as enhanced preservation of particular proteins. Hecky *et al.* (1973) showed that diatom cell wall proteins were relatively enriched in serine and glycine; Cowie and Hedges (1992) found that these amino acids were relatively unreactive in sinking POM and concluded that the observed pattern represented selective preservation of diatom cell wall material within POM. Glycine is enhanced in HMWDOM relative
Figure 3.6 The spatial distribution of the D/L–aspartic acid (Asp), –glutamic acid (Glu), –alanine (Ala), and –serine (Ser). Adapted from Perez *et al.* (2003).

to POM, and both DOM and HWMDOM contain relatively more serine than phytoplankton and bacteria (Fig. 3.6A).

Yamashita and Tanoue (2003) examined vertical and horizontal variations in the amino acid composition of DOM (Fig. 3.5B) along a coastal to oceanic transect and found that the concentration of valine, isoleucine, phenyalanine and leucine varied together. Based on the spatial distribution of these amino acids (along the transect)

the authors concluded that these amino acids were present in bioavailable DOM. Alanine and glycine also varied together but their spatial distribution was better explained by their presence in diagenetically altered DOM. However Yamashita and Tanoue (2003) were unable to discern strong patterns of variability in just their open ocean samples (for example, surface (S) and deep (D) ocean amino acid distributions were similar; Fig 3.5B), which they attributed to the already diagenetically altered nature of open ocean DOM.

In the Arctic and Antarctic Ocean amino acids were also found in humic substances isolated from DOM by XAD-2 resins (Hubberten et al., 1995). The concentration of THAA in humic substances was between 233–246 nM, with all hydrolysable amino acids in the deep ocean and ∼60% of amino acids in the surface ocean residing in this fraction. Glycine was by far the most abundant amino acid detected in the humic fraction. These authors concluded that amino acids in the XAD-2 extracts represent a "refractory protein" background that is present throughout the ocean. The dominance of this "refractory protein" background in the surface and deep ocean could explain the relatively stable amino acid distribution observed by Yamashita and Tanoue (2003) at their open ocean sites.

Studies examining the amino acid distribution in DOM and HMWDOM have revealed some consistent trends. The general similarity of amino acid distributions across molecular size classes suggests that proteins isolated as HMWDOM are representative of total dissolved proteins; this similarity has also been used to suggest continuity in peptide subunits (Dittmar et al., 2001). The observed trends may also be consistently imparted by the nearly identical hydrolysis procedures used to analyze the composition of various DOM fractions. However, small differences, such as the relative enrichment of glutamic acid in HMWDOM, are noticeable and may be indicative of the relative "freshness" of this fraction. The latter conclusion is consistent with the strong correlation between amino acid distributions in HMWDOM and organisms (Fig 3.5A). In addition, biodegradation (Amon and Benner, 1996) and radiocarbon (Aluwihare et al., 1999) studies (see Section V) do suggest that total HMWDOM is enriched in a more labile, recently produced component. Several studies have also concluded that relative increases in the abundance of glycine and alanine reflect diagenetically altered DOM (Amon et al., 2001; Dauwe et al., 1999; Dittmar et al., 2001; Yamashita and Tanoue, 2003). It is important to note however, that amino acid composition and concentration studies target the protein fraction alone and cannot provide conclusive information about processes affecting total DOM; particularly since amino acids represent only a small fraction of the DOM reservoir.

4.1.2. The enantiomeric signature of amino acids

One potentially powerful indicator of source and diagenetic state is the D/L-amino acid ratio within DOM. Although proteins in nature contain primarily the L-enantiomer of amino acids, certain compounds, many of bacterial origin, do contain D-amino acids. Proteins do not contain D-amino acids but peptidyl compounds such as peptidoglycan (a structural component of bacterial cell walls; Osborn, 1969), peptide antibiotics (Bodanszky and Perlman, 1969) and peptide

siderophores (Martinez *et al.*, 2000) have all been shown to contain both the D and L enantiomer.

In 1977, Lee and Bada first reported the presence of D-amino acids in total DOM. They detected the D enantiomer of aspartic acid, glutamic acid, alanine, valine, isoleucine and leucine. This early study also observed both depth and site-related variations in the D/L-amino acid ratio within DOM. For example, the D/L-aspartic acid ratio was 0.14 in surface waters of the central North Pacific and 0.36 in the surface Sargasso Sea; and the D/L ratio of aspartic acid and glutamic acid decreased from surface to 4000 m depth in the central North Pacific but no such vertical trend was apparent in the Sargasso Sea. Recent studies in the North Atlantic by Perez *et al.* (2003) and Dittmar *et al.* (2001) also observed spatial (vertical and horizontal) variations in dissolved D/L-amino acid ratios, but no clear vertical trend was reported. Data from Perez *et al.* (2003) are shown in Fig. 3.6 and average D/L ratios in these samples were 0.49, 0.42, 0.15, and 0.09 for alanine, aspartic acid, glutamic acid and serine, respectively. McCarthy *et al.* (1998) reported the presence of D-amino acids in HMWDOM from the central Pacific; at this site alanine, aspartic acid, glutamic acid and serine had the highest D/L ratios (average values of 0.50, 0.37, 0.20, and 0.2, respectively). Serine was the only amino acid in HMWDOM that exhibited any vertical variation in its D/L ratio. The hierarchy of amino acid-specific D/L ratios and the magnitude of each ratio in HMWDOM are similar to those values reported for DOM above and confirm that HMWDOM is representative of total DOM.

Based on D/L–amino acid ratios and the dominant amide signal in the ^{15}N–NMR spectrum of HMWDOM McCarthy *et al.* (1997, 1998) argued that N in HMWDOM is contained primarily in peptidoglycan. D/L-amino acid ratios provide the strongest evidence in support of this conclusion as peptidoglycan commonly contains D-alanine and other D-amino acids such as D-glutamic acid and D-aspartic acid. The ^{15}N–NMR spectrum supports a strong amide contribution to HMWDON, but *protein*-N recoveries from HMWDON are low. As a result, McCarthy *et al.*, (1998) argued that amides must be present in the form of acetylated amino sugars, an essential component of peptidoglycan (Fig. 3.7). These interpretations led McCarthy *et al.* (1998) to conclude that D-amino acids and amides in HMWDOM are directly added from a bacterial source.

Alternatively, over very long time periods, L-amino acids can racemize to produce D-amino acids. However, measured D/L ratios for certain amino acids cannot be achieved based on known racemization rates of amino acids in seawater. For example, Lee and Bada (1977) calculated D/L ratios of 0.01 and 0.004 for aspartic acid and alanine, respectively, assuming an oceanic residence time of 3,400 years for these amino acids. These calculated values are much lower than the measured values and led Lee and Bada (1977) to conclude that the enhanced D-amino acid concentrations in marine DOM must be derived from a bacterial source. In a later paper, Bada *et al.* (1982) suggested that the near–racemic mixture (50% each of the D and L enantiomer) of alanine at depth in the ocean was a result of the dehydration of serine or threonine to produce racemic alanine. These authors also detected near racemic α–amino-*n*-butyric acid (ABA), which can be produced from the dehydration of threonine. This mechanism of D-alanine formation
Figure 3.7 Model structure of peptidoglycan in gram–negative Bacteria. *N*-Acetylglucosamine (G) and *N*-Acetylmuramic acid (M) form the backbone, and the *N*-Acetylmuramic acid molecules are cross-linked with amino acids. There is some variation in amino acid composition of the peptides between organisms. For example, the DAP residue of the tetrapeptide is replaced by a lysine residue in gram–positive Bacteria. Any of the peptides of the tetrapeptide chain may occur in the peptide bridge along with glycine, threonine, serine, and aspartic acid. Figure is modeled after Madigan *et al.* (2000).

requires a vertical decrease in the concentration of serine and an increase in the D/L–alanine ratio, which was observed by Lee and Bada (1975). However, neither McCarthy *et al.* (1996) nor Perez *et al.* (2003) observed this trend in HMWDOM or DOM. In addition, McCarthy *et al.* (1998) found no ABA in their HMWDOM samples. In summary, recent studies examining D/L–amino acids in both HMWDOM and DOM conclude that D-alanine in HWMDOM is derived directly from bacterial production and not from post-production modification (through dehydration reactions for example) of peptides in the water column.

A study conducted in deep waters of the North Atlantic found no preferential microbial utilization of L– or D–amino acids during uptake experiments (Perez *et al.*, 2003); yet, the presence of D–amino acids may retard the *hydrolysis* rate of peptides. But D/L–amino acid ratios in DOM and HWMDOM rarely exceed 1 even in the deep ocean (some surface ocean samples analyzed by Perez *et al.* (2003) did show values >1 for D/L–aspartic acid). The ratio could approach or exceed 1 if peptides containing D–amino acids (e.g., peptidoglycan, which contains only a few amino acids) were preferentially preserved with depth. Instead, near constant D/L ratios

with depth and ratios below 1 for a variety of amino acids imply either no removal of the protein/peptide fraction of DOM with depth, or that a common source of the protein/peptide fraction exists throughout the water column. Either of these conclusions is also consistent with the near constant relative distribution of amino acids in DOM.

Relatively stable D/L ratios for diverse samples may also result from racemization during sample hydrolysis and processing. For example, in a comprehensive study Kaiser and Benner (2005) noted that D–amino acids in HMWDOM are overestimated following acid hydrolysis. However, based on the magnitude of the racemization blank and observed patterns within marine samples these authors concluded that the overestimation is negligible compared to naturally occurring concentrations of some D–amino acids (Dittmar et al., 2001; Kaiser and Benner, 2005; McCarthy et al., 1998). However, the distinct matrix of marine samples may introduce additional cross-reactions that have not been quantified. For example, one study noted a positive correlation between D/L ratios and salinity (Dittmar et al., 2001).

Rogers (1983) defined a relationship where the total peptidoglycan-N content of a sample could be estimated based on its D-Ala content (peptidoglycan-N = $5.7 \times$ D-Ala-N). Based on this relationship it was estimated that peptidoglycan contributed $7 \pm 2\%$ of THAA-N in Arctic rivers, $53 \pm 11\%$ of THAA-N in the deep waters of the Arctic Ocean (Dittmar et al., 2001), and 20–25% of the THAA-N (and 2.5% of the total DON) in North Atlantic surface waters (Perez et al., 2003). McCarthy et al. (1998) calculated a peptidoglycan-N content of 4.5–16% in HMWDON. However, intact peptidoglycans have not been isolated from any fraction of DOM, and D-amino acids identified in DOM could be present in other peptides.

4.1.3. Isotopic composition of amino acids

The stable C isotopic (δ^{13}C) signature of organic compounds is commonly employed for source apportionment, but few studies have applied this strategy for specific compounds within DOM. Recently, in an effort to identify specific HMWDOM sources McCarthy et al. (2004) compared the δ^{13}C signature of individual amino acids in HMWDOM to those amino acids isolated from a variety of autotrophic and heterotrophic organisms. Based on patterns of amino acid–specific δ^{13}C values these authors concluded that amino acids in HMWDOM were derived from an autotrophic source. However, this study focused on a limited sample set and considerable variations in δ^{13}C signature of amino acids was apparent.

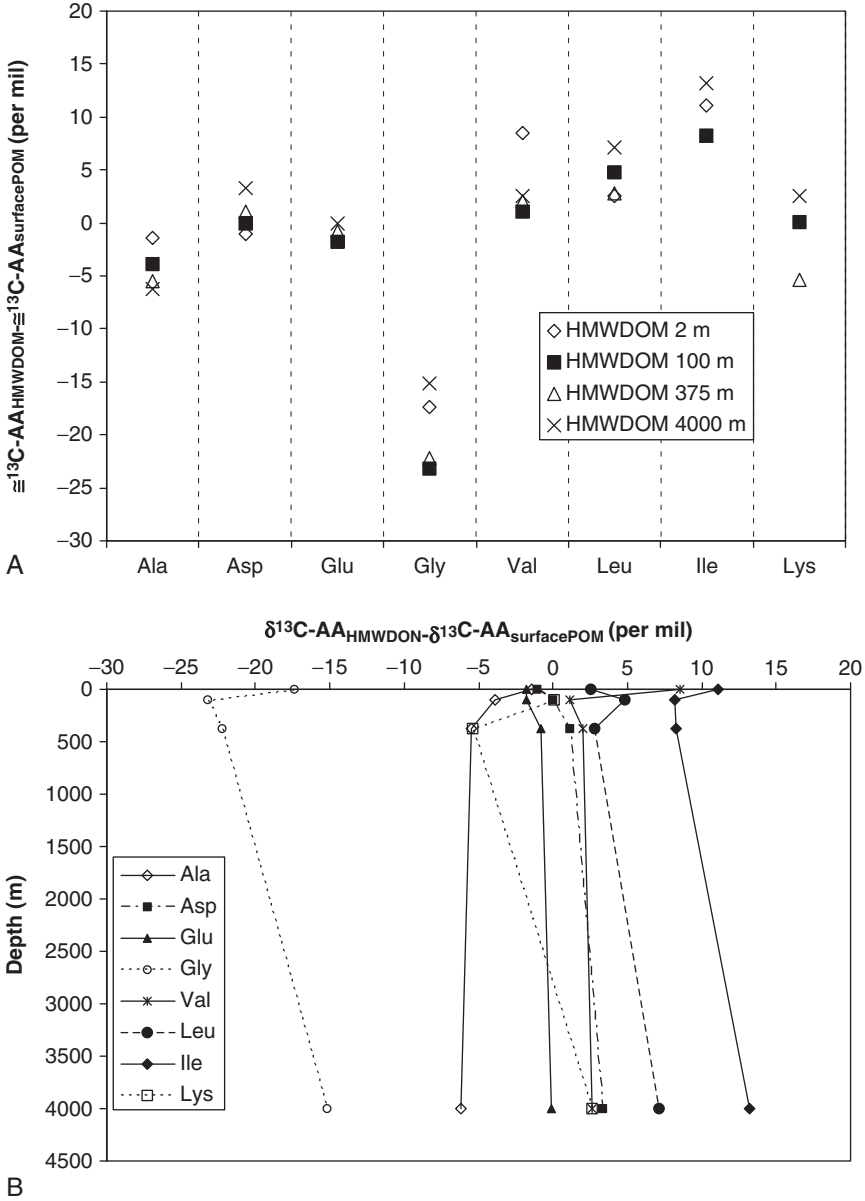
Amino acid-specific δ^{13}C signatures reported by McCarthy et al. (2004) may also serve as a degradation index for certain amino acids in HMWDOM. To examine this possibility the δ^{13}C signature of individual amino acids in both HMWDOM and sinking POM collected at 105 m were compared (Fig. 3.8A, data from McCarthy et al., 2004). It is assumed here that POM represents relatively "fresh" organic matter. Relative to sinking POM the most ^{13}C-depleted amino acid in HMWDOM was glycine. This complements findings from other studies which have suggested that the relative abundance of glycine reflects the extent to which DOM has been degraded. Depth profiles of the distribution of ^{13}C in amino acids revealed additional trends (Fig. 3.8B). For example glycine, lysine, leucine and


Figure 3.8 (A) Deviations in $\delta^{13}C$ values (‰) for amino acids in HMWDOM from amino acids in sinking POM ($\delta^{13}C\text{-AA}_{HMWDOM}-\delta^{13}C\text{-AA}_{POM}$) isolated from several depths in the central North Pacific Ocean (adapted from McCarthy *et al.*, 2004; only surface POM data from 2°N are used here). Note that we assumed a value of -23.9 for Ile *not* 23.9 (as shown in Table 3.1 of that paper). (B) Depth profiles of $\delta^{13}C_{HMWDOM}-\delta13C_{POM}$ for various amino acids.

isoleucine isolated from HMWDOM showed ^{13}C-enrichments below 500 m, but alanine did not. Also δ^{13}C signatures of all amino acids changed between the surface and 100 m—most values decreased over this depth range. The observed vertical variation in amino acid–specific δ^{13}C signatures may be explained by (1) unique amino acid–sources at different depths, (2) a similar biological source using a C source whose δ^{13}C composition is changing with depth or (3) amino acid–specific degradation/transformation processes. In general, the main conclusion provided by Fig. 3.8B is that all dissolved proteins/peptides do not share the same production and transformation history.

McCarthy *et al*. (2004) also measured the δ^{13}C signature of D–Ala isolated from HMWDOM. Within the error of their measurement, D and L enantiomers were found to have identical δ^{13}C signatures in surface waters and at 375 m depth in the central Pacific; based on these data the authors argued that both D- and L–Ala are derived from the same source. Using their early conclusion that amino acid–specific δ^{13}C patterns within HMWDOM resembled an autotrophic signature (see previous section), McCarthy *et al*. (2004) further inferred that alanine (both D and L) in HMWDOM is derived from an autotrophic source. Furthermore, as D–amino acids (including D–Ala) are commonly derived from bacteria the authors concluded that all of the amino acids preserved in HWMDOM are derived from autotrophic bacteria. However, it is not known whether D–Ala and L–Ala in bacteria have the same δ^{13}C signature (i.e., no fractionation takes place during racemization). Second, only a few of the amino acids found in HMWDOM are likely to be present in peptidoglycan (<50% of the THAA-N), and so, the total amino acid–specific δ^{13}C pattern does not argue for an autotrophic source of peptidoglycan (if present in HMWDOM). Finally, identical δ^{13}C signatures of D- and L–alanine do not require that all amino acids in HMWDOM are derived from bacteria. Ascribing source information based on δ^{13}C signatures alone is difficult in the current context as these values reflect only an average for each amino acid and each amino acid is likely to be found in many different dissolved proteins/peptides. Therefore, more work in this area is needed before the source of HMWDOM can be deduced from δ^{13}C signatures alone. Recently, McCarthy *et al*. (2007) have provided δ^{15}N isotopic signatures for amino acids in HMWDOM. Because the ^{15}N isotope composition of specific amino acids has been shown to either remain unaltered, or exhibit identifiable fractionation effects during N trophic transfer (Montoya *et al.,* 2002), this compound specific analysis has the potential to identify both amino acid source and degree of heterotrophic processing. McCarthy *et al*. (2007) found no statistically significant variation in δ^{15}N patterns of HMWDOM with depth. They also could not identify distinct source δ^{15}N patterns in HMWDOM. Thus, the transformation of marine DON evident in DON concentration profiles does not appear to be captured by the nitrogen isotope signature of HMW amino acids. This finding is consistent with the small contribution of hydrolyzable proteins to total DON. Again, this isotopic study was limited to a few HMWDOM samples (n = 4) and should be developed further by 1) expanding sample sets of HMWDOM, autotrophic and heterotrophic plankton cultures, and environmental, size fractionated POM, and 2) examining dual stable C and N isotopic composition of amino acids important in identifying trophic N transfer.

4.1.4. Isolation of proteins from HMWDOM

The analyses described above have provided valuable insights and raised interesting questions about the cycling of DOM. However, they only focus on amino acids that are released from dissolved proteins by acid or base hydrolysis. It is imperative that the field now focus its efforts toward separating and isolating intact dissolved molecules for chemical characterization. Recently, efforts have been made by Eiichiro Tanoue's group for example, to isolate, sequence, and identify intact dissolved, marine proteins isolated from HWMDOM.

Tanoue's group (e.g., Tanoue, 1995) reports results for HMWDOM isolated from seawater following pre-filtration through GF/F filters (Whatman; 0.7 μm pore size) and concentration by tangential flow ultrafiltration using a MW cutoff of 10 000 Da. A direct contribution to ''HMWDOM'' (10 kDa–0.7 μm) from microbial cells cannot be ruled out on the basis of the pre-filtration step used in the isolation of HMWDOM. In all cases, 0.01% (w/v) SDS and in some cases NaN_3 (5 mM) was added to the seawater before ultrafiltration. Both of these compounds may have enhanced the dissolution of cell-surface and intracellular proteins of organisms passing through the GF/F filter; in fact SDS is often used to lyse cells because it can effectively dissolve the phospholipid and protein components of cell membranes.

Tanoue et al. (1995) and Tanoue (1995) first reported the isolation and characterization of a 48 kDa protein isolated from HMWDOM as above. Since these initial studies, several papers from the same group have identified the presence of this and other proteins (e.g., 34, 37, and 39 kDa proteins) at many sites and depths in the Pacific, Indian and Antarctic Oceans (Suzuki et al., 1997; Tanoue, 1995; Tanoue et al., 1996; Yamada and Tanoue, 2003). The N–terminal amino acid sequence of the 48 kDa protein isolated from a depth of 45 m in the western North Pacific Ocean was GTVTTDGADIVIKT, a sequence that resembles bacterial porin P of the gram-negative bacterium Pseudomonas aeruginosa (Tanoue et al., 1995). Based on the homology between the 48 kDa protein and porin P, Suzuki et al. (1997) developed a fluorescence based immunochemical assay to detect these proteins in seawater. Natural populations of bacteria throughout the water column stained positive for this assay indicating that the 48 kDa protein is derived from bacteria and has a ''fresh'' source at all depths. The abundance of positively stained bacteria was approximately $10^{5.5}$ cells/L in surface waters; for comparison the total abundance of microorganisms in surface waters is approximately 10^9 cells/L. Yamada and Tanoue (2003) showed that a 40 kDa dissolved protein was also derived from a bacterial source based on homology to an outer membrane protein (OmpA) of Acinetobacter spp. Intact HMW proteins identified to date appear to be derived primarily from a bacterial source; in some cases these proteins have an in situ source throughout the water column.

Are the proteins identified in the previous section selectively preserved in DOM? In general, porins are expected to be resistant to bacterial degradation (Powell et al. (2005) and reference therein), and modification of these proteins, by saccharide moieties for example, may further retard their bacterial degradation. For example, in a laboratory experiment Keil and Kirchman (1993) noted longer turnover times for glycosylated ribulose 1,5-bisphosphate carboxylase (RuBPCase) when compared with unmodified RuBPCase. In accordance with this report Suzuki et al. (1997) suggested that the glycosylation of porins could help to explain their enhanced preservation/accumulation in seawater. Subsequently Yamada and Tanoue (2003)

showed, using a periodate oxidation method to oxidize these dissolved proteins, that the 48 kDa protein and a 34 and 39 kDa protein were indeed glycosylated. Based on the experimental conditions (i.e., strong or weak oxidation) these authors were able to distinguish sialic acids (a saccharide) and other saccharides in the 48, 34, and 39 kDa proteins. Sialic acids are primarily present in animals of the deuterostome lineage and are rare in bacteria and even plants, where their presence is still controversial (Varki, 2004). In fact, the few sialic oligosaccharides detected in bacteria to date have been found in pathogenic bacteria where it is hypothesized that genes for synthesis may have been acquired by gene transfer from a host eukaryote (Varki, 2004). The suggestion that sialic acids may be present in DOM is intriguing. In pathogenic bacteria, when sialic acids are present, they occur primarily on the outer membrane of the cell, consistent with the detection of porin membrane proteins in HMWDOM.

Based on the results discussed in this section it appears that bacterial membrane components, particularly glycosylated proteins, may be selectively preserved in DOM. However, based on the filtration method discussed above we cannot rule out the possibility that these membrane components represent contamination by living organisms where extracellular proteins were most easily released during the analysis. Also, most of the proteins that have been identified by Tanoue and co-workers are closely related to proteins of pathogenic bacteria. The link to pathogenic bacteria is interesting but could have several different explanations. For example, pathogens are the best studied bacteria and are well-represented in the protein data base; therefore, when any new protein sequence is entered into the data base and searched against known similar proteins, there is a high probability that proteins from pathogens will be recovered (Yamada and Tanoue, 2003).

Recently, other investigators have also successfully used SDS–polyacrylamide gel electrophoresis (PAGE) to isolate dissolved proteins. For example, Jones *et al.* (2004), working in the everglades, reported the presence of a 48 kDa protein (along with several other proteins) in one of their marine DOM samples. A recent study by Powell *et al.* (2005) identified ≤25 dissolved proteins (as gel electrophoresis bands) with MWs >25 kDa. To identify these proteins Powell *et al.* (2005) applied a liquid chromatography–mass spectrometry method to characterize peptide fragments produced from the enzymatic degradation of intact dissolved proteins separated from DOM by SDS–PAGE. Mass spectra of the peptide fragments were compared to theoretical mass spectra of known proteins in NCBI's databases to identify which protein families were present in DOM. Using this technique, Powell *et al.* (2005) detected some membrane/envelope proteins that appeared to be primarily of bacterial origin. Although porin P as identified by Tanoue and coworkers was not detected, the predominantly bacterial origin of identified proteins is consistent with the finding of Tanoue *et al.* (1996). Proteins in the database with similar amino acid sequences included long chain fatty acid acyl CoA synthetase, a component of anthranilate synthase, RuBisCo and a luminal binding protein (the latter is a bacterial outer membrane protein). Powell *et al.* (2005) added 0.01% SDS to seawater before pre-filtration and ultrafiltration (as did Tanoue and coworkers) in at attempt to keep dissolved proteins in solution during ultrafiltration The effect of SDS on dissolving proteins that were originally attached to living or non-living particles is not discussed and could explain the presence of previously undetected proteins.

The analytical approach applied in the Powell *et al.* (2005) study represents a major advancement in our current study of the chemical structure of DOM. SDS-PAGE remains one of the few methods that will allow separation and purification of intact dissolved proteins; proteomics, as applied by Powell *et al.* (2005), is now routinely applied in the biochemical and biomedical fields but is rarely applied in the environmental sciences. A major advantage of these mass spectrometry based techniques (i.e., proteomics) is the relatively small quantity of material required for the analysis; this opens up the possibility for analyzing peptides and proteins in total DOM with little or no pre-concentration. However, the presence of salts still needs to be minimized before effective mass spectra can be generated. A recent review by Mopper *et al.* (2007) highlights the application of high-resolution analytical techniques to study marine DOM composition, and we refer the reader to this review for a more comprehensive discussion of recent analytical advances.

Proteins identified in DOM contribute only a small fraction of N to total DON. Therefore, future studies should also seek to improve our ability to recover and quantify marine, dissolved proteins. For example, Section IIIc discussed the abundance of amide-N resonances in the ^{15}N-NMR spectrum of HMWDON; proteins are a likely source of these resonances but current inventories based on amino acid analyses and protein mass spectrometry are too low. Alternatively, protein-N may indeed be rare in HMWDOM and other molecule could be responsible for the amide-N identified in HMWDON. The next section focuses on polysaccharides as some of these biochemicals can contain amide functional groups.

4.2. Polysaccharides

4.2.1. Monosaccharide composition

Carbohydrates comprise a large percentage (20–40%) of the dry weight of phytoplankton and bacterial cells where they often play a role in structural integrity or energy storage. Accordingly, dissolved carbohydrates have been detected in the media of several laboratory phytoplankton cultures and in the field. In general, a major fraction of total identifiable C in both sinking POM and total DOM is comprised of carbohydrates suggesting that this biochemical in abundant in a variety of organic phases (Aluwihare *et al.*, 1997, 2002; Biddanda and Benner, 1997; Cowie and Hedges, 1984; Hamanaka *et al.*, 2002; Mopper, 1977; Tanoue and Handa, 1987; Wakeham *et al.*, 1997). Although ^{1}H- and ^{13}C-NMR spectra suggest that carbohydrates dominate HMWDOM, only 10–20% of C is recoverable as monosaccharides following the acid hydrolysis of HMWDOM. Despite the application of a variety of acid hydrolysis conditions and detection techniques, the same novel distribution of seven neutral monosaccharides has been described in HMWDOM – four hexoses galactose, glucose, mannose and xylose; two deoxysugars rhamnose and fucose; and the pentose arabinose (e.g. Aluwihare *et al.*, 1997; Borch and Kirchman, 1997; McCarthy *et al.*, 1996; Skoog and Benner, 1997). The yield of neutral monosaccharides decreases with depth in the ocean, but the relative abundance of individual monosaccharides is nearly the same irrespective of sample location, depth, or time of collection.

Of particular relevance to this discussion is the detection of amino sugars in DOM. The presence of amino sugars in HMWDOM was first quantified by

GC-MS and shown to be a minor component of hydrolyzed HMWDOM (Aluwihare et al., 1997, 2002). Boon et al. (1998), using direct temperature resolved mass spectrometry (DT-MS) following chemical (NH$_3$) ionization, confirmed the presence of N-acetyl amino sugars in HMWDOM but were unable to quantify their contribution to HMWDOC and HMWDON. In 2000, Kaiser and Benner developed an HPLC method to quantify amino sugars (N-acetyl glucosamine, N-acetyl galactosamine and muramic acid) following HCl hydrolysis of total DOM. Using this method Benner and Kaiser (2003) reported that 2–3% of total C and 2–7% of total N can be recovered from HWMDOM as amino sugars. Based on monosaccharide recoveries they were able to estimate that amino sugars contributed 22.9 ± 4.6% of all carbohydrate-C in HMWDOM. The two most abundant amino sugars detected in HMWDOM are N-acetyl glucosamine and N-acetyl galactosamine (Aluwihare et al., 2002; Benner and Kaiser, 2003; Kaiser and Benner, 2000) and their surface water concentrations are approximately 17–56 nmol/L and 10–36 nmol/L, respectively. Deep water concentrations are 2.3–5.8 nmol/L. Benner and Kaiser (2003) also detected muramic acid, the acetylated amino sugar unique to bacterial cell wall polymers, in HMWDOM; the concentration of this N-species in the surface ocean is reported to be in the range 0.12–0.78 nmol/L. The ratio of N-acetyl glucosamine to N-acetyl galactosamine in HMWDOM is between 1 and 2, and is fairly stable throughout the water column. This relatively constant composition is reminiscent of the near-constant ratio of various neutral monosaccharides in HMWDOM as discussed above. Additionally, both amino sugars and neutral monosaccharides exhibit a marked depth-dependent decrease in their contribution to total HMWDOC (and HWMDON). These lines of evidence could be indicative of a surface contribution to HMWDOM from a family of reactive polymers that contains all of these monosaccharides.

The presence of muramic acid in HMWDOM suggests that intact or degraded fragments of the polysaccharide backbone of peptidoglycan (alternating residues of N-acetyl glucosamine and muramic acid) are present in HMWDOM, consistent with the conclusion of McCarthy et al. (1997, 1998). However, the accumulation of intact peptidoglycan in HMWDOM has yet to be demonstrated and the data of Benner and Kaiser (2003) and Aluwihare et al. (2005) confirm that most N-acetyl amino sugars present in HMWDOM are not associated with peptidoglycan.

4.3. Molecular reconstruction of nitrogen in HMWDOM

The amino acid and amino sugar recoveries discussed above account for only a small fraction of the total C and N in HMWDOM. Either these biochemicals are scarce in HMWDOM, or strong acid hydrolysis conditions that are typically used in the analysis of dissolved proteins and polysaccharides result in a low yield of individual monosaccharides or amino acids. Aluwihare et al. (2005) developed a method based on mild hydrolysis of HMWDOM coupled with ^{15}N-NMR spectroscopy to identify the chemical environment surrounding amide bonds. Given the prominence of these bonds in DON (Fig. 3.3), these authors were particularly interested in quantifying any contribution to amide N from N-acetyl amino sugars. Mild acid hydrolysis of acetylated amino sugars yields acetic acid without depolymerizing the

molecule. That is, for each molecule of acetic acid that is generated, a mole of amide–N is converted to an amine, but the glycosidic bonds remain intact. In the case of proteins, mild acid hydrolysis is expected to leave the polymer untouched, in which case the N of the peptide bond will remain in the amide form. If hydrolysis of the peptide bonds does occur, then amino acids will be released and so this depolymerization of the protein will convert amide-N to amine-N. In either case, the products of the hydrolysis (acetic acid and amino acid) can be directly quantified, while the conversion of amide to amine can be monitored and quantified by ^{15}N–NMR spectroscopy. A simple schematic of this hydrolysis is shown in Fig. 3.9 for a protein/peptide and N-acetyl glucosamine.

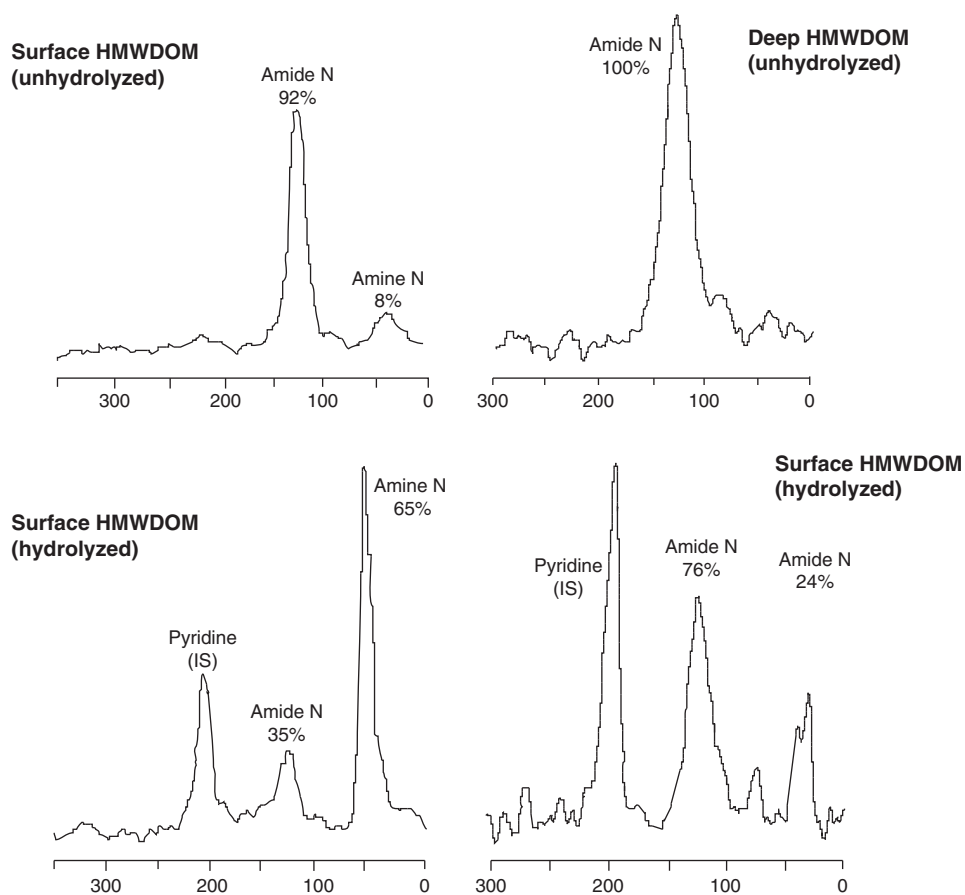
Mild acid hydrolysis affected the chemical environment surrounding amide-N in both surface and deep HMWDOM. These changes were recorded by ^{15}N-NMR spectroscopy as shown in Fig. 3.10 (after Aluwihare *et al.*, 2005). Based on NMR quantification and molecular level analyses of acetic acid and amino acids released during the hydrolysis, Aluwihare *et al.* (2005) reported that half ($\sim$45%) of the N in surface HMWDOM was present in acetylated amide groups such as those found in N-acetyl amino sugars. Of the remaining N, approximately 20% was recovered as amino acids (following additional acid hydrolysis at 6 M HCl) but the remaining
Figure 3.9 A simplified scheme for the mild acid (1 M HCl) hydrolysis of an amide containing molecule. Products of the hydrolysis for proteins and *N*-acetyl glucosamine are shown. After Aluwihare *et al.* (2005).


Figure 3.10 ^{15}N-NMR spectra of HMWDOM from surface and deep waters before and after mild acid (1 M HCl) hydrolysis (after Aluwihare *et al.*, 2005). Pyridine is used as an internal standard (IS) to quantify N recoveries.

amide N was not transformed by acid hydrolysis; this is consistent with previous findings for the amino acid content of HMWDOM (e.g. McCarthy *et al.*, 1996, 1998). Aluwihare *et al.* (2005) also reported that the unhydrolyzable amide-N dominated the HWMDON inventory in the deep ocean (Fig. 3.10); only ~30% of the amide-N in the deep ocean was hydrolyzable (detected as either amino acids (~15% of N) or inferred to be present in *N*-acetyl amino polysaccharides). As mentioned previously in Section 3.3, aromatic N compounds may also be present in the deep ocean but cannot be quantified by ^{15}N-NMR spectroscopy. The abundance of acetylated amides (amino sugars) in the surface ocean was surprising; however, more intriguing is the fact that ~30% of the amide N is surface waters and ~70% of the N is deep waters cannot be transformed by (strong) acid or base hydrolysis (Fig. 3.11). Low recoveries of *N*-acetyl amino sugars following hydrolysis of HMWDOM imply that these polysaccharides are resistant to hydrolysis. Amino
Figure 3.11 Amounts of carbon or nitrogen present as various biochemicals in HMWDOM isolated from the surface and deep (1000 m; open symbols) ocean. Carbon percentages in each sample are shown as open bars (and (C) notation); nitrogen percentages are shown as solid bars (and (N) notation). The range of calculated values is noted by the "error" bars. Biochemicals are assigned based on the functional groups identified by ^{1}H, ^{13}C, and ^{15}N-NMR spectroscopy and molecular level analyses. Carbohydrate C is calculated based on monosaccharide recoveries and amino sugar C estimated by ^{15}N-NMR (see text). Carbohydrate N and unydrolyzable amide N and C (assuming a C:N ratio of 4) is calculated from ^{15}N-NMR spectroscopy (see text). Amino acid recoveries (noted Protein AA in the figure) are based on molecular level analyses. Data are taken from Aluwihare *et al.* (2002, 2005) and McCarthy *et al.* (1998).

sugars may be present in a homopolymer, or in a homogeneous region of a hetero–polymer, that is not completely depolymerized; alternatively, Maillard type cross–reactions as shown in Fig. 3.12 may render them unhydrolyzable. Other explanations for low recoveries include the possibility that amino sugars are destroyed during hydrolysis and that amide-N is present within other unidentified molecules.

Given the general structure of *N*-acetyl glucosamine and the quantity of acetic acid recovered following acid hydrolysis, an estimated 20% of C in surface waters is
Figure 3.12 The Maillard Reaction. Shown are the preliminary rearrangements of functional groups (common to the proteins and sugars in DOM) that could serve as the foundation for addi–tional cross–reactions that may occur during *in situ* transformations of DOM or during analytical hydrolysis protocols. This could provide a mechanism for the formation of hydrolysis resistant amides that prevent bulk and monomer level characterization of DON.

present within acetylated amino sugars (assuming that all of the acetic acid is present in acetylated amino sugars). Together with directly determined neutral monosaccharide recoveries (between 10–20% C) carbohydrates account for approximately 30–40% of the total C in surface HMWDOM (Fig. 3.11); closer to NMR estimates of the carbohydrate content of HMWDOM (60–70%).

5. SOURCES AND SINKS BASED ON CHEMICAL INFORMATION

So far, this review has focused on establishing what is known about DON composition, but has also alluded to the important role that chemical composition plays in establishing DON sources and sinks. In fact, a major impetus for identifying the chemical composition of DOM is the hope that this information will allow us to better constrain the sources, inventory, residence times and sinks of various DOM components in the marine environment. In the following discussion we highlight the progress that has been made in this pursuit. Readers are also referred to Carlson (2002) for a thorough review of processes controlling DOM production and removal.

5.1. Sources

Source identification has relied primarily on chemical characteristics of *bulk* DOM or HMWDOM. For example, stable C isotope signatures of total DOM have proved very useful in establishing the predominantly marine origin of DOM (e.g., Williams and Druffel, 1987). More recent studies of the $\Delta^{14}C$ content of HMWDOM components, particularly polysaccharides (Santschi *et al.*, 1998; Aluwihare *et al.*, 2002; Repeta and Aluwihare, 2006) are also consistent with a primarily marine origin. In coastal and estuarine environments elevated C/N ratios of HMWDOM may be indicative of a terrestrial contribution from humic substances which have been shown to have relatively high C/N ratios. But in most cases the multiple components that are averaged in the bulk C/N ratio make it a poor source indicator. Bulk spectroscopic (e.g., NMR) or spectrometric (e.g. fluorescence, mass spectrometry) techniques do allow us to compare DOM samples and gain insight into chemical structure, but they do not suffice for unequivocal source assignment.

The $\delta^{15}N$ signature of DOM (Knapp *et al.*, 2005) and HMWDOM (Benner *et al.*, 1997; Guo *et al.*, 2003; Meador *et al.*, 2007) is comparable to the $\delta^{15}N$ value of deep ocean NO_3^- (Sigman *et al.*, 2000) and appears to vary independently of the $\delta^{15}N$ signature of suspended POM (Knapp *et al.*, 2005; Meador *et al.*, 2007). However, interpreting these $\delta^{15}N$ data in the context of N sources has proven challenging because $\delta^{15}N$ signatures of various inorganic N and particulate N reservoirs show marked variability in marine and terrestrial systems (e.g. Sigman and Casciotti, 2001). However, our ability to apportion sources based on $\delta^{15}N$ signatures will improve as studies aim to assign $\delta^{15}N$ values to all (or most) N reservoirs (e.g., suspended and sinking PON, DON, DIN etc) simultaneously at a

given location. In addition, compound-specific $\delta^{15}N$ measurements may allow DON source apportionment to particular marine biogeochemical processes such as N_2-fixation (Meador *et al.*, 2007).

Monomer composition studies of HWMDOM have revealed surprising similarities in the composition of marine HWMDOM isolated from various sites and depths; and studies seeking to assign sources based on these analyses have provided some clues but still lack complete and convincing data. For example, Cowie and Hedges (1992) concluded that amino acid composition served little use as a source indicator in marine environments. This was confirmed by the work of Yamashita and Tanoue (2003) who found no discernible spatial pattern in the relative distribution of amino acids in DOM isolated from various open ocean sites. Alternatively, Cowie and Hedges (1984) found that the ribose and fucose content of organic matter could be used to differentiate terrestrial and marine DOM; other studies have observed that the relative abundance of rhamnose is higher and fucose is lower in riverine DOM (e.g., Amon and Benner, 2003). Although these monomers are all present in HMWDOM, it is still difficult to conclusively identify sources based on monosaccharide composition alone because most monosaccharides are widely distributed in a variety of polysaccharides. In addition, Cowie and Hedges (1984) note that differentiating between various marine sources based on monomer composition is particularly difficult because small, metabolically active organisms have variable and diverse biochemical compositions.

Several authors have also compared bulk chemical properties between marine HMWDOM and HMWDOM produced in culture (Aluwihare and Repeta, 1999; Biersmith and Benner, 1998; Ogawa *et al.*, 2001). By comparing HMWDOM produced in phytoplankton cultures with oceanic HMWDOM, Aluwihare and Repeta (1999) noted that various phytoplankton produced dissolved compounds that were compositionally similar to HMWDOM accumulating in seawater. Proton NMR spectroscopy of some phytoplankton exudates even exhibited the dominant acetate peak observed in marine HMWDOM suggesting that *N*-acetyl amino sugars were produced by these organisms. These authors also showed that most exudates contained the same variety of neutral monosaccharides and that upon degradation, the general monomer distribution tended towards that observed for marine HMWDOM. In general, this monosaccharide distribution developed through a loss in neutral hexoses and a relative increase in the amount of deoxy sugars (rhamnose and fucose) over the course of the degradation experiment. Amon *et al.* (2001) and Amon and Benner (2003) also observed similar changes in the sugar composition of DOM during degradation, and additionally noted that the relative abundance of glucose increased as a result of diagenesis. Other investigators have also noted variations in the relative abundance of glucose in organic matter fractions (see references in Amon and Benner, 2003). In summary, these analyses have yielded mixed results—some have suggested that polysaccharides in HMWDOM are eventually sourced from phytoplankton products (Aluwihare and Repeta, 1999; Biersmith and Benner, 1998) while others studies have suggested that refractory HMWDOM is derived from bacteria (e.g. Ogawa *et al.*, 2001).

Cell membrane and cell wall components may also represent part of the accumulating DOM reservoir; these compounds may be selectively preserved as a result

of complex structural features that are not easily accessible to common bacterial enzymes (McCarthy et al., 1998; Nagata et al., 1998). Tanoue (1995) identified the presence of bacterial Porin P in HMWDOM, and subsequent studies from this laboratory have suggested that other structural polymers derived from bacteria are also present in seawater (e.g. Yamada and Tanoue, 2003). Based on their functional significance, a variety of microbial cell wall components may be designed to escape enzymatic hydrolysis and therefore, accumulate in DOM.

Short-term laboratory experiments have shown that the bacterial degradation of known biochemicals can result in the formation of refractory DOM (Brophy and Carlson, 1989; Ogawa et al., 2001; Stoderegger and Herndl, 1998). Brophy and Carlson (1989) added glucose and glutamate (at marine concentrations) to a natural population of marine microbes and showed for the first time, that heterotrophic organisms formed biologically refractory HMW organic compounds. Bacteria utilized only 17% of the C within the newly formed HMWDOM over a 6-month period. Ogawa et al. (2001) similarly showed that a natural bacterial assemblage grown on simple compounds such as glucose and glutamate produced DOM that was only slowly degraded on annual timescales.

Boon et al. (1998) used the presence of methylated and amino sugars, both also reported by Aluwihare et al. (1997) as minor constituents of HMWDOM, to argue that bacteria produce HMWDOM. However, methylated sugars and amino sugars have also been detected in eukaryotes (see below). Other authors have also arrived at a similar conclusion based on the work by McCarthy et al. (1997, 1998) which suggested that D-amino acids in HMWDOM are derived from peptidoglycan, a compound rich in acetylated amino sugars and found only in bacteria. Muramic acid, one of the two acetylated amino sugars present in peptidoglycan, has been detected in small quantities in HMWDOM (Benner and Kaiser, 2003; Kaiser and Benner, 2000). The N-acetyl glucosamine:muramic acid ratio detected in HMWDOM is in the range ∼20–120 (Benner and Kaiser, 2003), whereas this ratio is 1:1 in peptidoglycan. Bacteria are the only known source of muramic acid and the presence of this sugar in HMWDOM explicitly indicates a bacterial contribution to HMWDOM, albeit small. The low abundance of muramic acid in HMWDOM could result from low recoveries following acid hydrolysis of peptidoglycan. In fact, Benner and Kaiser (2003) report that muramic acid recoveries from peptidoglycan were on the order of 63%—lower than recoveries for N-acetyl glucosamine. However, lactic acid, which is present in muramic acid, is easily released upon treatment with base. When this method is applied to HMWDOM, only a small amount of lactic acid is detected. In fact, lactic acid recoveries from HMWDOM are too small for the sugar backbone of peptidoglycan to be a dominant component of DOM (Aluwihare et al., 2005). Although separate from the origin of N-acetyl amino sugars, it is still possible and likely that D-amino acids are present in peptides (not proteins) that are derived from bacteria. For example, several compounds derived from bacteria including antibiotics and siderophores do contain these amino acids (e.g. Bodanszky and Perlman, 1969; Martinez et al., 2000). Some reports also suggest that Archaea and eukaryotes may contain peptidyl D-amino acids (Nagata et al., 1998). In most cases, D-amino acids are present in non–protein peptides; however, there are several other amino acids in HMWDOM

and bulk DOM that are probably present in proteins which are not necessarily derived from bacteria.

The abundance of peptidoglycan in HMWDOM was inferred primarily from the strong amide resonance observed by ^{15}N-NMR spectroscopy (Fig. 3.7). However, other compounds could give rise to the observed amide resonance. For example, chitin, a homopolymer of β (1→4)–(*poly*) *N*-acetyl D-glucosamine is likely the most abundant polysaccharide in the ocean (similar to the ubiquity of cellulose in terrestrial environments). Since chitin is abundant in marine eukaryotes (e.g., diatoms, zooplankton, and fungi; this compound does not occur widely in prokaryotes) it is also abundant in detritus (Hashimoto *et al.*, 1997; Minor and Eglinton, 1999). The presence of chitin in the cell walls of diatoms and other algae has been well documented (Smucker, 1991; Shahgholi *et al.*, 1996 for example). In diatoms, investigators have shown that chitan is present in the fully acetylated, highly crystalline form with little or no cross-linking with amino acids or glycans. Chitan can contribute as much as 34% of the total cell mass (including hard-parts) of diatoms (McLachlan *et al.*, 1965). A study of cell wall carbohydrates in *Chlorella* sp. (from freshwater; Kapaun and Reisser, 1995) found a molecular ratio of amino sugars to neutral sugars in the range of 1:2–1:3. This is similar to the distribution of amino and neutral sugars in marine HMWDOM (Aluwihare *et al.*, 2002, 2005). Acid hydrolysis of the *Chlorella* polysaccharide released neutral monosaccharides (arabinose, xylose, rhamnose, fucose, galactose, mannose and glucose) but amino sugars were not released until strong acid hydrolysis conditions were applied (4 or 6 M HCl). Benner and Kaiser (2003) examined several different microorganisms for the presence of amino sugars and consistent with reports above, *N*-acetyl glucosamine was commonly present. *N*-acetyl galactosamine was found to be equally ubiquitous, and smaller quantities of mannosamine were also detected in several of the organisms. Although chitin and related, soluble polysaccharides are common in the marine environment, current molecular-level analytical methods have not been able to recover significant quantities of these polysaccharides from HMWDOM. Chitinase genes are ubiquitous in both free and particle-attached marine bacteria and have been shown to be predominant in the marine α-proteobacteria and the *Cytophaga-Flavobacter* clades (Cottrell *et al.*, 2000); these genetic data could imply that chitin is an important substrate for bacterial growth in the marine environment.

The compositional studies discussed in this paper have provided some insights into the DOM cycle. For example, monomer level studies have shown that the chemical composition of HMWDOM is homogeneous in the surface ocean (Aluwihare *et al.*, 1997; McCarthy *et al.*, 1996). Compositional differences between the surface and deep ocean have demonstrated that polysaccharides are reactive and removed with depth (Aluwihare *et al.*, 2002; Benner *et al.*, 1992); furthermore, the relative abundance of amides resembling those found in *N*-acetyl glucosamine also decreases with depth suggesting that these compounds are reactive and likely derived from surface ocean productivity (Aluwihare *et al.*, 2005; Benner and Kaiser, 2003). Amino acid compositions and quantities exhibit no vertical trend and certain amino acids could have a common source throughout the ocean (McCarthy *et al.*, 1998). D enantiomers of several amino acids are also ubiquitous in HMWDOM and indicate the presence of dissolved peptides derived from bacteria.

What is clear from these discussions is that intact molecules must be isolated from HMWDOM before a more accurate picture of the DOM cycle can be generated. So far studies have focused on the primary structure (or monomer composition) of complex biochemicals and this level of structural information cannot provide conclusive source information. Recently, gel electrophoresis and proteomics have been applied to characterize individual proteins in DOM. These techniques are very promising and cell membrane proteins and proteins involved in particular biosynthetic pathways have already been identified. In addition to providing source information, these techniques will enable us to identify chemical characteristics that favor the preservation of certain molecules in seawater. In the case of polysaccharides, attempts have been made to determine secondary structure through linkage analysis for example (Aluwihare *et al.*, 1997, 1999). However, beyond showing the predominance of highly branched heteropolysaccharides (interpreted to be present primarily in structural polysaccharides) over straight chain, homopolysaccharides (storage polysaccharides) these analyses have failed to identify specific sources.

5.2. Sinks and transformations of DON

Existing protocols for sampling DOM provide, at best, only a snapshot of a matrix of compounds that are cycling on dramatically different timescales and are subject to a variety of degradation processes. Carlson and Ducklow (1995) identified three types of DOM based on reactivity: (1) a labile fraction with rapid turnover rates and little to no accumulation in surface waters; (2) a semi labile fraction that is present at depths <1000 m and is only slowly degraded over seasonal timescales, and (3) a refractory fraction which is well mixed throughout the water column and is degraded on millennial timescales. Based on this reactivity scheme and an assumed biological source for the entire DOM reservoir, organisms in the surface ocean must synthesize biopolymers with widely differing rates of biological reactivity. Also, post-production modification of labile polymers may render them less susceptible to degradation. Bacterial uptake is responsible for the rapid turnover of the so-called labile fraction of DOM (Carlson and Ducklow, 1995) and tight coupling between production and consumption of labile DOM implies that these compounds do not accumulate in seawater and therefore, escape chemical characterization. Using the dissolved remnants from biological and abiotic transformation processes studies of DOM thus focus on reconstructing the cycles of semi-labile and refractory DOM.

Enzymatic assays can be applied in the marine environment to provide indirect information on dissolved compounds that are available to fuel bacterial production. Approaches that have been commonly applied include measuring hydrolytic enzyme activities in seawater and monitoring degradation rates of model compounds. Protein hydrolysis in seawater is rapid as expressed by model protein studies (e.g., Nunn *et al.*, 2003; Pantoja and Lee, 1999). This rapid and selective removal of dissolved proteins explains the relatively minor contribution from proteins to the accumulating DOM reservoir even though proteins are by far the most abundant intracellular biochemical. In an elegant study, Nunn and coworkers (2003) used matrix assisted laser desorption/ionization (MALDI) time of flight (TOF) mass

spectrometry (MS) to follow structural changes associated with the degradation of bovine serum albumin (BSA) in seawater. BSA was degraded rapidly in seawater and enzymatic attack occurred at a variety of sites on this protein. Based on these results the authors concluded that either non-specific proteases or a diverse collection of specific proteases were abundant in seawater. Consistent with these findings, the $\delta^{15}N$ signature of HMWDOM and proteins isolated from HMWDOM indicate that dissolved proteins are turning over more rapidly than bulk HMWDOM (Meador et al., 2007).

In the case of carbohydrates, bacteria produce a variety of ectoenzymes that are capable of hydrolyzing many different glycosidic bonds (Arnosti, 2000). Studies in the field have focused primarily on glucosidases, chitinases and cellulases because their assays are well developed (Pinhassi et al., 1999; Riemann and Azam, 2002) but degradation experiments with model polysaccharides have also indirectly monitored the activity of other glycosidases (Arnosti, 2000). These and other studies have shown that enzymes capable of degrading a variety of different polysaccharides are ubiquitous in seawater. Furthermore, genetic studies confirm the cosmopolitan existence of free bacteria capable of expressing many of these enzymes (e.g., Cottrell et al., 2000; Venter et al., 2004).

Despite the ubiquity of enzymes involved in polysaccharide and protein hydrolysis and the observed rapid degradation of model polymers, many biopolymers still accumulate in seawater. Can the chemical composition of semi-labile and refractory dissolved compounds provide insight into the extent to which these fractions of DOM have been transformed relative to labile biochemicals? Can chemical composition help identify processes responsible for these transformations? It has been suggested that the hydrolysis-yield of amino acids, normalized to the C content of the sample, serves as an index of organic matter diagenesis. Specifically, relative enrichments of glycine and alanine relative to distributions in phytoplankton, POM etc are expected to be indicative of highly degraded DOM (Amon et al., 2001; Dauwe et al., 1999; Yamashita and Tanoue, 2003). Various DOM fractions do appear to be enriched in glycine relative to phytoplankton and bacteria (see Fig. 3.5A) but no obvious vertical trend in amino acid yield or composition has been recorded. The absence of a vertical trend is consistent with the hypothesis that DOM and HMWDOM present at all depths in the water column has already undergone substantial degradation (Dauwe et al., 1999). However, since recoverable amino acids represent such a small fraction of total HMWDON, factors controlling amino acid production and preservation do not necessarily reflect those factors controlling the cycling of major HMWDON components.

Some laboratory degradation studies have shown the selective preservation of particular polysaccharides suggesting that certain structural features may render recently biosynthesized compounds unavailable for rapid bacterial utilization (Aluwihare and Repeta, 1999; Nanninga et al., 1996). Mechanistic studies imply that monomer composition, carbohydrate stereochemistry, linkage pattern, degree of cross polymerization and/or chemical substituents other than monosaccharides contribute significantly towards retarding the degradation rate of polysaccharides (e.g. Arnosti, 2000). A classic example is the degradation rate of starch versus cellulose (articles in Aubert et al., 1988). The monomer composition of these two

polysaccharides is identical (repeating units of glucose) but the β (vs α) stereochemistry about the glycosidic bond renders cellulose resistant to rapid bacterial degradation. This simple case expresses the importance of determining the absolute structure of intact molecules before a particular chemical characteristic of DOM can be applied as a degradation index.

In the case of refractory DOM, additional abiotic transformation processes resulting from chemical interactions are often considered (Degens, 1970; Harvey et al., 1983; Hedges, 1978; Ishiwatari, 1992). Like the Maillard reaction (see Fig. 3.12) these proposed transformations are expected to create bonds that are resistant to both biological and chemical hydrolysis; these processes have often been collectively referred to as humification. Hedges (1988) proposed that labile monomers (amino acids, sugars) could react through abiotic processes and form refractory organic matter. Ishiwatari (1992) proposed a similar mechanism by which the remnants of abundant biopolymers such as carbohydrates and proteins react to form refractory molecules. Alternatively, labile proteins may be physically protected from enzymatic attack by other cell wall materials (Nagata et al., 1998). Other physical processes may also be important for removing organic compounds from the dissolved phase. For example, the aggregation of dissolved compounds is thought to contribute to the formation of transparent exopolymer particles (TEP) and marine snow (Logan et al., 1995; Passow, 2002 and reference therein). Once formed, these particles can be exported from the surface ocean and so aggregation processes also represent a DOM sink. The carbohydrate composition of marine snow is very similar to the carbohydrate composition of HMWDOM (Mopper et al., 1995); and recently Engel et al. (2004) showed that up to 30% of the C in POM of an Emiliania huxleyi laboratory culture was derived from DOM. Staining with dyes such as Alcian Blue have shown the importance of charged functional groups in promoting the aggregation; and Chin et al. (1998) showed that carboxylic acid groups play a critical role in the spontaneous aggregation of natural DOM to form micrometer sized particles. Although aggregation processes could play an important role as a DOM sink few studies have examined whether/how DON is explicitly transferred to the particulate phase.

A number of studies have also examined the photochemical conversion of DOM into its inorganic components and into labile fragments that may then be rapidly utilized by bacteria (e.g. Benner and Biddanda, 1998; Kieber et al., 1989; Mopper et al., 1991; Moran et al., 2000). Mopper et al. (1991) suggested that 12–48% of the photochemically reactive DOC is degraded by sunlight during each ocean-mixing cycle. Based on this turnover rate the authors calculated a residence time of 1000–4000 years for the photoreactive fraction of DOM. A similar residence time for refractory DOM ($\sim$6000 years) has been estimated based on ^{14}C measurements (e.g., Druffel et al., 1992). Therefore, photodegradation could be the dominant removal process for refractory DOM.

Based on the above discussion, it is expected that chemical structure plays some role in controlling rates of DOM removal by biological and non-biological processes. For example, some studies have suggested that the glycosylation of proteins retard their bacterial degradation in seawater; other studies suggest that heteropolysaccharide structure and linkage patterns control dissolved polysaccharide

degradation rates in seawater; carboxylic acid functional groups appear to assist in transforming DOM to POM through their involvement in aggregation processes. However, few of these studies have quantified the relative incorporation of N into POM or refractory DOM. A firmer understanding of DOM structure will undoubtedly provide greater insights into processes controlling DOM preservation and accumulation in seawater.

5.3. Residence time of DOM components

Determining the chemical structure of refractory compounds is the definitive approach to understanding how and why compounds escape degradation and accumulate in the ocean on long timescales. However, refractory compounds must first be identified and we suggest that compound-specific Δ^{14}C measurement techniques must be developed and applied in DOM studies to identify semi-labile and refractory DOM components. For example, the refractory nature of the marine DOM reservoir was first conclusively demonstrated using Δ^{14}C measurements (Williams and Druffel, 1987).

Recent Δ^{14}C measurements have shown that HMWDOM is enriched in labile compounds relative to total DOM (Aluwihare et al., 2002; Loh et al., 2004; Repeta and Aluwihare, 2006). In fact, some of these studies have shown that polysaccharides (Aluwihare et al., 2002; Repeta and Aluwihare, 2006) and protein-like fractions (Loh et al., 2004) isolated from surface ocean HMWDOM have modern ^{14}C signatures—i.e., a Δ^{14}C signature that is within the range of values observed for the post-1950s DIC reservoir in the surface ocean (e.g., Williams and Druffel, 1987). In the case of polysaccharides, studies confirm that these compounds are probably synthesized and recycled on sub-decadal timescales in the surface ocean (Repeta and Aluwihare, 2006). Meador et al. (2007) found that dissolved proteins isolated from HWDOM at a site in the N. Atlantic Ocean had a Δ^{14}C value consistent with a sub-decadal residence time in the upper ocean. The modern radiocarbon content of carbohydrates and proteins suggests that these biochemicals are turning over on short timescales relative to an average residence time of 6000 years for total DOM in the deep ocean. However, more compound specific radiocarbon measurements are needed to conclusively establish the residence time of N-containing molecules.

Several studies have labeled various inorganic N pools and shown that labeled DON is released by phytoplankton during growth (Antia et al., 1991; Bronk, 2002 and references therein). However, the extent to which these processes contribute DON to the oceanic semi-labile reservoir is not well constrained. Stable N isotopes may be helpful in constraining the residence time of DON on short and perhaps even seasonal time scales. For example, δ^{15}N values of HMWDOM do not show large temporal or spatial variations although nitrate concentrations and δ^{15}N values of suspended PON at the same location are more variable, suggesting that the majority of DON is cycling on > annual timescales (Meador et al., 2007). Therefore, DON production measured during incubation studies probably represents a fraction that is rapidly recycled by mixotrophic and heterotrophic organisms and does not accumulate in seawater.

6. Summary and Future Direction

The preceding discussion on the chemical composition of DON in seawater demonstrates that bulk analytical methods (e.g., bulk stable isotope measurements, elemental analysis, ^{1}H-, ^{13}C-, and ^{15}N–NMR spectroscopy) have made significant progress in identifying and quantifying various components of this N reservoir. However, molecular-level investigations are required before definitive sources and sinks for these molecules can be identified in the marine environment. On the basis of amino acid analysis and monosaccharide analysis, proteins and amino sugars, which could contribute to the dominant amide functional groups as observed in HWMDOM by ^{15}N–NMR spectroscopy, have been shown to constitute only ∼15% of total DON. In the deep ocean as much as 70% of the N accumulate as amides that are resistant to common analytical methods (such as acid hydrolysis) and has so far escaped identification at the compound level. Our conclusion is that the methods employed in the study of HMWDOM structure—acid hydrolysis induced depolymerization followed by identification and quantification of monomers—is inadequate for making progress toward identifying the chemical composition of oceanic DON. Current hydrolysis methods (including acids such as TFA, HCl and H_2SO_4) likely induce cross-reactions and/or cannot effectively hydrolyze particular bonds present in DON. Therefore, we suggest that analytical approaches should focus on isolating individual components and intact molecules from DOM for further analysis. To date, ultrafiltration, which isolates only ∼25% of total DOM, seems to be the best method for concentrating N-rich compounds for this analysis. In addition, the application of tools routinely used in biomedical and immunological research (e.g., synthesis of antibodies, lectin affinity chromatography, proteomics) to study HMWDOM structure may provide the most useful insights into the DON cycle. Recent studies coupling gel electrophoresis, enzyme degradation, and mass spectrometry have identified intact proteins in HMWDOM, providing a window into what the future holds. The application of techniques used in molecular biology, such as enzymatic hydrolyses, may also help to deconvolute complex HMWDOM structures by producing identifiable and representative monomers and oligomers that are easier to quantify by common analytical methods such as HPLC. As always, structural investigations must strive to include as much of the DOM reservoir as possible and recent advances in DOM isolation methods combining reverse osmosis and electrodialysis (Mopper *et al.*, 2007) holds promise for isolating a major fraction of DOM. This will be most effectively achieved if we continue to develop sensitive analytical techniques such as mass spectrometry and methods involving fluorescent detection (such as antibody labeling).

Nitrogen Fixation in the Marine Environment

Edward J. Carpenter *and* Douglas G. Capone

Contents

1. Introduction

Tremendous progress has been made in the past several decades in the realm of marine nitrogen (N_2) fixation. The spectrum of organisms recognized to contribute to N_2 fixation in the sea has been greatly expanded, and there has been a virtual revolution

in our understanding of its quantitative significance, the interplay between N_2 fixation and the C cycle and the major controls on this process. The pace of discovery in this area has increased rapidly with the infusion of new geochemical and molecular approaches augmenting the traditional microbiological and physiological methods. Several recent reviews have summarized aspects of progress on marine N_2 fixation (Capone, 2001; Karl et al., 2002; Mahaffey et al., 2005). See Mahaffey et al. (2005) for a comprehensive synthesis. The purpose of this review will be to provide a current synopsis and update to recent developments.

Diazotrophic organisms are found across the tree of life (Fig. 4.1A and B), and marine representatives of clades I and III have been either isolated or identified as environmental clones (Table 4.1). Phylogenetic trees of diazotrophic sequences have been generated from nifH sequences and related genes (hetR, nifD, nifK) are very congruent with analyses based on 16s rRNA (Zehr et al., 2003; Raymond et al., 2004). See Zehr et al. (2003) for a comprehensive treatment of nitrogen fixer phylogeny including marine specific examples.

The earliest organisms identified as diazotrophic in the sea were heterotrophic bacteria grown on nitrogen (N)-free media or isolated into pure culture (see e.g., Capone, 1988; Guerinot and Colwell, 1985; Maruyama et al., 1970; Pshenen, 1963; Waksman et al., 1933). However, with the recognition that some heterocystous cyanobacteria were diazotrophic (Fogg, 1942), attention was largely focused for a time on marine representatives in various nearshore ecosystems (Fogg, 1978; Stewart, 1965; Wiebe et al., 1975). Generally, heterocystous cyanobacteria are largely distributed/ confined to fresh and brackish waters, and benthic environments. One exception are the heterocystous cyanobaterial symbionts (cyanobionts) of various open ocean diatoms.

In 1961, Dugdale et al. (1961) first reported that the planktonic non-heterocystous cyanobacterium Trichodesmium was also diazotrophic, an observation which was greeted with considerable skepticism at the time (e.g., Fogg, 1974). Trichodesmium had been studied by planktologists for decades (Wille, 1904) and was known to be cosmopolitan throughout the world's oligotrophic ocean (Carpenter, 1983a,b) and to form extensive blooms (Carpenter and Capone, 1992), but since it did not possess heterocysts and lived in an aerobic environment, it was initially thought by many that it was unlikely to be a diazotroph.

The development of a convenient field assay for N_2 fixation in the late 1960s (Stewart et al., 1967; Hardy et al., 1968) which was rapidly adapted for marine studies (see Capone 1983, 1993), led to a flurry of field efforts in a range of open ocean and shallow water and benthic marine environments. We will first summarize some of the recent advances and insights relative to N_2 fixation in benthic marine environments, move on to the water column, summarize the controls on N_2 fixation and comment on the broader, biogeochemical impacts of N_2 fixation.

2. BENTHIC NITROGEN FIXATION

Several reviews have previously summarized benthic N_2 fixation (Capone, 1983, 1988; Herbert, 1999; Howarth et al., 1988a,b). More recent research in marine benthic environments has focused on seagrass (see also Chapter 23 by

Bold lines indicate lineages with the nif operon. Dashed lines have nif homologues. Shaded major phyla indicated those containing diazotrophs. B. An unrooted tree of inferred amino acids of selected *nifH* sequences recreated with a *nifH* database courtesy of J.P. Zehr and based on Fig. 4.2 from Short *et al.*, 2004. Sequences and GenBank accession numbers, *nifH* group, and phylogenetic affiliation are provided for reference with results from 1000 bootstrap analyses using a Kimura correction. With the exception of *Phormidium* sp., the sequences highlighted in gray designate the most common open ocean diazotrophic phylotypes to date. Figure was courtesy of R.A. Foster.

McGlathery, this volume) and coral reef habitats (see Chapter 21 by O'Neil and Capone, this volume).

2.1. Deep sea sediments

Deep sea sediments are vast microbial habitats covering almost two thirds of the planet's surface and often with 100s of meters of accumulated sediment (D'Hondt *et al.*, 2004). Relative to near shore environments which are much more accessible,

deep sea sediments have only been preliminarily characterized microbiologically and with respect to their global biogeochemical importance. Recent culture-dependent approaches within the International Deep Ocean Drilling Program (IODP) have isolated a number of potential diazotrophic bacteria, including organisms closely related to *Rhizobia* and *Vibrio diazotrophicus* (based on 16S rRNA) (Biddle *et al.*, 2005) (Table 4.1). Diazotrophic bacteria have also been recently isolated from Mediterranean sapropels (Süß *et al.*, 2004).

2.2. Macrophyte communities

A variety of macrophyte communities, including seagrass, salt marsh and mangrove ecosystems, have been examined for the importance of N_2 fixation to plant nutrition and biogeochemistry, and much of the early findings have been summarized (Capone, 1983, 1988; Welsh, 2000) (See also Chapter 23 by McGlathery, this volume).

A comprehensive study of seagrass N_2 fixation was recently undertaken by Welch and his colleagues in meadows of *Zostera noltii* in the Bassion d'Arcachon. N_2 fixation represented an important input of nitrogen in this system contributing about 6–12% of the nitrogen requirement of the seagrass (Welsh *et al.*, 1996a,b,c). This is comparable to earlier reports for *Z. marina* (Capone, 1982).

Sulfate respiring bacteria (SRBs) were reported to be an important component of the diazotrophic flora of these systems based on both experimental studies. Using molybdate (MoO_4) inhibition, a specific inhibitor of sulfate reduction, (Oremland and Capone, 1988), severely reduced nitrogenase activity in rhizosphere sediment, and led to seasonal patterns of rhizosphere N_2 fixation and sulfate reduction. Similar observations with regard to the importance of SRBs to rhizosphere N_2 fixation have been made for sea grass communities of *Thalassia testudinum* (Capone *et al.*, 1977) and *Z. marina* (Capone, 1982; McGlathery *et al.*, 1998). Later studies determined that acetate was a major metabolite supporting nitrogenase activity, and an appreciable fraction (about 17%) of the energy derived from sulfate reduction supported N_2 fixation (Nielsen *et al.*, 2001; Welsh *et al.*, 1996a,b,c).

Controls on rhizosphere N_2 fixation appear to be a combination of organic substrate supply from the plant to support heterotrophs such as SRBs, balanced by the negative feedback of elevated ammonium concentrations in porewaters (Welsh *et al.*, 1997). For a salt marsh sediment with high ammonium concentrations, Capone and Carpenter (1982a,b) had earlier shown that removal of ammonium greatly stimulated nitrogenase activity. Interestingly, about 30% of the nitrogenase activity remained after addition of 1 mM NH_4Cl (Welsh *et al.*, 1997) which contrasted with the study of (McGlathery *et al.*, 1998) which found that N_2 fixation in the rhizosphere of *Z. marina* beds from a fjord in Denmark were not sensitive to ammonium additions.

Two recent studies have assessed the importance of nitrogenase activity associated with roots and rhizomes of seagrasses. Nielsen *et al.* (2001) reported that roots and rhizomes accounted for about 31% of rhizosphere N_2 fixation in *Z. nolti*, while they accounted for 91% of the activity in *Spartina maritima*. McGlathery *et al.* (1998) found that in *Z. marina*, about 39% of depth-integrated N_2 fixation was associated

with roots with only 4% associated with rhizomes, and the root–rhizome activity could account for about 65% of the total plant N demand.

The overall importance of N_2 fixation to seagrasses has been evaluated recently in a few studies employing a $\delta^{15}N$ stable isotope approach. Relatively low $\delta^{15}N$ values for seagrass tissue ranging from 1.1 to 2.2 per mil (with individual samples as low as –1.2 per mil) have been reported by Anderson and Fourqurean (2003) for Florida Bay. Similarly low $\delta^{15}N$ values were reported for several species of seagrass from various tropical sites in the western Pacific (Yamamuro *et al.*, 2003) and for *Posidonia oceanica* at several sites in the northwest Mediterranean. These observed low $\delta^{15}N$ values provide independent evidence that a substantial input by N_2 fixation does occur in seagrass communities.

2.2.1. Molecular ecology

Molecular approaches have been extremely effective in discerning the identity and dynamics of N_2 fixer activity in marine sediments and macrophyte communities (Table 4.1) (also see Chapter 30 by Jenkins and Zehr, this volume). Kirshtein *et al.* (1991) isolated and characterized the *nifH* sequence from 2 *Klebsiella* sp. isolates obtained from the roots of the seagrass *Ruppia marina*, and subsequently obtained *nifH* sequences from another seagrass, *Halodule wrightii*, which had greatest sequence similarity to *Clostridium pasteurianum*. Burns *et al.* (2002) obtained and compared *nifH* sequences from the sediments of the Chesapeake Bay and Neuse River, finding sharp differences between the sites. The Chesapeake Bay sequences clustered with each other and showed similarity to several anaerobic clades (e.g., related to *nifH* sequences from species of *Desulfobacter, Cholorobium* and *Acetobacterium*), while the sequences derived from Neuse River samples were highly divergent. As noted above, much of the diazotrophy in seagrass sediments is associated with SRBs. In this regard, (Smith *et al.*, 2004) using the dissimilatory bisulfite reductase (dsrA and B), found very high diversity and largely unknown identities (and therefore physiologies) of sulfate respiring bacteria in a *Thalassia testudinum* seagrass bed.

Lovell and colleagues have undertaken perhaps the most comprehensive study of the physiological and molecular ecology of N_2 fixation in a marine macrophyte community. Initial studies isolated hundreds of diazotrophic strains from the salt marsh rhizosphere and subjected them to physiological characterization. They found representative species of the *Enterobacter, Vibrio, Azotobacter, Spirilla, Pseudomonas* and *Rhizobia*, as well as numerous unknown clone sequences using *nifH* primers (Bagwell *et al.*, 1998) (Table 4.1). Piceno *et al.* (1999) compared the activity and diversity (using a *nifH* fingerprinting approach) of diazotrophs in tall and short *Spartina alterniflora* stands, finding that while nitrogenase activity differed between and within these communities, there was a relatively high stability in the composition of the diazotrophic flora both spatially and temporally. Perturbations with short term nutrient additions (Piceno and Lovell, 2000) and clipping or shading plots to reduce plant organic input to the sediments, also resulted in relatively insignificant shifts in nitrogenase activity and diazotroph composition, reinforcing the considerable short-term stability of these assemblages. While rhizoplane diazotrophs were

responsive to longer term fertilization studies with respect to their activity and relative occurrence of phylotypes, none were fully displaced by the experimental treatment, thereby indicating their resilience, perhaps through niche specialization (Bagwell and Lovell, 2000a,b). Sequencing partial fragments of the *nifH* gene from the rhizoplane, revealed three major clusters: a large clade composed of sequences with high identity to γ-proteobacteria, and many unknown sequences, a second group composed of sequences similar to α-, β- and γ- proteobacteria and a third cluster of sequences derived from anaerobic bacteria and more unknown phylotypes (Lovell *et al.*, 2000). Most recently, (Brown *et al.*, 2003) demonstrated that many of the organisms they have implicated as diazotrophs through culture-dependent and culture independent techniques do in fact express *nifH* mRNA in the *S. alterniflora* rhizosphere.

Several studies have compared diazotrophic assemblages from *S. alterniflora* with other salt marsh plants including *Juncus roemerianus* (Bagwell and Lovell, 2000a,b) and *Spartina patens* (Bergholz *et al.*, 2001). Bagwell and Lovell (2000a,b) used whole genome hybridization and substrate utilization patterns to differentiate among 50 isolates determined to be diazotrophic by the presence of *nifH*. Interestingly, They found that strains that were phylogenetically related could be physiologically diverse in their metabolism, while phylogenetically diverse strains often displayed similar substrate utilization patterns, providing support for functional redundancy in these systems. Sequences derived from isolates of *S. patens* (Bergholz *et al.*, 2001) form two major clades, the isolates were largely microaerophilic, and except for 1 strain, were physiologically distinct from the isolates from the other two grasses. Surveys of rhizosphere diazotrophs from two tropical seagrass beds yielded sequences most similar to anaerobes, with some sequence identity to β- and γ-proteobacteria and showed some similarity to the communities in *S. alterniflora* communities (Bagwell *et al.*, 2002).

2.3. Microbial mats

Microbial mats have been a longstanding focus of N_2 fixation studies (Paerl *et al.*, 1996, 2000) (Table 4.1). Most recently, applied molecular approaches have revealed much more information about these systems. Zehr *et al.* (1995) examined a microbial mat from an intertidal mat from coastal North Carolina and found a wide variety of diazotrophic bacteria were present, with the majority of sequences related to *nifH* sequences of anaerobes (sulfate reducers and *Clostridia*), particularly deeper in the mat.

Using MoO_4 inhibition (see above), Steppe and Paerl (2002) showed that SRBs could account for the majority of the dark activity, but that MoO_4 had little effect during the day, suggesting a predominance of phototrophic-based activity. Reverse transcription (RT)-PCR with *nifH* revealed transcripts from diverse anerobes including SRBs. In this same system, Steppe *et al.* (2001) have also recently reported on the diel patterns of both nitrogenase activity and *nifH* gene expression, and responses to the specific photosynthetic inhibitor dichorophenyl-dimethyl urea (DCMU) and the protein synthesis inhibitor chloramphenicol.

Their studies revealed a diverse assemblage of diazotrophs contribute distinct diel patterns that vary over the seasonal cycle depending on the exact composition of the diazotrophic assemblage.

Moisander *et al.* (2005) developed a *nifH* microarray with 96 oligonucleotide probes with broad representation of the major clades of diazotrophs. They examined mat community in Guerrero Negro (GN), Baja California, portions of which had been fertilized. Fertilized plots, although showing no *nifH* expression, had higher diversity than the unfertilized plots.

Steppe *et al.* (2001) have also examined modern stromatolites, laminated sedimentary structures with associated microbial populations similar to microbial mats, finding a temporal separation of photosynthesis and nitrogenase activity. *NifH* sequences of diverse cyanobacteria, α & δ proteobacteria were recovered.

2.4. Coral reefs and associated habitats

Coral reefs have been long recognized as active sites of N_2 fixation (Wiebe *et al.*, 1975) (see also Chapter 21 by O'Neil and Capone, this volume). Earlier results that indicated the importance of N_2 fixation in these environments were previously summarized by Capone (1996, 1988). More recent findings have confirmed these studies in a broader range of locations and with newer techniques.

Coral reef sediments are sites of N_2 fixation (O'Neil and Capone, 1989), and can account for a substantial fraction of N flow in the organic poor carbonate sediments surrounding reefs (Capone *et al.*, 1992). Results from the Red Sea found high rates of nitrogenase activity in substrates such as coral rubble and carbonate sands (Shashar *et al.*, 1994a,b), consistent with earlier reports from the Great Barrier Reef (Capone *et al.*, 1992; Crossland and Barnes, 1976; O'Neil and Capone, 1989). Carbonate sands accounted for more than 70% of the overall activity on the reef. Lower rates were associated with macroalgae and living corals. Activity that was associated with living corals appeared to be associated with bacteria as it was stimulated by glucose (Shashar *et al.*, 1994a,b). Charpy-Roubaud *et al.* (2001) examined nitrogenase activity associated with lagoon sediments, cyanobacterial mats and limestone surfaces in Tikehau Lagoon, French Polynesia. Activity was greater in the light than dark, apparently due to the presence of cyanobacteria in each of these substrata. Rates associated with the sediments ranged between 30 and 280 µmol N m^{-2} day^{-1} and were about 140 µmol N m^{-2} day^{-1}. N_2 fixation in the lagoon benthos could account for about 25% of the N demand of benthic primary production. A subsequent study examined the reef rim and found similarly high areal rates largely associated with cyanobacterial mat communities and accounting for an average of 332 µmol N m^{-2} day^{-1} of new N input, or roughly 28% of total N_2 fixation in the entire lagoon (Charpy-Roubaud and Larkum, 2005).

Yamamuro *et al.* (1995) were the first to use a ^{15}N–natural abundance approach in a coral reef environment, surveying various components of the ecosystem and concluded that much of the nitrogen demand on the reef is met by N_2 fixation.

France *et al.* (1998) surveyed benthic macroalgae in the reef environments of Puerto Rico, comparing them to macroalgal samples from the northeast coast of the U.S. and freshwater environments, finding further support for the notion that N_2 fixation is associated with macroalgal–cyanobacterial consortia on the reef.

Rohwer *et al.* (2002) initiated studies of the bacterial flora associated with corals, and has identified 16s rRNA sequences from potentially diazotrophic taxa (e.g., *Rhodobacter, Vibrio, Clostridium*). Specific studies examining the molecular ecology of N_2 fixation in reef communities remain to be undertaken. Hewson and Fuhrman (2006) have directly examined the diversity of diazotrophs, first using a rapid DNA fingerprinting approach, and more recently by culture independent approaches including development of clonal libraries, and direct amplification of *nifH* DNA and mRNA. Phylotypes of both oceanic cyanobacteria as well as cyanobacteria and proteobacteria of both groups I & III (Fig. 4.1), presumptively indigenous to the reef environment, were identified.

With regard to other diazotrophic symbioses on reefs, Paerl (1984) reported evidence for nitrogenase activity associated with an intact *Procholoron*-Ascidian association (*Lissoclinum* sp.). However, activity could not be directly associated with the isolated symbiont. Later, Odintsov (1991) provided evidence that the nitrogenase activity associated with encrusting ascidians was in fact not associated with the symbiont. More recently, Kline and Lewin (1999) concluded that, based on the low isotopic ratio of $^{15}N/^{14}N$ in *Lissoclinum* sp. associations, at least a portion of the cellular N may be derived (directly or indirectly) from N_2 fixation.

An important recent observation was the presence of putatively diazotrophic coccoid cyanobacteria in the tissues of certain *Montastrea* corals (Lesser *et al.*, 2004). In this initial study, immunological evidence indicated the presence of nitrogenase enzyme. Subsequent research has directly determined nitrogenase activity and reported low isotopic ratios of $^{15}N/^{14}N$ in zooxanthellae from orange pigmented corals containing the cyanobacterial symbiont (Lesser *et al.*, 2007). Further research is needed to quantify the importance of these organisms in introducing new N to coral reef ecosystems.

2.5. Directions in benthic nitrogen fixation

While progress has clearly been made in understanding the process of N_2 fixation in a range of benthic environments, research in this area has not been nearly as intensive as in water column systems (see below). Nonetheless, we now know that SRBs appear to be very important components of the diazotrophic flora of seagrass, salt marsh and mat communities. However, their physiology remains unclear and more remains to be done in defining the composition and dynamics of diazotrophs in such environments.

Given the preliminary geochemical and microbiological evidence for a potential role for N_2 fixation in both hot vent and cool seep environments, these are clearly systems requiring closer scrutiny with regard to the ecological importance of this process. Similarly, for coral reefs where the quantitative importance of N_2 fixation is not debated, we have only begun to scratch the surface with regard to the identity and diversity of diazotrophic populations.

3. PELAGIC NITROGEN FIXATION

3.1. Pelagic diazotrophs

In the open ocean, N_2 fixation research has focused most intensively on the cyanobacterium, *Trichodesmium* (Carpenter, 1973; Saino, 1977). Much of the earlier work has been summarized by Carpenter (1983a,b), Howarth *et al.* (1988a,b) and more recently by Karl *et al.* (2002). In its colonial form, or as surface slicks, *Trichodesmium* is obvious and relatively easy to collect by bucket or plankton tow. There are at least five species of *Trichodesmium* extant (Janson *et al.*, 1995), and samples of the five species from the Atlantic and Pacific Oceans and Caribbean Sea can be separated into three clades on the basis of 16S rDNA and *het*R sequences (Janson *et al.*, 1999a,b) (Table 4.1). One clade contains *T. hildebrandtii* and *T. thiebautii*, the second consists of *T. contortum* and *T. tenue*, and the third has *T. erythraeum*. A second recent study on *Trichodesmium* diversity was carried out by Orcutt *et al.* (2002), and three different genetic techniques were used on samples from the Sargasso Sea and Indian Ocean. These investigators reported that *T. thiebautii, T. hildebrandtii, T. tenue* and the non–heterocystous *Katagnymene spiralis* displayed remarkable similarity based on three independent analyses (i.e., DNA fingerprinting of a highly iterated palindrome, intergenic spacer analysis and DGGE of a hetR fragment). The largest genetic variation was found between *T. erythraeum* and all other species of *Trichodesmium. Katagnymene* has long been recognized in the tropical ocean plankton (Wille, 1904); however, it was only recently that its diazotrophic nature was confirmed (Lundgren *et al.*, 2001). More detailed analysis by Lundgren *et al.* (2005) has further shown that despite the morphological differences of *K. spiralis and K. pelagica,* based on *hetR* and partial 16sRNA sequences, they are a common species, and fall directly within the *Trichodesmium* cluster.

Early reports also described N_2 fixation in the pelagic zone associated with the cyanobacterial epiphytes *(Dichothrix fucicola)* of the brown macroalga, *Sargassum* (Carpenter, 1972) and cyanobacterial endosymbionts of certain oceanic diatoms (Mague *et al.*, 1977; Villareal, 1994). The diazotrophic cyanobacterial endosymbiont *Richelia intracellularis* is found in several species of diatoms within the genera *Rhizosolenia* and *Hemiaulus* (Villareal, 1992). Unlike *Trichodesmium*, this cyanobacterium has a single, terminal heterocyst. Genetic analysis (*het*R) of *R. intracellularis* samples from these diatom genera plus a similar appearing cyanobacterium, *Calothrix rhizosoleniae,* which is an epiphyte on several species in the diatom genera *Chaetoceros* and *Bacteriastrum*, revealed that they all belong to the same clade but diverge into separate lineages (Janson *et al.*, 1999a,b). Similarly, Foster and Zehr (2006) recently concluded the cyanobionts associated with *H. hauckii, R. clevei*, and *C. compressum* were distinct strains based on analysis of their *hetR* and *nifH* sequences. The *nifH* lineages derived from the symbionts of *Rhizosolenia, Hemiaulus*, and *Chaetoceros,* have been designated as het–1, het–2, het–3, respectively; and there is some evidence for a further delineation of the het–2 group into het–2A and het–2B (see Foster and Zehr, 2006). The same three cyanobiont lineages were however, highly similar (>98%) based on their 16 S rRNA sequences (Foster and Zehr, 2006).

Some unicellular coccoid cyanobacteria in the plankton of the subtropical North Pacific have now been shown to express *nifH* and are capable of N$_2$ fixation Ocean (Zehr *et al.*, 1998, 2001; Montoya *et al.*, 2004), (see Chapter 30 by Jenkins and Zehr, this volume). Closely related cyanobacteria have also been observed in the tropical Atlantic Ocean (Falcon *et al.*, 2002). These cyanobacteria, approximately 3–10 mm in diameter, are larger than the abundant picoplankter *Synechococcus*, and two clades are currently recognized (Zehr *et al.*, 1998). Group A have distant phylogenetic affinities with *Cyanothece*, and group B are most similar to *Crocosphaera watsonii* WH8501 while a recently observed Group C has close phylogentic affinities to *Cyanothece* (Langlois *et al.*, 2005; Foster *et al.*, 2007) (Table 4.1).

Diatom/*Richelia intracellularis* associations can be spatially extensive and contribute intensive input of N through N$_2$ fixation in the upper water column. For instance, a *Hemiaulus hauckii*/*Richelia* bloom encountered by Carpenter *et al.* (1999) off the northeast coast of South America in Oct 1996 was observed over a linear cruise track of 2500 km and accounted for very substantial levels of N$_2$ fixation (see below). The symbionts for individual diatoms such as *Hemiaulus* and *Rhizosolenia* while morphologically similar are genetically distinct and discrete probes for each association have been developed and applied in the Amazon River plume to enumerate the relative densites of these two associations (Foster *et al.*, 2007).

Novel groups are continuing to be uncovered. Foster *et al.* (2006) also reported that some coccoid cyanobacteria living symbiotically with dinoflagellates might possess nitrogenase and that some symbionts posess 16S rRNA sequences most similar to other known diazotrophs (i.e., *Cyanothece* sp.).

Coccoid cyanobacterial endosymbionts within the planktonic diatom *Climacodium frauenfeldianum* are potential planktonic N$_2$ fixers (Carpenter and Janson, 2000). (see also Chapter 27, Foster and O'Mullin, this volume). These symbionts have 16S rRNA sequences most closely related to the coccoid diazotroph *Cyanothece*, and likely fix N$_2$ at night within the host diatom. Using a coupled immunocytochemistry-TEM approach, a symbiotically associated *C. frauenfeldianum* was collected and preserved at night. The symbionts of the *C. frauenfeldianum* were coccoid in morphology, had cell diameters approximately 5–7 μm, possessed large glycogen stores, and localized both nitrogenase and phycoerythrin antiseras (Foster, unpubl.). One filamentous heterocystous cyanobacterium, *Anabaena gerdii*, has been collected within the plankton of the South Pacific Ocean and Arabian Sea (Carpenter and Janson, 2001), but concentrations of *A. gerdii* and *C. frauenfeldianum* are low, and it is doubtful that they are important in a global sense in N$_2$ fixation.

NifH gene diversity studies reported a significant fraction of *nifH* sequences clustered with proteobacteria rather than cyanobacteria, thus suggesting that components of this clade also are involved with N$_2$ fixation (Falcón *et al.*, 2004; Langlois *et al.*, 2005; Zehr *et al.*, 2001) (Table 4.1). Bird *et al.* (2004) examined the distribution of an uncultured diazotrophic γ-proteobacteria most closely related to *Vibrio natriegens* and *Azotobacter vinelandii* in the Arabian Sea. While they found it most

commonly amplified and expressing transcript in warm, near surface waters, they also observed active samples from below the nutricline expressing nitrogenase. (Church *et al.*, 2005) determined the abundance of Cluster III *nifH* copies in DNA in the oligotrophic North Pacific using qPCR. Langlois *et al.* (2005) also found Cluster III and proteobacterial *nifH* sequences to be abundant in the tropical Atlantic Ocean. Interestingly, Hewson *et al.* (2007), using both amplification and cloning of *nifH* sequences as well as a micro-array approach, have reported the presence of *nifH* sequences closely related to non-cyanobacterial diazotrophs, including α, β & γ proteobacteria, derived from samples obtained below the euphotic zone from the north Atlantic and northeast Pacific. The physiology and metabolism of these diazotrophic proteobacteria remains to be determined and could potentially include heterotrophs, methylotrophs, chemotrophs, and potentially some types of phototrophs (Kolber *et al.*, 2000; Beja *et al.*, 2001). Resolving the contribution of different physiological groups to N_2 fixation will be a challenge, but could be significant since nitrogenase activity could potentially take place through the entire diel period rather than just at night and, also possibly, deeper in the water column.

Diverse N_2 fixers have been detected in the water column of temperate estuaries such as the Chesapeake Bay (Affourtit *et al.*, 2001) (Table 4.1). Affourtit *et al.* (2001) found a variety of diazotrophs from Cluster I (which includes cyanobacteria and most proteobacteria) with rarer samples yielding Cluster II (some δ-proteobacteria, spirochaetes and some Archaea, some alternative nitrogenases) and III (firmicutes, spirochaetes and Archaea) in samples from the Neuse River. Short *et al.* (2004) reported the densities of two representative *nifH* sequences in the Chesapeake Bay using a quantitative PCR approach, and they detected specific seasonal and spatial patterns for each. Interestingly, expression of *nifH* was never detected.

Other unique sites of N_2 fixation remain to be discovered. Dense populations of Archaea are also found throughout the water column of the worlds' oceans (DeLong, 1992; Fuhrman *et al.*, 1992), and some methanogens have the capacity for diazotrophy (Murray and Zinder, 1984). Indeed, diazotrophic archaeal *nifH* sequences have been obtained from a marine vent community and in deep sea waters away from vents (Mehta *et al.*, 2003, 2005). They also obtained an isolate capable of growth and N_2 fixation up to 92°C (Mehta and Baross, 2006). N_2 fixing bacteria, including purple sulfur bacteria, are also associated with the intestinal flora of zooplankton (Braun *et al.*, 1999; Proctor, 1997).

Attention has also been lately focused on Oxygen Minimum Zones (OMZs) as sites for a recently discovered pathway in the nitrogen cycle, the Anammox reaction (Kuypers *et al.*, 2005) (see Chapter 6 by Devol, this volume). OMZs feature both low oxygen and combined nitrogen concentrations through denitrification and anammox and relatively low N:P ratios, characteristics which would make them suitable habitats for some groups of diazotrophs. Furthermore, recent geochemical evidence suggests that OMZs may also promote conditions that foster N_2 fixation in surface waters affected by the OMZs (Sigman *et al.*, 2005; White *et al.*, 2007, see below). The recent global analysis by Deutsch *et al.* (2007) examining the decrease in excess P (expressed as P★) in waters upwelled from OMZ areas and advected offshore provides strong supporting evidence for this (Capone and Knapp, 2007).

3.2. What happens to all that fixed nitrogen?

We still lack a good understanding of pathways of fixed N from marine diazotrophs to other members of the marine plankton. However, there is plenty of evidence that newly fixed N is utilized by other members of the plankton community. From the distribution of N⋆ anomalies in the range of 10°N–40°N in the N. Atlantic Ocean, it is strongly suggested that much of the nitrate in near-surface water originated through diazotrophy (Gruber and Sarmiento, 1997; c.f. Hansell et al., 2004). Furthermore, the low δ^{15}N of zooplankton in broad areas of the tropical Atlantic Ocean clearly originates from either the direct or indirect consumption of nitrogen originating from diazotrophs (Montoya et al., 2002). The magnitude of this signal indicates that N$_2$ fixation is a major source of "new" N in this area.

During an extended station in a Trichodesmium bloom in the Indian Ocean, sediment trap material from that station clearly reflected diazotrophic input, compared to stations away from the bloom (Capone et al., 1998). Another example was observed during the massive bloom of R. intracellularis within H. hauckii off the NE coast of South America (Carpenter et al., 1999). Suspended particles and zooplankton collected within the bloom were depleted in ^{15}N, reflecting the dominant contribution of N$_2$ fixation to the planktonic N budget.

There are multiple pathways for newly fixed N to be taken up by non-diazotrophs. Importantly, the fate of recently fixed N may be quite distinct among the various potential agents of N$_2$ fixation. Whereas Trichodesmium is not readily grazed by planktonic copepods (O'Neil and Roman, 1992) and much of its recently fixed N may enter food webs as DON after exudation (Capone et al., 1994; Glibert and Bronk, 1994) or lysis. Coccoid cyanobacteria and heterotrophic bacteria are directly grazed by protists (Caron et al., 1991). Recent research has shown the existence of specific viruses which lyse Trichodesmium (Hewson et al., 2004), and conservative calculations suggest that in samples collected near Hawaii, 0.3–6.5% day^{-1} of trichomes could potentially be lysed, and this represents 3–64% fixed N day^{-1}. Yet a third fate may be autocatalytic programmed cell death (PCD) which can be induced by a number of stressors such as iron or phosphorus starvation, high irradiance and oxidative stress (Berman-Frank et al., 2004).

Whereas Trichodesmium is buoyant and resides largely in the upper layers of the water column, endosymbiotic Richelia may be more prone to gravitational settlement to deeper layers in their diatom hosts (Scharek et al., 1999a,b; Subramaniam et al., 2008) (Fig. 4.2). Tropical river plumes may be particularly important sites of diazotroph-diatom associations (Voss et al., 2006; Subramaniam et al., 2008).

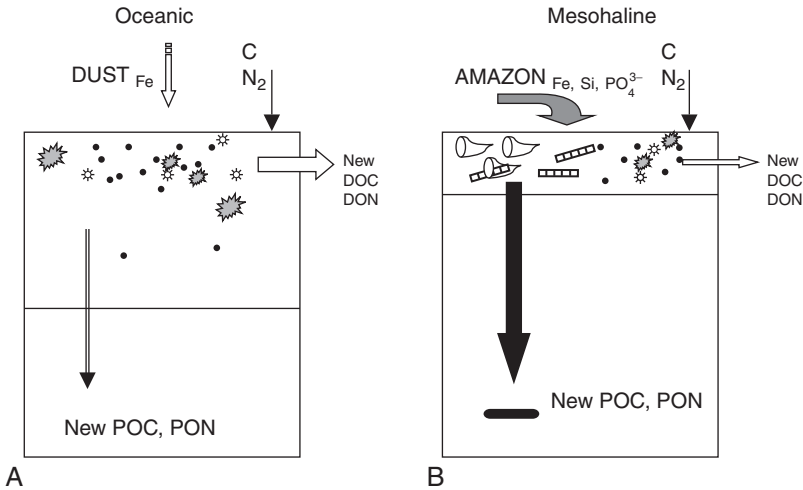
The microbial and metazoan community associated with Trichodesmium is rich, and in a study conducted near Bermuda, 85% of the Trichodesmium colonies examined harbored associated organisms (Sherman et al., 2002). These included bacteria, fungi, diatoms, dinoflagellates, chrysophytes, ciliates, amoebae, hydroids, copepods and juvenile decapods. One organism thought to be involved in N transfer is the harpactacoid copepod Macrosetella gracilis. This copepod uses the Trichodesmium colonies as a physical substrate for juveniles and adults, but also as a food source (Roman, 1978; O'Neil, 1998). Both O'Neil and Roman carried out studies on feeding of M. gracilis on Trichodesmium, and the results indicated that it was a


Figure 4.2 Conceptual model for differing fates of filamentous cyanobacterial diazotrophs (A) compared to diatom–diazotroph associations (B), from Subramaniam *et al.*, 2008.

voracious consumer. Roman (1978) found that adults could ingest from 90–126% of its body carbon per day when feeding on *Trichodesmium*. However, Eberl and Carpenter (2007), working in the Central North Pacific, found no significant correlation between *M. gracilis* and *Trichodesmium* population distributions. Further-more, natural abundance of stable isotopes of N and C suggested that the diet of *M. gracilis* was not predominately composed of *Trichodesmium*.

Trichodesmium is fed upon directly by larger nekton. Bryceson (1980) introduced juvenile clupeid fish into aquaria containing *T. erythraeum* from coastal waters of Tanzania, and the cyanobacterium was eaten rapidly. In the Indian Ocean, it has been observed to be eaten by two young fish species *Sardinella gibbosa* and *Mugil waigiensis* (Devanesan, 1942; Devanesan and Chidambaram, 1948), and there are data indicating that 60–90% of the diet of two other fish species, *Hilsa kanagurta* and *Rastrelliger kanagurta* consists of *T. erythraeum* (Ramamurthy, 1970).

We suggest that salps and perhaps other jellies are major consumers of *Trichodes-mium*. This very weakly supported supposition is primarily based on plankton net contents on numerous tropical cruises in which we observed that when *Trichodes-mium* is abundant, there are few salps, and when salps are abundant, the concentra-tions of *Trichodesmium* are almost nonexistent. In the western Pacific Ocean, Nemoto (1975) noted the possible feeding of *Salpa fusiformis* and *Weelia cylindrical* on *Trichodesmium*. In the Atlantic, Montoya *et al.* (1992) analyzed 37 *Salpa aspera* samples and obtained a mean δ^{15}N of *ca.* 4 per mil, values that were lower than other particulate material collected in the same area. The low values suggest that these salps had a diet that may have partially consisted of diazotrophs.

3.3. Directions in pelagic nitrogen fixation

The infusion into the field of innovative approaches is revolutionizing our under-standing of this process in the world's oceans. Sensitive new direct tracer methods of quantifying N_2 fixation and improvements in mass spectrometry in parallel

with modern molecular genetic approaches has catalyzed the current avalanche of new information. Molecular methods continue to improve and the advent of means to reliably and rapidly identify diazotrophs, quantifying their abundance (using qPCR) as well their physiological state with respect to nitrogenase gene expression using RT-PCR will continue to promote advances in the field. Similarly, new analytical approaches, the addition of moored systems with molecular biological capabilities provide the prospect for high density data streams which will allow detailed monitoring of the population dynamics of diazotrophs.

4. WHAT LIMITS NITROGEN FIXATION

Numerous factors, physical, chemical and biotic, can affect the extent of N_2 fixation in an ecosystem (Capone, 1988; Howarth *et al.*, 1988a,b; Karl *et al.*, 2002). Many factors which bear on nitrogenase activity are interdependent such as light, temperature, oxygen and turbulence. Indeed, a variety of different factors may limit the growth and activity of diazotrophs in various areas of the world's oceans at different times of the year.

4.1. Temperature

One key factor for tropical diazotrophs may be water temperature. For example, the distribution of *Trichodesmium* spp. is roughly limited by the 20°C isotherm, and other planktonic cyanobacteria are likewise primarily tropical or subtropical in distribution. Metabolically active populations of *Trichodesmium* have been observed at 18.3°C in the North Atlantic (McCarthy and Carpenter, 1979), but activity was low, and substantial growth is typically not seen until water temperature exceeds 20°C (Carpenter, 1983a,b). Moreover, water temperature co-varies inversely with surface nutrient concentrations (Kamykowski and Zentara, 1986). Indeed, in previous studies we have used sea surface temperature as a proxy for oligotrophic waters in order to estimate the areal range of *Trichodesmium* (Capone *et al.*, 2005).

Low, but measurable N_2 fixation rates were recently reported by Needoba *et al.* (2007), from the inter-convergence zone, 200 km off the coast of Northern California, where sea surface temperatures were >19°C. In addition, they reported the temporal dynamics of mRNA abundance for *nifH* down to 80 m, where temperatures ranged 14–19°C, and expression was dominated by a unicellular Group A phylotype, and to a lesser extent by Group B. Similarly, Holl *et al.* (2007) reported N_2 fixation in the upper water column of warm core and cold core eddies at temperatures at or below 19C in the Leeuwin Current off the west coast of Australia.

As for most enzyme mediated reactions, increases in temperature often increase activity in a characteristic fashion. The response of an enzyme to temperature increases, often evaluated as the Q_{10} parameter (i.e., the increase in activity over a 10°C range), varies among and within enzyme systems and can show compensation. Staal *et al.* (2003) have evaluated Q_{10} responses for N_2 fixation on short time scales in a range of cyanobacteria including *Trichodesmium*, which exhibited a Q_{10} of 1.12 for dark N_2 fixation over the temperature range of 20–35°C, and a much

higher value of 2.06 over the range 15–20°C. Light N_2 fixation showed less variation over the 2 temperature ranges at 1.64 for 15–20°C and 1.84 for 20–35°C.

In contrast to the tropics, high latitude (>50° latitude) marine waters are generally characterized by low temperatures and higher nutrient concentrations, and there is little evidence of marine diazotrophy in the water column of these systems. However, it should be recognized that low temperature does not intrinsically restrict nitrogenase activity, which has been observed at temperatures near 0°C in terrestrial environments (Englund and Meyerson, 1974; Fogg and Stewart, 1968; Vincent, 2000). One other exception to this generalization is the Baltic Sea which experiences extensive blooms of diazotrophic cyanobacterial blooms (*Aphanazominon, Nostoc* and *Nodularia*) during the summer when surface temperatures are warmest and water column stability greatest (Finni *et al.*, 2001; Wasmund *et al.*, 1998).

4.2. Light

For photoautrophic diazotrophs, nitrogenase activity is intimately linked to photosynthesis (Gallon, 2001). Thus, light is an obvious and important factor potentially regulating or constraining this process. The general influence of light on photoautrophic processes in the sea is covered comprehensively elsewhere (Falkowski and Raven, 1997; Kirk, 1995). There are potential interactions of light with other physical and chemical factors in the ocean such as water column stability and turbulence (Howarth *et al.*, 1995a,b), depth, particle density and the concentration of dissolved organic matter, all of which can affect the quantity and quality of the light field and in turn the activity of photosynthetic diazotrophs. Amongst the photoautotrophic diazotrophs, cyanobacteria have received the most attention and in marine systems this has largely been focused on *Trichodesmium* spp. in the open ocean and in cyanobacteria in shallow mat communities.

Carpenter (1983a,b) has summarized much of the early marine work largely relating to *Trichodesmium* spp. with respect to their relationship to light. Whereas many non-heterocystous cyanobacteria fix nitrogen during the night, and thereby uncouple N_2 fixation from photosynthesis (although photosynthesis is the ultimate source for energy and reductant for even these obligate autotrophic organisms, Gallon and Stall, 1992), *Trichodesmium* fixes nitrogen exclusively during the light period and shows a strong diel pattern of activity with maxima during midday (Berman-Frank *et al.*, 2001a,b; Capone *et al.*, 1990; Saino and Hattori, 1978). Indeed, an endogenous rhythm, rare in prokaryotes, underlies this pattern (Chen *et al.*, 1998). Mechanisms by which this happens have been proposed and are debated (see next section on Oxygen).

Natural populations of *Trichodesmium* which are often found in the upper layers of the euphotic zone (see Chapter 16 by Karl *et al.*, this volume), appear to be adapted to high light with a relatively shallow compensation depth (typically 100–200 μmol quanta m^{-2} s^{-1}) for photosynthesis (Carpenter, 1983a,b; LaRoche and Breitbarth, 2005). Several early studies considered the light–photosynthesis relationships of *Trichodesmium* (e.g., Lewis *et al.*, 1988; Li *et al.*, 1980). Half saturation (I_k) constants for photosynthesis are reported to be about 300 μmol quanta m^{-2} s^{-1} (based on results from four studies, LaRoche and Breitbarth, 2005). See LaRoche and Breitbarth (2005) for a recent comprehensive summary of observed physiological and photosynthetic parameters for *Trichodesmium*.

While several studies have reported photosynthetic parameters for *Trichodesmium*, there have been far fewer studies which have considered the relationship of light and N_2 fixation. N_2 fixation has recently been incorporated as an explicit feature of many ecosystems models (e.g., Fennel *et al.*, 2002; Hood *et al.*, 2001, 2004; Moore *et al.*, 2002, see also Chapter 33 by Hood and Christian, this volume). This has required parameterization of N_2 fixation and that has been done most often using an approach similar to that for photosynthesis. This involves representation of the relationship between light and N_2 fixation (assuming this is largely a photoautotrophic associated process). Hood *et al.* (2002) modeled the photosynthetic parameters, P_{max} and alpha, for field data from a series of stations in the tropical N. Atlantic; the model empirically examined the effect of light intensity on N_2 fixation by *Trichodesmium* (original data reported in Capone *et al.*, 2005). Values for alpha ranged from about 4 to 26 μmol N (mg chl a)$^{-1}$ (μmol quanta m^{-2} s^{-1})$^{-1}$ with a mean of about 11 μmol N (mg chl a)$^{-1}$ (μmol quanta m^{-2} sec^{-1})$^{-1}$. The data suggested a potential for photoinhibition at about 1200 μmol quanta m^{-2} s^{-1}.

Two recent studies have directly examined the effect of light on N_2 fixation in *Trichodesmium*. Breitbarth et al. (submitted) found diazotrophic growth in axenic cultures of *Trichodesmium* IMS 101 to be light saturated above 180 μmol quanta m^{-2} s^{-1} and did not vary significantly at higher light. During mid-exponential phase, N_2 fixation saturated at about 300 μmol quanta m^{-2} s^{-1} and was stable above that. They also noted photoinhibition of N_2 fixation at photon fluxes greater than 1100 μmol quanta m^{-2} s^{-1}.

Finzi (2006, Finzi-Hart *et al.* in review a) compared alpha and P_{max} for natural populations of *Trichodesmium* in the tropical N. Atlantic and N. Pacific finding consistently lower values in the N. Atlantic and hypothesized that this might be due to differences in major limiting factors in the two regions. Finzi (2006, Finzi-Hart *et al.* in review b) went on to demonstrate the effect of iron and P stress on these parameters in cultures of *Trichodesmium* IMS 101. They found that in both cases, both alpha and P_{max} for both carbon and N_2 fixation were severely reduced.

Benthic cyanobacteria also show strong diel patterns which depend on the composition of the cyanobacterial population. Mats dominated by heterocyctous cyanobacteria generally show a daytime maximum while those dominated by non-heterocystous forms exhibit maximum nitrogenase activity at night (e.g., Paerl *et al.*, 1988; Stal and Krumbein, 1987; Steppe and Paerl, 2005).

The relationship to light of the newly discovered planktonic coccoid groups is still being resolved. Group B coccoids appear to temporally segregate N_2 fixation with activity largely associated with the dark phase while Group A enigmatically exhibit maximum activity during daylight hours (Montoya *et al.*, 2004; Zehr *et al.*, 2001, 2007).

Over the last decade or so, two other groups of light-dependent prokaryotes have been discovered in the upper ocean: the Aerobic Anoxygenic Photobacteria or AAPs are found largely among the *Erythrobacter* and *Roseobacter* clades of the proteobacteria (Stackebrandt *et al.*, 1996). There is active debate as to the relative ecological importance of these groups in oceanic photosynthesis (see Kolber *et al.*, 2000) *cf.* (Goericke, 2002; Allgaier *et al.*, 2003). Another recent discovery is that of the presence of light-sensing rhodopsin molecules, termed proteorhodopsins, in a range of proteobacteria and cyanobacteria (Beja *et al.*, 2001), and perhaps other organisms. Proteorhodopsins have been implicated in energetic metabolism and sensory responses, and defining the

physiological role of these molecules is a current area of research. Neither AAP nor proteorhodopsin containing diazotrophs have been yet reported. However, many conventional anoxygenic (anaerobic) phototrophs are diazotrophic (Zehr *et al.*, 2003) and it is conceivable that diazotrophs of both types will soon be discovered.

4.3. Oxygen

The upper water columns of most of the world's oligotrophic oceans are well oxygenated. However, the molecular strategies by which *Trichodesmium*, diazotrophic coccoids and heterotrophic proteobacteria reconcile nitrogenase activity, high O_2 concentrations and, in the case of oxygenic photoautotrophs, active O_2 production in *Trichodesmium*, have been a particular enigma. In contrast to many other non-heterocystous cyanobacteria, *Trichodesmium*, fixes N_2 during the day while actively photosynthesizing. Berman-Frank *et al.* (2001a,b) have presented evidence to show that this may be accomplished by (1) the segregation of active nitrogenase into specialized cells termed "diazocytes" (El-Shehawy *et al.*, 2003) and (2) the down regulation of oxygenic photosynthesis during mid-day allowing a temporal window of opportunity. Staal *et al.* (2003) have put forth a solution to the puzzle regarding the paucity of heterocystous cyanobacteria in tropical seas and illustrate well the interaction of physical factors. As water temperature increase, nitrogenase activity also increases, but the differential diffusion of N_2 into the thick-walled heterocyst does not keep up with the increased nitrogenase activity, thus limiting the enzyme for substrate.

With respect to the low O_2 requirement of nitrogenase, oxygen minimum zones (or OMZs) in the water column exist globally both in the open ocean (e.g., eastern tropical North and South Pacific, Arabian Sea) and in more restricted areas (e.g., Cariaco Basin, Black Sea, Gulfo Dulce). These zones are globally important sites of denitrification, but may have elevated concentrations of ammonium in their anoxic cores. Recently, the anammox reaction has been reported to be important in several OMZ systems (Dalsgaard *et al.*, 2003; Kuypers *et al.*, 2005; Thamdrup *et al.*, 2006; Hamersley *et al.*, 2007), and combined nitrogen concentrations were relatively low even in the core of these anoxic plumes. Such sites may be suitable sites for N_2 fixation, particularly near the oxic/anoxic interface where both O_2 concentration and combined nitrogen may be reduced. However, N_2 fixation has not generally been considered in these systems.

In addition to affecting N_2 fixation directly through interaction with the nitrogenase enzyme, oxygen may also an important role in the global control of this process. As mentioned, OMZs are sites of removal of combined nitrogen by denitrification and Anammox, thereby affecting the relative availability of nitrogen to phosphorus. As mentioned above, modeling evidence by Deutsch *et al.* (2007) indicates this may indeed be the case. Several other modeling efforts have considered the interaction of OMZs with marine N_2 fixation (Canfield, 2006; Moore and Doney, 2007). Moreover, the redox associated with OMZs may affect the relative availability of key trace metals necessary for N_2 fixation.

4.4. Turbulence

Since conventional nitrogenase is uniformly very O_2 sensitive across the spectrum of physiological types (Gallon, 1992), physical mixing in planktonic systems has been recognized as a potentially important factor in regulating N_2 fixation, particularly for

non-heterocystous forms such as *Trichodesmium*. Carpenter and Price (1976) found agitation rapidly inactivates nitrogenase activity in *Trichodesmium*, and a strong inverse correlation exists between sea state and the extent of fixation by natural populations of this cyanobacterium. However, relatively dense populations of *Trichodesmium* are routinely encountered throughout the Trade Wind belts (Carpenter *et al.*, 2004) with their steady 20–30 knot breezes. How turbulence might affect planktonic microbial diazotrophs remains to be determined (e.g., see Howarth *et al.*, 1993, 1995; Paerl *et al.*, 1995).

Factors controlling N_2 fixation in reef environments have been considered in several recent studies. Williams and Carpenter (1998) investigated the importance of natural water flow on nitrogenase activity associated with algal turfs of coral reef environments and found a positive correlation between flow and activity. Higher activity was associated with oscillatory flow compared to unidirectional flow.

4.5. Salinity

Fu and Bell (2003a,b,c) have recently reported that a *Trichodesmium* isolate from the Great Barrier Reef was relatively euryhaline, showing growth over the range of 22–43. However, maximum growth and nitrogenase activity occurred over a much narrower range of 33–37. Recent evidence that Diatom-*Richelia* symbioses are tolerant to lower salinities was reported by Foster *et al.* (2007). They found significant *nifH* gene copy abundances for 2 of the 3 heterocystous cyanobiont lineages within the fresh water lens of the Amazon River plume (salinity >26). In addition, *Trichodesmium nifH* gene copies were also detected within the lower salinity water, however, abundances sharply increased for *Trichodesmium* below the lens (Foster *et al.*, 2007).

4.6. Trace metals

Over the last three decades, we have moved from the monolithic view that nitrogen is the primary limiting nutrient for phytoplankton in the world's oceans (e.g., Thomas, 1966; Ryther and Dunstan, 1971), to the recognition that iron, silicon or phosphorus may at times be in shortest supply. Further, it is recognized that separate groups with distinct biogeochemical functions exist within the phytoplankton that may concurrently exhibit limitation by different nutrient factors (Dugdale and Wilkerson, 1998).

N_2 fixers represent an important functional group that includes a variety of physiological types with unique nutrient requirements. Furthermore, N_2 fixers have unique or elevated cell quotas for certain metals as a result of possessing the nitrogenase enzyme system which requires both molybdenum and iron.

Since diazotrophs can be successful in oligotrophic regions due to their ability to utilize the largest reservoir of nitrogen, N_2 gas, their growth there must ultimately be constrained by the availability of other nutrients such as iron, phosphorus or molybdenum. Early attention focused on molybdenum as a possible growth constraint for marine diazotrophs through the interference with its uptake by the stereochemically similar species, sulfate, which occurs in very high concentrations in seawater (Howarth and Cole, 1985). However, molybdenum concentrations are relatively high (Millero, 1996), and subsequent experimental work has indicated that it is generally not growth limiting (Paerl *et al.*, 1987; Paulsen *et al.*, 1991). Recently, however, Marino *et al.* (2003) have reported on further experiments with diazotrophic lake planktonic that suggest sulfate inhibition of Mo transport.

The *in situ* chemical controls on oceanic N_2 fixation, in particular iron and phosphorus, are the topic of much current research effort and debate. Fueling these efforts has been the observation of extensive areas of excess N (relative to Redfield regeneration stoichiometry, often expressed as positive $N\star$ anomalies) relative to P in subeuphotic zone waters in the North Atlantic that roughly correspond to regions which receive substantial aeolian dust deposition (Michaels *et al.*, 1996; Gao *et al.*, 2001; Gruber and Sarmiento, 1997). Wet and dry deposition of mineral aerosols fertilize the surface ocean with Fe (along with N and P) (Mahowald *et al.*, 1999).

Hence, considerable attention has been focused and substantial progress made in evaluating the role of Fe with respect to *Trichodesmium* growth. Rueter (1988) first presented evidence that Fe can regulate *Trichodesmium* growth and nitrogenase activity. He found increases in CO_2 and N_2 fixation rates and cellular chlorophyll *a* content in natural samples of *Trichodesmium* collected near Barbados amended with Fe. Similarly, Paerl and others (Paerl *et al.*, 1994) reported stimulation of growth and nitrogenase activity by Fe in cultures and natural samples of *Trichodesmium*.

Several recent studies (Berman–Frank *et al.*, 2001a,b; Kustka *et al.*, 2003; Sañudo-Wilhelmy *et al.*, 2001) estimate that Fe requirements of photosynthetic diazotrophs are at most 10-fold greater than for strictly photosynthetic organisms assimilating NH_4^+, much less than earlier theoretical estimates which were 100 times higher (Raven, 1988). However, even an amplified cell quota of 10-fold is likely to be critical in waters where N_2 fixation occurs, as dissolved Fe levels are generally <1 nM (Wu *et al.*, 2000). Fe limited cultures of *Trichodesmium* strain IMS101 were shown to have reduced N_2 fixation rates compared to Fe-replete cultures (Berman–Frank *et al.*, 2001a,b). N_2 fixation rates in cultures of *Trichodesmium* were more greatly stimulated by Fe additions than were cell yields (Fu and Bell, 2003a,b,c). Various natural organic compounds may facilitate, or impede, how accessible Fe is to diazotrophs (Achilles *et al.*, 2003). No information is currently available on the Fe requirement of microbial diazotrophs.

A number of studies have speculated on diazotroph response to mineral dust Fe fertilization in the Atlantic (Mahaffey *et al.*, 2003), and Pacific Oceans (Johnson *et al.*, 2003). Circumstantial evidence for dust stimulation of marine diazotrophic biomass has recently been reported. A 1999 Saharan dust event coincided with increases in dissolved Fe concentrations on the west Florida shelf and a 100-fold increase in *Trichodesmium* biomass. N_2 fixation rates were not measured, but DON concentrations doubled, presumably due to exudation by N_2 fixers (Lenes *et al.*, 2001). A recent Saharan dust addition experiment to surface water samples collected along a west African cruise transect ($35°W–17°W$), found a minimal increase in CO_2 fixation and a large stimulation in N_2 fixation, suggesting that diazotrophs were co-limited by both P and Fe (Mills *et al.*, 2004). Note however, analysis of aerosol dust shows that while providing Fe, it also supplies P and combined N (Baker *et al.*, 2003; Mills *et al.*, 2004; Ridame and Guieu, 2002).

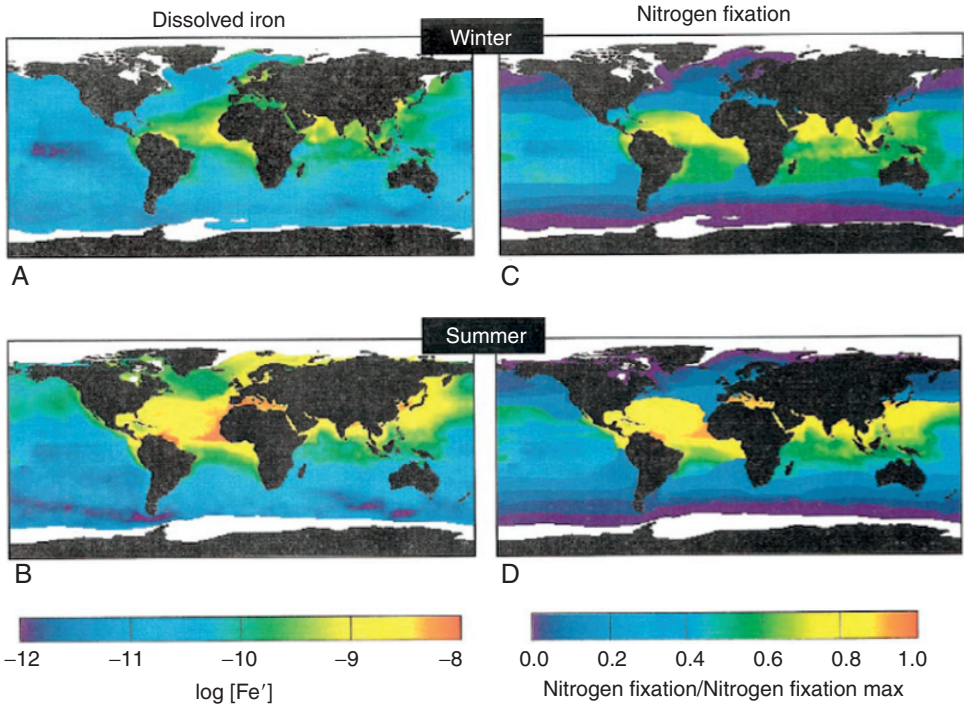
Due to the presumed elevated Fe requirement of photosynthetic diazotrophs and low atmospheric dust deposition to many oligotrophic areas (low nutrient, low chlorophyll, or LNLC), some have suggested that Fe limits N_2 fixation globally (Falkowski, 1997; Rueter *et al.*, 1992;). Combining data on *Trichodesmium* Fe quota and data on aeolian dust fluxes, (Berman–Frank *et al.*, 2001a,b) estimate that N_2 fixation is Fe limited in 75% of the world's oceans, a conclusion echoed by Moore *et al.* (2002) (Figs. 4.3 and 4.4).


Figure 4.3 Seasonal maps showing the potential for nitrogen fixation in the world oceans. Maps were generated by converting global dust iron fluxes to total dissolved iron and using the relationship shown in between log[Fe'] and nitrogen fixation: maximum nitrogen fixation. From Berman–Frank *et al.*, 2001 (Fig. 4.6) with permission.

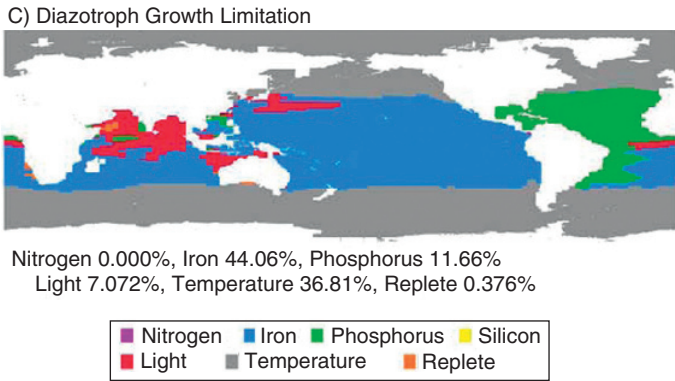

Figure 4.4 Modeled areas of diazotroph nutrient limitation. Nutrient-limitation patterns for the diazotrophs during summer months. Areas where all nutrient cell quotas are >97% of the maximum cell quota values are arbitrarily defined as nutrient-replete. Also shown is the percentage of total ocean area where each nutrient is limiting growth. From Moore *et al.* (2004) with permission.

4.7. Inorganic nutrients

4.7.1. Phosphorus limitation

In contrast to the general sense that Fe is the predominant limiting factor for oceanic N_2 fixation, Wu *et al.* (2000) reported that the subtropical North Atlantic is more depleted in P in comparison to the sub-tropical North Pacific. They suggested that this occurs because more Fe reaches the subtropical North Atlantic than the subtropical North Pacific via aeolian dust deposition (Prospero and Lamb, 2003). They posit that the available Fe in the North Atlantic increases N_2 fixation, leading to a draw-down of all available P. With the accumulating observations in the North Atlantic and North Pacific, there is indeed a suggestion of somewhat higher rates of N_2 fixation for at least *Trichodesmium* in the North Atlantic (Capone et al., in prep.), consistent with the hypothesis that P is more severely limiting for diazotrophs in the North Atlantic while Fe is more limiting in the North Pacific. Corroborating this suggestion, Sañudo-Wilhelmy *et al.*, (2001) found that internal nutrient stoichiometry of field populations of *Trichodesmium* exhibits a stronger relationship of N_2 fixation with cellular phosphate concentration compared to Fe content (Sañudo-Wilhelmy *et al.*, 2001) indicating that *Trichodesmium* from the North Atlantic are more likely limited by P. More recently; Sañudo-Wilhelmy *et al.* (2004) reported that a substantial fraction of the inorganic P associated with *Trichodesmium* (and other algae) is adsorbed to the surface. Dyhrman *et al.* (2002) also provided evidence of P stress in populations of *Trichodesmium* from the Atlantic.

In the Central North Pacific Ocean (CNPO) it has also been reported that phosphorus availability limits N_2 fixation and primary production (Karl *et al.*, 2001a,b) (but iron availability may also play a role as suggested by Wu *et al.* (2000). Karl *et al.* (2001a,b) contend that since the mid 1970s there has been an enhanced stratification in the CNPO and a decreased inorganic nutrient availability which selects for diazotrophs and shifts from a N-limited phytoplankton population to one that is either P or Fe limited (see Karl *et al.*, Chapter 16, this volume).

In contrast, Wu *et al.* (2003) have concluded that N rather than P is limiting to phytoplankton in the South China Sea, and that a relative paucity of Fe, despite considerable atmospheric deposition, limits the ability of diazotrophs to compensate for the N deficiency.

Diazotrophs such as *Trichodesmium* exhibit a relatively high and variable cellular N:P ratio (Krauk *et al.*, 2006; Letelier and Karl, 1996, 1998; Mague *et al.*, 1977; White *et al.*, 2006). Considering surface absorption, intracellular N:P ratios are substantially higher than bulk measurements. The ability of diazotrophs (like many organisms) to sequester P coupled with their relative plasticity in N:P stoichiometry of diazotrophs may allow them to sustain relatively high growth over a range of P concentrations. Such factors need to be considered in the interpretation of short-term measurements of P uptake and growth.

Also, inorganic P is not the only P source for *Trichodesmium* in the open ocean (Mulholland *et al.*, 2002). *Trichodesmium* produces alkaline phosphatase (APA), which cleaves PO_4^{-3} from dissolved organic P compounds to provide an additional P source to the organism. APA activity in natural populations of *Trichodesmium* can indicate P stress to some degree. APA was much higher in the North Atlantic, where inorganic P concentrations are extremely low, than off the northern coast of

Australia where P concentrations are perhaps 10-fold higher (Mulholland et al., 2002). APA was also found to be 10-fold higher in P-deplete cultures of Trichodesmium strain WH9601 compared to P-replete cultures (Stihl et al., 2001). Sohm and Capone (2006) report that APA can account for a major fraction of the P uptake by this organism. However, APA is not a direct index of general P limitation, but an indication that Trichodesmium are experiencing low levels of inorganic P (Scanlan and Wilson, 1999) and may be exploiting organic pools of P.

Several studies have examined the P uptake kinetics of Trichodesmium (Table 4.2). McCarthy and Carpenter (1979) first reported a relatively low affinity (Ks = 9 μM) and long P- based doubling times (>200 d) for natural populations of Trichodesmium. More recently, Fu et al. (2005) determined half saturation values of 0.4–0.6 μM and 0.1–0.2 μM for a strain they isolated from the Great Barrier Reef and for the widely used strain IMS 101 (Prufert-Bebout et al., 1993), respectively.

In contrast, Moutin et al. (2005) reported that natural populations of Trichodesmium, mostly as free trichomes, in the SW Pacific, had relatively high affinity for phosphate, with a Ks of 630 nM and a V_{max} of about 0.31 h^{-1} (Table 4.2). They stated that these are the first accurate determinations of these parameters at environmentally relevant concentrations. They further asserted that the high Ks values presented in the text of McCarthy and Carpenter (1979) were due to a calculation which used an incorrect value for the colony specific rate of 1.2 pmol colony^{-1} h^{-1}, and which Moutin et al. (2005) state should have been 1.2 nmol^{-1} colony^{-1}. This would result in values more in line with their observations. However, McCarthy (personal communication to DGC) stated that the original calculation and values given in the text of McCarthy and Carpenter (1979) are correct but that Fig. 4.4 in McCarthy and Carpenter (1979) had an incorrectly labeled y axis.

Most recently, Sohm and Capone (2006) compared kinetic constants of bulk plankton and Trichodesmium colonies on a transect in the subtropical and tropical N. Atlantic. They found a K_s of about 0.015 μM and V_{max} of about 12 nmol P (μg chl a h^{-1}) for the plankton. K_s for Trichodesmium colonies were substantially higher (0.38–1.1 μM) and V_{max} estimates much lower (5–15 nmol P μg chl a^{-1} h^{-1} or 0.19–0.5 nmol P colony^{-1} h^{-1}).

Sohm et al. (in press) have extended their studies of APA and P uptake kinetics by Trichodesmium colonies in the N. Atlantic to a comparative study of these two indices in the tropical N. Pacific and coastal northern Australian waters as well. They detected sharp contrasts among the sites with much higher V_{max} and APA values in their tropical N. Atlantic stations compared to the N. Pacific and northern Australia indicating more severe P limitation in the tropical N. Atlantic. Dyhrman et al. (2002) also reported evidence of severe P stress in Trichodesmium in the N. Atlantic based on a enzyme linked fluorescence (ELF) assay. A follow up study also saw less evidence of P stress in samples from the N. Pacific (Hynes et al., Pers. Comm.).

Results by Zehr et al. (2007) from a recent comprehensive experimental study examining the response of diazotrophic populations from station ALOHA in the N. Pacific gyre to phosphorus additions saw little effect on either the composition of the populations or on rates of N_2 fixation, reinforcing the supposition that diazotrophy in this system may be constrained by other factors (see also Chapter 16, Karl et al., this volume).

Table 4.2 Estimates of P Uptake and Turnover by *Trichodesmium* as Reported in Several Studies

[a] Assumed 34 ng chl/colony, from Carpenter, 1983.
[b] Assumed 180 pg chl *a* and 100 cells per trichome.
[c] Assumed 100 cells per trichome and 200 trichomes per colony.
[d] Assumed 100 cells and 50 trichomes per colony.

In contrast, an open ocean phosphorus enrichment experiment (CYCLOPS) conducted in the eastern Mediterranean did find evidence for P limitation of N_2 fixation in bulk water (Rees *et al.*, 2006).

An exciting, recent development is the detection of the potential for *Trichodesmium* to exploit phosphonate compounds as another source of P (Dyhrman *et al.*, 2006). More research is needed to clarify the importance of phosphonates as P source for this organism in nature. This pathway was predicted after the sequencing and analysis of the *Trichodesmium* genome (http://genome.jgi–psf.org/draft_microbes/trier/trier.home.html).

In the benthic realm, working in the framework of the ENCORE coral reef research program in Australia, Koop *et al.* (2001) reported stimulation of lagoon sediment N_2 fixation by additions of phosphate suggesting sediment N_2 fixation in carbonate systems may also be limited by phosphorus as earlier observed for seagrasses (Short *et al.*, 1990).

4.7.2. Combined nitrogen

Only a limited number of studies have considered the interaction of combined N sources with oceanic N_2 fixers. Some early work suggested that *Trichodesmium* only had a weak capacity for inorganic N uptake (Carpenter and McCarthy, 1975; Glibert and Banahan, 1988). However, more recent studies indicate that *Trichodesmium* is capable of exploiting some inorganic and organic N pools. Both Carpenter *et al.* (1992) and Capone *et al.* (1994) reported the capacity of *Trichodesmium* to take up some amino acids. Mulholland and colleagues undertook a comprehensive series of studies examining the uptake capacity for several combined N sources by *Trichodesmium* in culture and in the field (see Mulholland and Capone, 2000, for a general overview). With the NIBB1067 culture, they reported high affinity and capacity for ammonium, urea and glutamate but relatively low capacity for nitrate during growth on N free media, but that nitrate and urea supplied the bulk of daily N demand when they were available in excess (Mulholland *et al.*, 1999). In cultures without added N, ammonium uptake and release was dynamic and accounted for the bulk of N turnover while N_2 fixation represented only about 16–18% of total N turnover but 100% of the demand for net growth. The high turnover of N may support a high level of gross production accounting for some of the mismatch between C based and N based growth in the literature (Carpenter, 1983a,b; Lipschultz and Owens, 1996). Further studies note similar results in another culture of *Trichodesmium*, IMS101 and field populations (Mulholland and Capone, 1999). In another study of *Trichodesmium* IMS101 where similar levels of ammonium turnover were also documented, Mulholland and Capone (2001) were able to mass-balance C and N accumulation in biomass. They found that whereas C_2H_2 reduction estimates of N_2 fixation closely predicted net particulate organic nitrogen (PON) accumulation, short term (1 h) $^{13}CO_2$ uptake estimates during the light period overestimated particulate organic carbon (POC) accumulation in mid to late exponential phase. Again, this may be a result of the high ammonium turnover. In a subsequent study, Mulholland *et al.* (2004) also tracked the flux into dissolved organic nitrogen (DON), finding that DON release could account for the difference between $^{15}N_2$-based and C_2H_2 reduction based estimates of N_2 fixation.

Relatively few studies have considered the influence of combined N on nitrogenase activity in oceanic marine diazotrophs, perhaps because of the often low concentrations encountered in the upper ocean of oligotrophic areas (see Capone, 1988) for a summary of such work in benthic systems). Capone *et al.* (1990) used relatively high doses (100 μM) of ammonium to experimentally shut off nitrogenase synthesis, which typically resulted in a decrease in activity within 2 h. Mulholland *et al.* (2001) saw little short term effect of low (1 μM) additions of glutamate, glutamine, ammonium, nitrate and urea on nitrogenase activity by natural and cultured populations of *Trichodesmium*. However, 10 μM concentrations of ammonium and nitrate did reduce nitrogenase activity within 2–4 h. In contrast, Fu and Bell (2003a,b,c) reported little inhibition at this level for short term (first generation, 3 h) exposures to ammonium, nitrate or urea, although by the fifth generation, inhibition became evident.

Most recently, Holl and Montoya (2005) examined the interactions of nitrate with nitrogenase activity in *Trichodesmium* IMS 101 in continuous culture. Interestingly, maximum inhibition of nitrogenase activity occurred at 10 μM nitrate, but was not complete, with 30% of the activity remaining. This is in contrast to some earlier studies (Ohki *et al.*, 1991) where inhibition was complete. This may indicate fundamental differences in response between the continuous culture approach, relative to the batch cultures used in all earlier studies. At high concentrations, nitrate could account for most of the N demand, and more than made up for the decrease in N_2 fixation.

4.7.3. Inorganic carbon

Because of the high concentrations of inorganic carbon in surface waters of the ocean, it is rarely thought about as a potential limiting factor for plankton growth. However, several recent studies taking confluent research tracks have shown elevated DIC stimulates both growth and N_2 fixation in *Trichodesmium*.

Levitan *et al.* (2006) noted enhanced N_2 fixation, C:N ratios, filament length and biomass of *Trichodesmium* isolate IMS 101 at pCO_2 of 900 ppmv relative to 400 ppmv or 250 ppmv. Photosynthesis and respiration did not elicit a strong response to increasing pCO_2. Similarly, Hutchins *et al.* (2007) found a 35–100% increase in N_2 fixation and a 15–128% in CO_2 fixation rates in 2 isolates of *Trichodesmium* (IMS 101, and another strain isolated from the Great Barrier Reef) at 750 ppm relative to 380 ppm. The response occurred under both P replete and P depleted conditions. No growth was recorded at 150 ppm and a 4°C temperature increase only had minimal affects.

The model of Barcelos e Ramos *et al.* (2007) predicts both N_2 fixation rates and cell division rates will double at year 2100 from the projected increases in CO_2 levels, and would potentially result in lower C, N and P cell content as well as reduced cell size and steady C:N content (the last observations in contrast to Levitan *et al.*, 2006).

4.7.4 . Global patterns of nutrient limitation

As noted above, there is an emergent view that oceanic diazotroph populations may be limited by different nutritional factors in different ocean basins. In contrast to the general perception that Fe is the predominant limiting factor for oceanic N_2 fixation, Wu *et al.* (2000) noted that diazotrophs in the subtropical North Atlantic are more likely stressed for P in comparison to populations in the sub-tropical North Pacific. They suggested that this occurs because more Fe reaches

the subtropical North Atlantic than the subtropical North Pacific via aeolian dust deposition (Prospero and Lamb, 2003). They posited that the available Fe in the North Atlantic increases N_2 fixation rates, leading to a draw-down of all available P. Indeed, surface ocean concentrations of Fe are often relatively high in the North Atlantic (Wu *et al.*, 2001) and this input may drive the North Atlantic Ocean to P limitation, at least for N_2 fixation (Wu *et al.*, 2000). As noted, several lines of evidence have provided corroboration for this supposition (Sañudo-Wilhelmy *et al.*, 2001; Dyhrman *et al.*, 2002; Krauk *et al.*, 2006; Sohm and Capone, 2006).

In the Central North Pacific Ocean (CNPO) it had been hypothesized that P availability limits N_2 fixation and primary production (Karl *et al.*, 2001b; see also Karl *et al.*, Chapter 16, this volume). Karl *et al.* (2001a) suggested that since the mid 1970s there has been enhanced stratification in the CNPO and decreased inorganic nutrient availability, which has selected for diazotrophs and has caused a shift from an N-limited phytoplankton population to one that is P limited. However, except for the recent bioassay experiment, Zehr *et al.* (2007) noted above which found no increase with P addition in the transcription of *nifH* genes or in rates of activity over a control for samples from station ALOHA. experimental evidence for P limitation of N_2 fixation is currently lacking. Indeed, recent P★ analyses by Deutsch *et al.* (2007), find large excesses of P, relative to N, in surface waters of the eastern Pacific associated with the selective removal of N by denitrification and anammox in OMZ. They further note that this excess decreases in the absence of surface nitrate as waters advect offshore from sites of upwelling and associate this removal with nitrogen fixation. Again, these observations reinforce the suggestion by Wu *et al.* (2001) that iron limitation of diazotrophs is more likely in this system.

Field surveys using classical microscopic methods in limited areas of the ocean have reported high densities of *Trichodemium* at times in the southwest Sargasso Sea, in the Caribbean and tropical N. Atlantic, and China Sea/Kurishio (see Carpenter, 1983) for early work, also Carpenter *et al.* (2004)). There is some evidence for a bimodal distribution in nitrogen fixation zonally across the tropical Atlantic, with some shift in the dominant diazotrophs from *Trichodesmium* in the western basin and coccoids in the eastern basin (Montoya *et al.*, 2007; Langlois *et al.*, 2008), Tyrrell *et al.* (2003) noted a distinct drop in *Trichodesmium* densities in the S. Atlantic compared to the N. Atlantic. New molecular techniques have provided valuable tools to address some of the inherent limitations of traditional microscopic assessments of diazotrophic abundance and species composition, which cannot address variations on large spatial and/or temporal scales. Specifically, several recent papers have provided quantitative information on large scale distributions of several diazotrophs using qPCR methods. These data provide some corroboration for the perception that diazotrophic populations may vary both quantitatively and qualitatively among different basins. Foster *et al.* (2007), working in and around the plume of the Amazon River noted high abundances of *Richelia* at many stations. *Richelia* associations with diatoms accounted for about 60% of the *nifH* genes in surface waters, and were dominant at 12 of 22 stations. *Trichodesmium* dominated at 4 of the stations whereas Type A and type B cyanobacteria were dominant at only 1 station each. Type C cyanobacteria dominated at 4 stations. Langlois *et al.* (2008) reported results from 4 major cruises and about 76 discrete stations which sampled over a broad swath of the temperate to tropical N. Atlantic Ocean. They found filamentous

non-hetercyctous cyanobacteria to account for 53% of *nifH* sequences retreived in all samples, followed by Group A coccoids which accounted for 34% of all samples. Group B coccoids accounted for 4.3% of the total phylotypes.

In contrast, a recent study by Church *et al.* (2008) provided data from 7 stations in the Pacific Subtropical Gyre, 3 in the North Equatorial Counter Current and 3 stations in the North Pacific Transition Zone which indicated that filamentous cyanobacteria were not dominant at any of the stations whereas Type A coccoid cyanobacteria did account for the majority of *nifH* sequences (10 of 13 stations). Heterocystous forms dominated at 3 stations. Hence, quantitative field data suggest fundamental differences in the assemblages of diazotrophs between the N. Pacific and N. Atlantic subtropical gyres reinforcing the suggestion of basin-scale differences in factors limiting diazotrophs and structuring their populations.

Recent modeling efforts explicitly representing oceanic N_2 fixation using physiological growth requirements also have come to the conclusion that there are distinct oceanic zones with regard to predominant limiting factors for diazotrophs (Coles and Hood, 2006; Krishnamurthy *et al.*, 2007).

5. Biogeochemical Significance of Marine Nitrogen Fixation

In 1982, we had estimated annual global rate of N_2 fixation in the sea was 0.34×10^{12} mol N among the near surface plankton (Carpenter, 1983a,b) and 1.1×10^{12} mol N in sediments (coral reefs, sea grass beds, estuarine sediments, salt marshes and mangroves)(Capone and Carpenter, 1982a,b; Capone, 1983; Carpenter, 1983a,b) (Table 4.3). Our estimates were based on the relatively limited direct field data that had accumulated to that point and, for the plankton, historical data sets on the density of *Trichodesmium* in the world's oceans. We concluded at the time that this appeared to be a relatively minor input to the sea (Capone and Carpenter, 1982a,b).

Over the last several decades, independent lines of indirect geochemical evidence have strongly indicated that N_2 fixation rates are of greater quantitative significance than this early estimate (Mahaffey *et al.*, 2005) (Table 4.3). During the late 1970s and 1980s, N stable isotope distributions of suspended particulate matter first suggested that N_2 fixation was substantial in tropical waters (Altabet, 1988; Saino and Hattori, 1980; Wada and Hattori, 1976) as did subsequent observation of anomalously high DON concentrations in tropical surface waters (Hansell and Feely, 2000; Vidal *et al.*, 1999) and CO_2 drawdown in the absence of combined N at the Bermuda Atlantic Time Series (BATS) station (Michaels *et al.*, 1994). Inferences and rate estimates on basin scales have shown the global importance of N_2 fixation. For example there have been many reports of environment where substantial deviations from the Redfield ratio in N and P regenerated in some sub-euphotic zone waters occur (Deutsch *et al.*, 2001; Gruber and Sarmiento, 1997; Michaels *et al.*, 1996) (see Chapter 1 by Gruber, and Chaper by 13 by Hansell, this volume) and results from stable N isotope studies in the water column suggestive of N_2 fixation (Karl *et al.*, 1997; Montoya *et al.*, 2002). More recently, inorganic carbon budgets (Gruber *et al.*, 1998; Lee *et al.*, 2002) and ecosystem models in which physiological characteristics of diazotrophs are explicitly represented (Coles *et al.*, 2004; Hood *et al.*, 2004), (see Chapter 33 by Hood and

[a] Assuming an N:P ratio of 45 for diazotrophs rather than 125 as originally computed by Gruber and Sarmiento (1997).
[b] Assuming a domain area of 27.8 k m^2×10^6 (Gruber and Sarmiento, 1997).

Christian, this volume) have also concluded that N_2 fixation is of greater quantitative significance. Factors which led to the relatively low early estimates have been summarized by Capone and Carpenter (1999) and were largely a result of (1) scaling cell specific rates to global distributions of *Trichodesmium* based on historical surveys which systematically under-sampled their population densities and (2) ignoring the input of other diazotrophs (e.g., unicellulars and diatom–diazotroph associations) which have subsequently been discovered and shown to be of quantitative significance as well. Current estimates of oceanic N_2 fixation based on direct observations (largely to date of *Trichodesmium* alone) are much greater, but substantial differences still exist among independent geochemical estimates of N_2 fixation, and with direct biological estimates (Capone *et al.*, 2005; Mahaffey *et al.*, 2005).

5.1. Directly assessing nitrogen fixation

Today, with comprehensive data from more spatially extensive surveys, the direct estimate for open ocean planktonic N_2 fixation far exceeds that in sediments and rivals terrestrial biological rates. For instance, a recent accounting of N_2 fixation at 154 stations from 6 cruises in the tropical Atlantic yielded a conservative annual input of at least 1.6×10^{12} mol N (22×10^{12} g) by *Trichodesmium* alone (Capone *et al.*, 2005) (Table 4.3).

Numerous other potential agents of N_2 fixation have been recognized (see above). However, the quantification of their input has been a greater challenge and is an ongoing endeavor. While the isolation of diazotrophic heterotrophic bacteria and coccoid cyanobacteria led to early speculation that these components of the oligotrophic food web might also contribute to aggregate N_2 fixation (Carpenter, 1983a,b), initial attempts to quantify activity through sample concentration were unsuccessful (Carpenter, Capone and Zehr, unpublished data), perhaps because of the rarified densities of these organisms and the possibility of sample concentration artifacts. The detection of *nifH* transcripts in the small (<10 μm) fraction (Zehr *et al.*, 2001) has prompted renewed interest in assessing the quantitative significance of microbial diazotrophs. Improved methods with higher sensitivities in isotopic analyses have made quantification of activity in this smaller size fraction more amenable to study (Montoya *et al.*, 1996).

Several reports in varied locations have now provided quantification of N input in the small size fraction of the plankton. Montoya *et al.* (2004) found highly variable but at times, extremely high, rates of N_2 fixation in studies in the sub-tropical N. Pacific and along the north coast of Australia (Tables 4.4 and 4.5). Average rates (excluding one extreme value) for 10 stations on the North Pacific transect north of the Hawaiian Islands were about 520 μmol N $m^{-2}day^{-1}$. Curiously, rates were considerably and consistently lower at station ALOHA in the vicinity of the Hawaiian Islands. This was also concordant with an earlier study (Dore *et al.*, 2002) and another recent effort that employed plankton concentrates (Falcón *et al.*, 2004).

Falcón *et al.* (2004) also reported rates of N_2 fixation by plankton concentrates for the tropical Atlantic, which were modest. Garcia *et al.* (2006) have undertaken a size fractionation study in waters near New Caladonia in the southwest Pacific (Tables 4.4 and 4.5). They found that while the contribution in the larger size fraction (>10 μm– associated with *Trichodesmium*) often dominated the input, it was highly variable relative to a steadier background in the <10 μm fraction, which tended to dominate in the absence of macro-diazotrophs. They also examined the <3 μm fraction, which occasionally showed low levels of enrichment from the $^{15}N_2$ isotopic tracer. However, it was not clear that this was endogenous N_2 fixation in this size fraction or a result of trophic transfer. Holl *et al.* (2007), in studies of cold and warm core eddies in the Leeuwin current off the west coast of Australia found the bulk of N_2 fixation in the <10 μm fraction. In any event, there are far too few observations at present to be able to generalize the importance of N_2 fixation in the smaller size fractions of the plankton.

As mentioned, diazotrophic diatom associations (DDAs) can, at times, be of quantitative significance. A bloom of the endosymbiont *Richelia intracellularis* within

the diatom *Hemiaulus hauckii* encountered off the NE coast of South America in 1996 had areal rates of N_2 fixation rate that exceeded that by *Trichodesmium* spp. in the same region by tenfold or more (Carpenter *et al.*, 1999). These associations may be particularly important in sequestering C to the ocean's interior (Scharek *et al.*, 1999a,b; Subramaniam *et al.*, 2008). Factoring these episodic events into basin scale budgets remains a challenge.

Several studies have examined unconcentrated bulk water using a $^{15}N_2$ tracer approach. Goering *et al.* (1966) first reported on unconcentrated, bulk water $^{15}N_2$ uptake studies off the northeast coast of South America. Their results could account for rates of about 86 and 271 μmol N_2 m^{-2}day^{-1} for 2 observations and 9 observations in the fall of 1966 and spring of 1967, respectively. They reported appreciable *Trichodesmium* in most of their samples. Voss *et al.* (2004) recently found relatively high rates on the eastern side of the basin off NW Africa, with somewhat lower rates on the western boundary, and activity was below detection limits in the central portion of the basin (Tables 4.4 and 4.5). Rees *et al.* (2006) observed very high rates of N_2 fixation in the eastern Mediterranean which were apparently limited by phosphorus availability (Table 4.4).

We recently assayed bulk (unconcentrated) water $^{15}N_2$ uptake during a cruise off the NE coast of South America during a period of relatively high Amazon River flow and abundant populations of the diatom *Hemiaulus* with the symbiotic cyanobacterium, *Richelia*, at many stations. Areal rates of N_2 fixation exceeded 1000 μmol N_2 m^{-2}day^{-1} (Subramaniam *et al.*, 2008). The earlier cruise to the same area mentioned above in which we encountered an extensive monospecific bloom of *Hemiaulus/Richelia* yielded comparable rates using gently concentrated surface water (Carpenter *et al.*, 1999). White *et al.* (2007) have also found *Richelia*/diatom associations to be an important source of N_2 in the Gulf of California.

Bonnet *et al.* (2008) recently reported on a transect through the southeast Pacific from the high nutrient (HNLC) region in the northwest of the gyre through its core and on to the eastern edge of the gyre. Despite the extreme oligotrophy, rates of N_2 fixation were below detection limits and could not be stimulated with additions of either iron or phosphate.

N_2 fixation may also proceed in waters at low rates at higher latitudes with lower temperatures and higher combined nitrogen concentrations (e.g. Needoba *et al.*, 2007; Holl *et al.*, 2007) or perhaps even deeper in the water column (Hewson *et al.*, 2007).

5.1.1. Diazotroph densities

As is evident from the data, areal rates of activity can be highly variable for both *Trichodesmium* and microbial diazotrophs with extremes in the mmol N m^{-2} day^{-1} range, with a greater spread of values overlapping in the 10–100 μmol N m^{-2} day^{-1} (Mahaffey *et al.*, 2005) (Tables 4.4 and 4.5). With the help of epifluorescent microscopy, quantification of macrodiazotrophic organism such as *Trichodesmium* and *Richelia* symbiotic in diatoms has been relatively straightforward.

However, determining the *in situ* density of micro-diazotrophs is more problematic. While coccoid cyanobacteria such as *Synechococcus* are reported to occur at densities of about 10^4 ml^{-1} in oligotrophic waters, presumptively diazotrophic

coccoids appear to occur at much lower densities of 10s to 100s of cells per ml (Falcón *et al.*, 2004; Montoya *et al.*, 2004).

With the recognition of several distinct groups of coccoid cyanobacteria based on recovered *nifH* sequences (Table 4.1), specific primers and probes have been developed to directly evaluate the abundance of target phylotypes using quantitative PCR (qPCR). Short *et al.* (2004) first applied this method to determine the abundance, and spatial and temporal patterns of 2 diazotrophic phylotypes in Chesapeake Bay. Densities of up to 140 and 340 copies ml^{-1} were found for one phylotype (being associated with higher salinity) and the other most abundant phylotype was detected at mesohaline stations. Church *et al.* (2005) used a similar qPCR approach examining the *nifH* gene copy densities of *Trichodesmium*, two coccoid cyanobacterial diazotrophs (Groups A and B), one heterocytous group (het-1, later recognized as *Richelia* associated with *Rhizosolenia* (Foster and Zehr, 2006)) and a group III phylotype at Station ALOHA. They reported that on a gene copy basis, Group A cyanobacteria were dominant (Table 4.6). In a second study by Church *et al.* (2005), they demonstrated that *nifH* gene copy expression for Group A occurred during the day, as did *Trichodesmium*.

Recently, Foster *et al.* (2007) reported on densities of seven groups of diazotrophic cyanobacteria in the plume of the Amazon River. In mesohaline waters, the highest densities were found for *Richelia* associated with *Hemiaulus*, while in more marine waters, *Trichodesmium* dominated *nifH* copy density. The three coccoid groups (Groups A, B, and C) were generally in lower in abundance than the two of the larger diazotrophs (het-1, *Trichodesmium*) and showed higher abundances at the more saline stations. Group B *nifH* copy abundances co-varied with *nifH* copies of *Trichodesmium*.

Less information is currently available on the density of diazotrophic bacterioplankton in marine ecosystems. Church *et al.* (2005) used a primer and probe set designed to target a Group III phylotype and found relatively high densities ($\sim$70 copies ml^{-1}) in the near surface, which declined with depth. However, this phylotype became predominant over the cyanobacteria below the euphotic zone. Hewson *et al.* (2007) recently reported their analysis of diazotrophic populations in the Sargasso Sea and elsewhere, including deep waters, a few *nifH* phylotypes and transcripts from deeper depths below the euphotic (up to about 6000 m) were amplified and quantified (Table 4.6). Microarray fingerprints of diazotroph diversity patterns from samples obtained in the upper water column in samplings two years apart were remarkably similar.

Two recent studies first mentioned above have provided the most comprehensive coverage to date for the N. Pacific Gyre (Church *et al.*, 2008) and tropical and subtropical N. Atlantic (Langlois *et al.*, 2008). No diazotrophs were detected at stations in the Pacific Sub-Artic Gyre. As mentioned above, Type A and B coccoid were dominant at most stations both within the NPSG and in transitional zones to the north and south. Within the NPSG they were most abundant between 14 and 29° N where they could occur in densities exceeding 100 and 10 cells per ml, respectively (Table 4.6). At several stations, heterocyctous forms were found to dominate while non-heterocyctous filamentous forms were rarely dominant. In contrast, Langlois *et al.* (2008) reported that in many of the warmer (28–30°C) regions of the N. Atlantic, particularly areas subject to high dust inputs, non-heterocystous filamentous forms were numerically more abundant. Type A coccoids also occurred in substantial numbers, although their greatest densities occurred in somewhat cooler (22–23°C) waters.

5.1.2. Diazotroph biovolume

As has been pointed out by Carpenter *et al.* (2004), while *Trichodesmium* cells may be relatively rare compared to *Synechoccocus* and *Prochlorococus*, they are also very large cells (up to 10 µm in diameter). Even a single colony of 200 trichomes in a liter of surface seawater would represent about 15,000–20,000 cells and could account for more than 40% of all prokaryotic autotrophic biovolume and carbon (assuming typical densities of *Synechoccus* and *Prochlorococcus*) (Table 4.7). Given the presumed lower densities of diazotrophic coccoid cyanobacteria, a colony of *Trichodesmium* per liter would also presumably dominate diazotroph biovolume (assuming a cell diameter for the coccoids of about 5 µm) (Table 4.7). Also, maximum cell specific rates of N_2 fixation appear to be higher in *Trichodesmium* (10–30 fmol N cell^{-1} h^{-1}, (Capone *et al.*, 2005) than those reported for diazotrophic coccoid cyanobacteria ($\sim$ 4 fmol N cell^{-1} h^{-1}; see Gallon and Stall, 1992; Grobbelaar and Huang, 1992; Mitsui *et al.*, 1987; Reddy *et al.*, 1993).

5.1.3. Final thoughts on activity and density of diazotrophs

Thus, diverse results from the field on both the density and activity of *Trichodesmium*, micro-diazotrophs and DDAs, the relative intensity of N_2 fixation is highly variable and heterogeneous. On a local basis, each component may make substantial contributions. A critical evaluation of the relative global importance of each awaits more extensive and robust estimates of the N input by symbiotic associations and the smaller microbial diazotrophs at diverse locations.

Galloway *et al.* (2004) recently estimated global oceanic N_2 fixation to be in the range of $100–200 \times 10^{12}$ g year^{-1}, roughly equal to the estimate for terrestrial N_2 fixation in the absence of human activities. It now appears that upwards of 50% of the nitrogen supporting new production of some tropical and sub-tropical marine upper water column ecosystems could be derived from N_2 fixation (Capone *et al.*, 2005; Karl *et al.*, 1997; Mahaffey *et al.*, 2005) (see Below).

5.2. Comparison of geochemical vs. direct estimates

Current global or basin-scale geochemical estimates, be they based on N excesses or isotopic mass balances, represent net fluxes integrated over relatively large spatial and temporal scales. Direct estimates, on the other hand, are snap shots and will reflect natural variability occurring over shorter (e.g., daily, seasonal & interannual) time scales. Furthermore, depending on the nature of the direct estimate, they may only capture specific components of the diazotrophic flora (see above). In order to accurately quantify N_2 fixation by direct or geochemical methods, an understanding of the temporal variation in N_2 fixation, residence time of the tracer, and ventilation timescales of the water column is vital.

At present, geochemical estimates are available for the North Atlantic (Gruber and Sarmiento, 1997), *cf.* (Hansell *et al.*, 2004, 2007) and Pacific (Deutsch *et al.*, 2001), while the greatest density of direct observations are for *Trichodesmium* in the tropical North Atlantic and North Pacific (Table 4.3). We have recently scaled globally averaged rates of *Trichodesmium* N_2 fixation to seasonally averaged waters greater than or equal to 25°C as a proxy for highly oligotrophic waters

Table 4.7 Relative Biovolume and C Content of Phytoplankton and *Trichodesmium* in 1L assuming 1 Colony per Liter and a Cell Diameter of *Trichodesmium* of 10 μm. Adapted from Carpenter *et al.*, 2004

		Diam		Cell vol		% of Total	% of Prok total	fg C/cell	fg C/μm3	cell C ng/L	% of Total	% of Prok total

[a] From Durand *et al.*, 2001.
[b] Assumes 5 μg C and 150 trichomes per colony and 100 cells per trichome (Carpenter 1983; Carpenter *et al.*, 2004).

(Galloway *et al.*, 2004). Given the basin-specific averages weighted for the extent of each study, *Trichodesmium* N_2 fixation scaled to waters of 25°C and above can explain about 40% and 59% of some of the geochemically inferred N_2 fixation in the North Atlantic and North Pacific, respectively (Mahaffey *et al.*, 2005).

We believe this is remarkable in explaining a substantial fraction of the geochemically derived estimate. The difference is likely a function of input from *Trichodesmium* blooms (Carpenter and Capone, 1992; Capone *et al.*, 1996), microbial diazotrophs (Montoya *et al.*, 2004) and symbiotic associations (Carpenter *et al.*, 1999). As noted, all three can contribute intense amounts of nitrogen, although the broader inputs over larger time and space scales are not currently well constrained.

Recent research has found low, but measurable rates of N_2 fixation in cooler surface waters (Table 4.6) (Needoba *et al.*, 2007). If this is a general observation in colder waters, it would further close the gap. Similarly, while they predominate in surface waters (Church *et al.*, 2008), diazotrophs can also be found below the euphotic zone (Hewson *et al.*, 2007), and do exhibit low levels of activity (Hamersley, Capone, Montoya et al. in prep).

An ongoing debate concerns the extent that the current N cycle is close to steady state (see Chapter 1, Gruber, this volume). Recent estimates of denitrification considerably exceed those of N_2 fixation (Codispoti *et al.*, 2001), perhaps because of our lack of understanding of the quantitative importance of other sources of N_2 fixation such as that occurring in the nano- and pico-plankton and associated with symbionts. Indeed, isotopic constraints suggest that the marine N Cycle is much closer to steady state, and that N_2 fixation and denitrification are tightly coupled and in fact provide a N homeostat (Deutsch *et al.*, 2004; Gruber, 2004).

As detailed above, there appears to be spatial patterns in the predominance of different diazotrophs in different oceanic regions, both within and among major basins, as well in the nature of nutrient limitation of these populations. These trends are likely related to the nature of external nutrient input in these regions. There is also an ongoing reevealuation with regard to the oceanic distribution of N_2 fixation itself (Fig. 4.5). Substantial research has documented the density and intensity of N_2 fixation by *Trichodesmium* in the tropical N. Atlantic (e.g. Carpenter *et al.*, 2004; Capone *et al.*, 2005; Montoya *et al.*, 2007; Langlois *et al.*, 2008) along with geochemical identification of regions of excess nitrogen in the thermocline (Gruber and Sarmiento, 1997). In contrast, reanalysis of the nitrate and phosphate field of the N. Atlantic suggest far less N excess than previously suggested (Hansell *et al.*, 2004, 2007) while isotopic mass balance studies at BATS, including the DON pool, suggest minor inputs by N_2 fixation (Knapp *et al.*, 2005). Several modeling studies point to other areas of the global ocean (e.g. the Pacific and Arabian Sea) as more significant in net N_2 fixation (Deutsch *et al.*, 2007; Moore *et al.*, 2004) (Fig. 4.5). Thus, there is a need to reconcile these divergent observations.

6. Summary and Future Directions

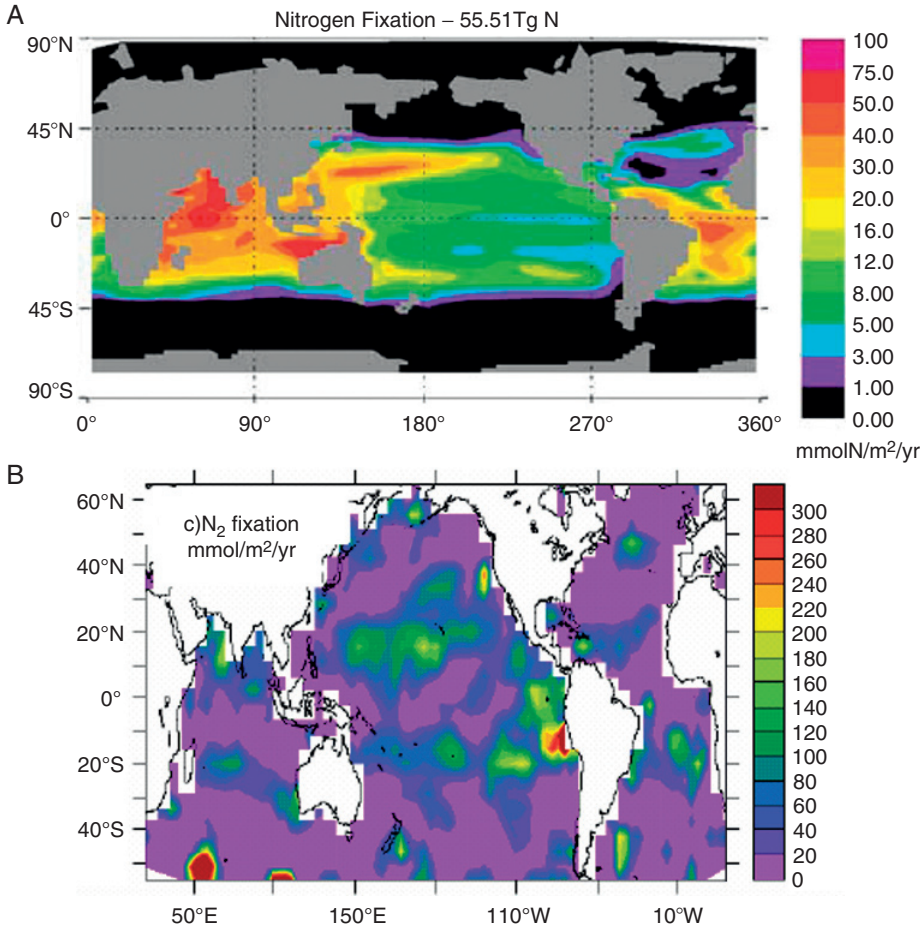
Recent research on oceanic diazotrophs has shown remarkable diversity, with numerous species in free-living genera (*Trichodesmium* spp., *Katagnymene* spp., *Crocosphera* spp. and *Anabaena gerdii*) as well as coccoid symbionts with dinoflagellate and


Figure 4.5 Modeled distributions of nitrogen fixation in the worlds oceans. (A) From Moore *et al.* (2004) with permission. (B) From Deutsch *et al.* (2007) based on P★ draw-down with permission.

diatom hosts and the heterocystous *Richelia intracellularis* and *Calothrix rhizosoleniae* living symbiotically with several diatom genera. The fact that a significant fraction of *nifH* sequences from tropical pelagic waters cluster with proteobacteria suggests that these organisms might also be important in nitrogen transformations, and recent research indicates that oxygen minimum zones may also promote N_2 fixation. More research is clearly needed to quantify rates of N_2 fixation and the factors that control growth rates in all these organisms.

In benthic environments, ranging from the rhizosphere of shallow water macro-phyte communities such as *Zostera, Thalassia* and *Spartina* hundreds of different diazotrophic strains have been isolated, and these are typically microaerophyllic or anaerobic, and often are sulfate respiring bacteria. These diazotrophs make signifi-cant contributions to the nitrogen economy of their respective plant communities.

Similarly, in coral reef communities, N_2 fixation in carbonate sands are a major source of N_2 fixation, and the recent discovery of diazotrophic coccoid cyanobacteria living within the tissues of *Montastrea* corals suggests that there may well be more diazotrophic symbioses with corals. Many sponges harbor cyanobacterial symbioses, and these may also be important sources of fixed nitrogen.

In the pelagic zone, iron and phosphorus availability is a major constraint on N_2 fixation. In the north Atlantic, positive $N\star$ anomalies in the sub euphotic zone, resulting from Aeolian dust deposition of Fe, corresponds to areas in which P limits growth of diazotrophs. Genomics research indicates the capacity of *Trichodesmium* to utilize phosphonates as a source of P, however research is needed to determine how significant this source might be. In the Pacific, Fe availability more severely limits diazotrophic activity, but P is in short supply as well. Iron requirements of diazotrophs are about 10 fold greater than non–diazotrophic phytoplankton, considerably less than previous estimates. While aeolian dust addition studies have shown increases in diazotrophic activity of tropical plankton, there is a need by climate modelers for more quantitative data on the effects of dust on overall primary productivity, N_2 fixation rate, plus a better understanding of the chemistry of dust dissolution.

There is precious little information on the pathways of fixed N from pelagic diazotrophs to other members of the plankton and nekton. Viral lysis may be a major pathway as is the "leakage" of fixed N from healthy *Trichodesmium* cells. Research on $\delta^{15}N$ of zooplankton in broad areas of the north Atlantic suggests that fixed N is readily incorporated. Clearly a better understanding of grazers, particularly salps, and grazing rates on *Trichodesmium* and other planktonic diazotrophs, is needed.

Recent estimates of global oceanic N_2 fixation are in the range of 100–200 $\times$ 10^{12} g year^{-1}, roughly equal to the estimate of terrestrial N_2 fixation in the absence of human activities. Thus it appears that about 50% of the N supporting new production in some tropical and sub-tropical ecosystems could come from N_2 fixation. The distribution of diazotrophs globally is very patchy both vertically and horizontally, and it is very labor intensive to obtain quality biomass data and N_2 fixation rates. The authors have spent many hours identifying and quantifying diazotrophs and assessing nitrogenase activity. The development of better remote sensing algorithms and sensors can help in assessing near surface populations of diazotrophs such as *Trichodesmium*. Better indirect methods such as those employing stable isotopes, $N\star$ or modeling efforts can also help, but since fixed N is such an important commodity in the ecology of marine organisms, it is important that we have a better assessment of rates in the marine environment.

Several conundrums remain to be resolved including 1) have we greatly underestimated marine N_2 fixation, 2) what are the quantitative contributions of the newly identified diazotrophs, 3) what is the spatial distribution of N_2 fixation and 4) to what extent does the nature of nutrient limitation control the composition of diazotrophic populations locally and over broader scales.

More novel insights into marine nitrogen may be just around the corner with the influx of new and improved methodologies and analytical capabilities. Stable isotope probing has been used with enriched C isotopes to identify directly active

components of microbial populations by isolation of nucleic acids and specific biomarkers (Boschker and Middelburg, 2002; Radajewski et al., 2000). A similar approach should be feasible for N isotopes as well. The identification of biomarkers which may be specific for discrete groups of diazotrophs would foster this area (e.g., Carpenter et al., 1997). Another technology which holds great promise is nanoscale secondary ion mass spectrometry (NanoSIMS) which allows analysis of intracellular distributions of elements, including discrete isotopes (Kuypers and Jørgensen, 2007; Popa et al., 2007).

As we come to fully appreciate the implications of increasing atmospheric carbon dioxide concentrations on upper ocean chemistry and physical structure, it is important that we evaluate these impacts on major biogeochemical processes. N_2 fixation is an obvious ecological function that requires such evaluation. Preliminary assessment of the effect of temperature shifts on the distribution of Trichodesmium populations in the upper ocean have been made (Breitbarth et al., 2006). The physiological effects of increasing CO_2 have only recently been realized (Levitan et al., 2006; Barcelos e Ramos et al., 2007; Hutchins et al., 2007). These studies necessarily need to be extended to other relevant diazotrophs as well as to the effects of pH.

Other indirect effects of climate change may bear on marine N_2 fixation rates. Increasing atmospheric deposition of combined nitrogen is occurring and will continue to increase into the future, with direct implications to marine diazotrophy (Duce et al., 2008). Initial modelling efforts predict an negative effect on marine N_2 fixation (Krishnamurthy et al., 2007).

For many areas of the ocean, dust input is held to be an important source of nutrients for N_2 fixation. Changes of patterns of dust inputs are therefore expected to affect this key process (Moore et al., 2006). Lastly, expansion of oceanic OMZs is predicted (Stramma et al., 2008). We have discussed above the potential interactions of OMZs and marine N_2 fixation.

Research on marine N_2 fixation promises to continue to be a dynamic area with surprises around each corner.

NITRIFICATION IN MARINE SYSTEMS

Bess B. Ward

Contents

1. INTRODUCTION

Nitrification is the process whereby ammonium (NH_4^+) is oxidized to nitrite (NO_2^-) and then to nitrate (NO_3^-). It thus links the most oxidized and most reduced components of the nitrogen (N) redox cycle and helps determine the overall distributions of these important nutrients. Ammonium rarely occurs at significant concentrations in oxygenated habitats. It is recycled rapidly between heterotrophic and N_2 fixing organisms (which excrete NH_4^+ directly or release organic N that is microbially degraded to NH_4^+) and many heterotrophic and photosynthetic plankton (which utilize NH_4^+ as a N source) in the surface ocean.

Similarly, NO_2^- rarely accumulates in oxygenated habitats (see below for exceptions), although NO_2^- is an essential intermediate in several oxidation and reduction processes in the N cycle. Nitrate, the end product of nitrification, however, accumulates in the deep ocean, and seasonally in the deep water of lakes, where there is no demand for inorganic N by phytoplankton.

The oxidation of NH_3 to NO_2^- and of NO_2^- to NO_3^-, although thermodynamically favorable when linked to reduction of oxygen, has long been considered a biological process, with only minor known abiotic contributions. For example, photochemical oxidation of NH_4^+ to NO_2^- was debated in the 1930s (Rakestraw and Hollaender, 1936; ZoBell, 1933). It was eventually demonstrated that NO_2^- that results from high doses of UV radiation actually comes from reduction of NO_3^- (Armstrong and Tibbitts, 1968). Photochemical oxidation likely occurs in the surface ocean, but is a minor flux. Oxidation of NH_3 and amino-level N in organic compounds to N_2 gas linked to reduction of manganese oxide has been demonstrated in sediments (Hulth *et al.*, 1999; Luther *et al.*, 1997) and this pathway may have significant ramifications for the N cycle of sediments. Whether the Mn^{++} reduction pathway represents abiotic nitrification or anaerobic biological nitrification (see below) remains to be resolved.

Ammonium often accumulates to quite high concentrations in anoxic sediments and in stratified waters where oxygen concentrations are very low, which is consistent with the obligate aerobic physiology of conventional nitrifying bacteria. Recently, however, a novel process referred to as anammox (for anaerobic NH_4^+ oxidation) has been elucidated and shown to be capable of oxidizing NH_4^+ to N_2 under anoxic conditions (Mulder *et al.*, 1995; van de Graaf *et al.*, 1995). This process is in fact a form of denitrification, because its function is to remove fixed N form the system. Perhaps we should refer this process as oxidative denitrification or NH_4^+ denitrification, to distinguish it from conventional nitrification, which does not result directly in the loss of fixed N from the system. Anammox is elaborately discussed in the Chapter on denitrification by Devol, this volume.

The most important organisms in aerobic nitrification are the so-called nitrifying bacteria and the NH_3 oxidizing archaea (AOA). Until very recently, the known nitrifiers were restricted to the Proteobacterial phylum. The Proteobacterial genera are not all closely related to each other, but appear to have arisen from a photosynthetic ancestor, diverging before the ability to nitrify was developed in various groups (Teske *et al.*, 1994). There are two functionally distinct groups of nitrifiers: those that oxidize NH_4^+ to NO_2^- (NH_3-oxidizing bacteria and archaea, AOB and AOA) and those that oxidize nitrite to NO_3^- (NO_2^--oxidizing bacteria, NOB). No organism is known to carry out both reactions. These unique metabolic traits are not without costs; the chemolithoautotrophic lifestyle enables nitrifiers to exploit a unique niche in natural systems, but also confers constraints such as slow growth and inflexible nutritional requirements.

A new group of aerobic NH_3-oxidizing nitrifiers was recently discovered, first by detection of NH_3 oxidizing genes of apparent Archaeal origin in environmental metagenomic libraries (Schleper *et al.*, 2005) and subsequently verified with the cultivation of a strain of Archaea (NH_3-oxidizing archaea, AOA) that oxidizes NH_3 to NO_2^-, apparently using a pathway very much like that known in AOB

(Konnecke *et al.*, 2005). It now seems likely that AOA are more abundant than AOB in marine systems (Wuchter *et al.*, 2006), and are also prevalent in soils (Leininger *et al.*, 2006).

Several other useful reviews are available (Hagopian and Riley, 1998; Kaplan, 1983; Ward, 1986, 2000, 2002; Ward and O'Mullan, 2005). The 2002 review contains expanded information on the molecular ecology of nitrifiers, the 2005 chapter contains detailed information on methods for both rate measurement and molecular ecological investigations of AOB, and the present chapter contains new information on the NH_3-oxidizing Archaea, which were unknown at the times of the earlier reviews.

2. Nitrifying Microorganisms

2.1. Aerobic nitrification

2.1.1. Autotrophic nitrification

Most of the aerobic nitrification that occurs in natural habitats is thought to be performed by obligately autotrophic, or in a few cases, mixotrophic, bacteria and archaea. The classical autotrophs are best known and have been assumed to be responsible for the major fluxes in this pathway, so we shall consider them first.

Most of our knowledge of autotrophic nitrifiers derives from studies on cultivated strains, and the best known of those are the NH_3-oxidizing genus *Nitrosomonas* and the NO_2^--oxidizing genus, *Nitrobacter*. The cultured autotrophic nitrifiers, both NH_3 oxidizers and NO_3^- oxidizers, depend on CO_2 as their major carbon source and fixation is carried out via the Calvin cycle. It is estimated that CO_2 fixation accounts for about 80% of the energy budget of an autotroph (Forrest and Walker, 1971; Kelly, 1978). In addition, the use of NH_4^+ or NO_2^-, respectively, as the sole source of reducing power for this autotrophic growth is relatively inefficient: about 35 mol of NH_4^+ or 100 mol of NO_3^- must be oxidized to support fixation of a single mole of CO_2 (Baas Becking and Parks, 1927). This "perverse insistence" on fixing their own CO_2, utilizing a unique but low yield energy source (Wood, 1986), accounts for their well deserved reputation for slow growth, even under optimal conditions in the laboratory. The commonly cultivated strains of *Nitrosomonas* and *Nitrobacter* have minimal generation times of 7–13 h (Bock *et al.*, 1989).

The only cultivated AOA, *Nitrospumilus maritimus*, depends on CO_2 as its only carbon source and the presence of even low levels of organic carbon were inhibitory to growth. The pathway of CO_2 fixation is, however, unknown. Hyperthermophilic Crenarchaeota generally utilize a 3-hydroxypropionate pathway or a reductive TCA cycle for autotrophic carbon fixation. Another cultivated marine Crenarchaeota strain, *Cenarchaeum symbiosum*, a sponge symbiont, appears to use the 3-hydroxypropionate pathway. It cannot be concluded on this basis which pathway is used by the AOA, but it very likely that is not the Calvin cycle. *N. maritimus* had a minimal generation time of 21 h, longer but roughly on the same scale as AOB.

The overall reaction for NH_3 oxidation (Eq. (5.4)) shows that the process consumes molecular oxygen and produces hydrogen ions, in addition to NO_2^-. A requirement for molecular oxygen occurs in the first step of the oxidation (Eq. (5.1)), which is catalyzed by a monooxygenase (NH_3 monooxygenase, AMO). The uncharged gaseous NH_3 is the actual substrate for AMO, as demonstrated by the pH dependence of the reaction rate (Suzuki et al., 1974; Ward, 1987a). Synthesis and activity of AMO in N. europaea, a terrestrial model organism, respond directly to NH_3 concentration (Stein et al., 1997), albeit at levels much greater than observed in the marine water column. Some AOB accumulate very high levels of NH_4^+ internally, however (Schmidt et al., 2004a), so the effective concentrations might not be those detected in the environment. Ammonia monooxygenase has never been completely purified and assayed in cell free conditions, although its gene sequence has been derived for both Nitrosomonas and Nitrosococcus type AOBs (Alzerreca et al., 1999; Klotz and Norton, 1995; Sayavedra-Soto et al., 1998). AMO contains copper and probably also iron in its active form (Zahn et al., 1996).

The immediate product of AMO is hydroxylamine, which is further oxidized by hydroxylamine oxidoreductase (HAO) to NO_2^- (Eq. (5.2)). AOA apparently do not possess the hydroxylamine reductase gene, so the pathway of ammonia oxidation in these organisms must be quite different from that outlined here for AOB. Oxygen is also consumed by the terminal oxidase (Eq. (5.3)), as a result of electron transport generating ATP for cellular metabolism.

$$NH_3 + O_2 + 2H^+ + 2e^- \rightarrow NH_2OH + H_2O \, (\text{ammonia monooxygenase})$$
$$(5.1)$$

$$NH_2OH + H_2O \rightarrow NO_2^- + 5H^+ + 4e^- \, (\text{hydroxylamine oxidoreductase})$$
$$(5.2)$$

$$2H^+ + 0.5O_2 + 2e^- \rightarrow H_2O \, (\text{cytochrome oxidase}) \qquad (5.3)$$

$$NH_3 + 1.5O_2 \rightarrow NO_2^- + H_2O + H^+ \qquad (5.4)$$
The overall reaction is energy yielding, and allows sufficient ATP production to support reverse electron transport for CO_2 fixation. However, the first step, oxidation of NH_3 to hydroxylamine, requires the input of reducing power. The second step, hydroxylamine oxidation, yields four electrons. These join the electron transport chain at the level of ubiquinone, from which two are shunted back to AMO for activation of NH_3. The N oxidation and electron transport pathways in Nitrosomonas are linked in the cytoplasmic membrane and periplasmic space; detailed information from the N. europaea genome (Chain et al., 2003) is consistent with the previous biochemical characterizations of the system (Whittaker et al., 2000). Depending on conditions (and enhanced at low oxygen concentrations), nitric oxide (NO), nitrous oxide (N_2O) and even dinitrogen gas (N_2) have been reported as secondary products

in autotrophic NH_3 oxidation by both marine and terrestrial strains (Schmidt et al., 2004b; Zart and Bock, 1998). Although N_2O and NO can be produced in vitro by HAO from hydroxylamine (Hooper and Terry, 1979), reduction of NO_2^- appears to be the dominant pathway in whole cells (Hooper et al., 1997; Poth and Focht, 1985; Remde and Conrad, 1990). Nitrite reductase activity has been demonstrated in Nitrosomonas europaea (DiSpirito et al., 1985; Miller and Wood, 1983) and in several marine AOB (Casciotti and Ward, 2001). Genes with homology for the copper type nitrite reductase and the nitric oxide reductase of heterotrophic denitrifiers have been detected in a group of marine Nitrosomonas isolates (Casciotti and Ward, 2001, 2005). Thus it appears that the marine AOB produce N_2O by a pathway that is homologous with that in denitrifiers (''nitrifier denitrification''). The pathway for nitrous oxide production in AOB remains controversial, however, because N. europaea mutants with nonfunctional NO_2^- reductase genes can also produce N_2O (Beaumont et al., 2002), implying that an alternative pathway is present in some strains. It remains to be verified whether marine nitrifiers exhibit the same phenomenon. There is evidence from the genomes of AOB that N. europaea, N. marina and N. oceani contain different suites of electron transport molecules and quite different NO_2^- reductase genes (Chain et al., 2003; Klotz et al., 2006), which may imply they also have different mechanisms for N_2O production. It remains to be determined whether AOA have similar pathways or capabilities.

The biochemistry of NO_2^- oxidation is simpler than NH_3 oxidation because it is only a two electron transfer and involves no intermediates. The additional oxygen atom in NO_3^- is derived from water (Eq. 5.5), and the molecular oxygen that is involved in the net reaction (Eq. 5.7) results from electron transport involving cytochrome oxidase (Eq. 5.6).

$$NO_2^- + H_2O \rightarrow NO_3^- + 2H^+ \text{(nitrite oxidoreductase)} \qquad (5.5)$$

$$2H^+ + 0.5O_2 \rightarrow H_2O \text{(cytochrome oxidase)} \qquad (5.6)$$

$$NO_2 + 0.5O_2 \rightarrow NO_3^- \qquad (5.7)$$
The energy yield of NO_2^- oxidation is even less that that of NH_3 oxidation, necessitating the oxidation of vast amounts of NO_2^- in order to fix small amounts of CO_2. For both processes, therefore, the biogeochemical impact is greater on the N cycle than on the C cycle.

The biomass produced by primary fixation of CO_2 by nitrifiers can be significant in some habitats. Under sea ice in Antarctica (Horrigan, 1981), an anchialine cave in the Yucatan Peninsula, Mexico (Pohlman et al., 1997) and the Mississippi River Plume in Gulf of Mexico (Pakulski et al., 2000b) are examples. In these cases, the significance of autotrophic nitrification as an in situ source of organic carbon is enhanced relative to the production of organic matter by photosynthesis. Photoautotrophic carbon production is minimal due to the absence of light caused by ice cover, the geometry of the cave itself, and in the Mississippi River system, high levels of suspended matter, respectively. Chemoautotrophy might also be a significant source of in situ production on sinking

particles (Karl *et al.*, 1984) and in hydrothermal plumes where elevated NH_4^+ (and perhaps methane) concentrations could support NH_3-oxidizing bacteria (Cowen *et al.*, 1998; Lam *et al.*, 2004). It now appears that AOA comprise a significant fraction of the prokaryotic cells in seawater (Wuchter *et al.*, 2006), but it is not known to what extent these cells are obligate autotrophs. If they possess a wider metabolic repertoire than the typical bacterial nitrifiers, i.e., if they predominantly access carbon and energy sources other than CO_2 and NH_4^+, they may make a very important contribution to microbial biomass that is not linked to nitrification.

a. **Phylogeny of bacteria and archaea involved in nitrification:** The history of the study of nitrifying bacteria has been described elsewhere (Ward, 2002; Watson *et al.*, 1989) and only the current status of their diversity and evolutionary relationships will be summarized here. The classic species distinctions were based on cell shape and the arrangements of internal membranes (Koops and Moller, 1992; Watson *et al.*, 1989). These have been largely superceded by the evolutionary relationships deduced from 16S rRNA sequencing.

The phylogeny of bacterial nitrifiers (Teske *et al.*, 1994) shows that most of them are descendents of a common ancestor that was photosynthetic, rather than descending from a common ancestral nitrifier. Extensive phylogenetic trees depicting the relationships among cultivated nitrifiers, and the relationships of sequences obtained without cultivation from environmental samples, are available in the publications cited in this section and are not reproduced here.

The NH_3-oxidizing bacteria (AOB), including the marine AOB, fall into two major phyla in the Proteobacteria (Koops *et al.*, 2003; Purkhold *et al.*, 2003). The β subdivision species, containing genera known as *Nitrosospira* and *Nitrosomonas*, have been the subject of many recent studies. The main tool for investigating them in both culture and environmental samples is polymerase chain reaction (PCR) followed by cloning and DNA sequencing. On the basis of 16S rRNA sequence analysis, several clusters and a large amount of microdiversity within clusters has been detected in a wide variety of environments, both terrestrial and aquatic. Stephen *et al.* (1996) surveyed enrichment cultures and gene libraries of soils and marine sediments and found that *Nitrosomonas* sequences were more often associated with enrichment cultures and *Nitrosospira* with libraries. Smith *et al.* (2001) compared the phylogenetic affiliations and diversity of AOB 16S rRNA clone libraries and enrichment cultures obtained from the same marine sediment samples from a seawater loch being used for salmon farming. Only one (a *Nitrosomonas* type) of 18 enrichment cultures was represented in the 40 AOB clones retrieved without culturing. *Nitrosospira*-like sequences are often dominant in NH_3-oxidizer sequence clone libraries retrieved from the oceanic environments (Bano and Hollibaugh, 2000; O'Mullan and Ward, 2005).

A few generalities linking species or strains to environmental conditions have emerged. For example, McCaig *et al.* (1999) investigated the community structure of β-subdivision AOB in marine sediments underlying fish farms, and found a novel *Nitrosomonas* group whose distribution correlated with elevated NH_4^+ concentrations. Purkhold *et al.* (2000) summarized the ecological characteristics of the known cultivated strains and the major clusters defined by environmental

sequences for the betaproteobacterial AOB. None of the major clades are restricted to seawater. There are two major clades, one in the *Nitrosospira* cluster and one in the *Nitrosomonas* cluster, which have been reported primarily from marine environments for which no cultivated representatives are known. These findings suggest that the *Nitrosomonas* lineages are less common in natural samples than *Nitrosospira*s, and raise concerns about biases introduced by relying on pure culture techniques.

The γ subdivision NH_3 oxidizers are represented by a single genus containing two species, *Nitrosococcus oceani* and *N. halophilus*, which have only been reported from marine or saline environments. Several different strains of *N. oceani* exist in culture, derived from various locations in the Atlantic and Pacific Oceans, but they all appear to be closely related (Ward and O'Mullan, 2002). *N. oceani* has been detected by immunofluorescence and by PCR in saline lakes in Antarctica (Voytek *et al.*, 1999) and in various marine systems (O'Mullan and Ward, 2005; Ward and Carlucci, 1985; Ward and O'Mullan, 2002; Ward *et al.*, 1989a) and by immuno-fluorescence in the Mediterranean Sea (Zaccone *et al.*, 1996). Two strains of *N. halophilus* were isolated from a salt lake and a salt lagoon, and both have NaCl optima of about 700 mM, compared to 500 mM for *N. oceani* (Koops *et al.*, 1990). Compared with the large amount of data available for the betaproteobacterial AOB, there are few reports of *Nitrosococcus*-like sequences obtained from the marine environment and none from freshwater environments, and no reports of finding *N.halophilus*-like sequences. This lack of information on *Nitrosococcus* may be a matter of PCR primer specificity and limited research effort at present, but it just as likely implies that *Nitrosococcus* is a minor component of the AOB assemblage.

The 16S rRNA sequence on only one AOA is currently available, and that sequence places *Nitrosopulilus maritmus* within the low-temperature marine Crenarch-aeota, a group abundant in seawater and distinct from low temperature Crnarchaeota in soils (Konnecke *et al.*, 2005). Phylogenetic analysis of several hundred AOA partial *amoA* sequences identified major groups that clustered by environment; water column sequences clustered together whether from the Black Sea, Monterey Bay or the eastern tropical North Pacific, while sediment sequences clustered together with other sedi-ment and soil sequences (Francis *et al.*, 2005). It is assumed that these are all derived from Crenarchaeota, but this is a large and more diverse group that previously appreciated, so the phylogeny of AOA remains largely unexplored.

The new phylogeny of NO_2^- oxidizing bacteria (Bock and Wagner, 2003), based on 16S rRNA sequences, shows that the best known autotrophic NO_2^- oxidizer, *Nitrobacter*, comprises a coherent genus in the α subdivision of the Proteo-bacteria. This genus is most closely related to non nitrifying genera that contain autotrophic members and strains capable of denitrification (Teske *et al.*, 1994). Like *Nitrosococcus oceani*, *Nitrococcus mobilis* (Watson and Waterbury, 1971) belongs to the γ subdivision of the Proteobacteria, the only example of both NH_3- and NO_2^--oxidizing phenotypes occurring in the same subdivision. *Nitrospina gracilis*, the only species in this genus, represented by two isolates (Watson and Waterbury, 1971), is assigned to the δ subdivision of the Proteobacteria. Possibly the most unusual nitrifier is the genus *Nitrospira*, which is represented by only two isolates, and does not share a common lineage with the other nitrifiers. A novel *Nitrospira* strain,

N. moscoviensis, isolated from a heating system in Moscow, Russia, was assigned to a new genus outside of the Proteobacteria (Ehrich *et al.*, 1995). These authors reanalyzed the *Nitrospira marina* sequence, which Teske *et al.* (1994) had placed in the δ Proteobacteria, and concluded that *Nitrospira* belonged outside the Proteobacteria, in a deeply branching cluster related to *Leptospirilla*. Sequences closely related to this group have now been reported from biofilms and freshwater sediments (Daims *et al.*, 2001), but the only report so far of *Nitrospira*-like sequences from marine clone libraries is from a sediment sample at 2339 m (Li *et al.*, 1999). In stream sediments (Altmann *et al.*, 2004), *Nitrospira* cells (enumerated by fluorescence *in situ* hybridization) were 5–9 times more abundant than *Nitrobacter* cells. The marine isolate (Watson *et al.*, 1986) was obtained from the Gulf of Maine and the authors reported that similar cells were present in many enrichments, suggesting it is a common member of the marine nitrifier assemblage.

Except for *Nitrospira* and *Nitrospina*, all of the bacterial nitrifiers cluster in phyla that are characterized by photoautotrophic ancestry and are themselves characterized by the possession complex intracytoplasmic membranes. These membranes are thought to be the site of the redox proteins involved in N oxidation, and therefore homologous with the photosynthetic membranes of photosynthetic bacteria and cyanobacteria. Nevertheless, the bacterial nitrifiers are polyphyletic, and the phenotype has apparently arisen independently numerous times. The homology of the functional genes (*amo, hao*) involved in their physiology implies gene transfer events, however, rather than independent evolution of these enzymes. The fact that the *amoA* genes from AOB and AOA are homologous raises the question of the ultimate origin of the NH_3 oxidizing phenotype. If the ancestral Crenarchaeota were thermophiles, it is possible that NH_3 oxidation originally arose in thermophiles and spread from the archaea to the bacteria. Internal compartmentalization was not observed in *N. maritimus*, but whether some of the AOA possess internal cytoplasmic membranes has not been established.

An understanding of the phylogeny of nitrifying bacteria is relevant to the study of nitrification in aquatic habitats because it has implications for detection and quantification methods. Although the bacterial nitrifiers are polyphyletic, they are not so diverse as to be unmanageable; their affiliation within a small group of lineages makes them amenable to identification and detection using a relatively small suite of molecular probes. This approach forms the basis of much current knowledge on the diversity and distribution of autotrophic nitrifying bacteria, and has already made important contributions to the study of nitrifying archaea as well.

The autotrophic bacterial NH_3 oxidizers show significant metabolic and morphological similarities with another group of autotrophic bacteria, the methane oxidizers. They are also closely related phylogenetically to the methane oxidizers, in both the γ and β subdivisions (Teske *et al.*, 1994). Prior to the availability of ribosomal RNA sequence data for determination of phylogenetic relationships, it had been reported that NH_3-oxidizing nitrifiers were capable of methane oxidation and vice versa (Dalton, 1977; Jones and Morita, 1983; Ward, 1987a). Thus it was an interesting verification of the metabolic studies when it was reported that the central genes in the two pathways, genes encoding NH_3 monooxygenase in the nitrifiers and methane monooxygenase in the methanotrophs, were evolutionarily related

(Holmes *et al.*, 1995). It has not been possible to determine unequivocally which process is the natural or predominant one for some nitrifiers and methanotrophs in nature (see later text).

2.1.2. Heterotrophic nitrification

The autotrophic NH_3 oxidizers are considered to be obligate chemolithoautotrophs with no source of energy other than NH_3 and no net source of cellular carbon other than CO_2. Obligate autotrophy had been attributed to the absence of one or more enzymes in the tricarboxylic acid cycle, but inspection of the complete genome for *Nitrosomonas europaea* shows that a complete TCA cycle is present (Chain *et al.*, 2003). *N. europaea* has limited genetic capability for transport and metabolism of organic molecules, but the basis for its apparent obligate dependence upon NH_4 and CO_2 is still not entirely clear.

The autotrophic NO_2^- oxidizers have been reported to exhibit various degrees of heterotrophy, although generation times and time required for adaptation to new substrates is on the order of weeks (Bock, 1976). Recently completed genomes of terrestrial nitrite oxidizers indicate that they too possess a complete TCA cycle, but do not have the complete pathways for utilization of carbon substrates larger than 3 carbons (Starkenburg *et al.*, 2006). The NOB also have very limited organic transport capabilities (Starkenburg *et al.*, 2008). Marine strains for AOB and NOB have not been thoroughly investigated for their heterotrophic capabilities, and the potential for them to exhibit this metabolism in the ocean is unknown. The only cultivated AOA is apparently an obligate chemoautotroph, but uncultivated marine Crenarchaeota are apparently capable of amino acid assimilation (Ouverney and Fuhrman, 2000), so the extent of the AOA metabolic repertoire remains an open question.

Heterotrophic nitrification has been reported for bacterial genera including *Bacillus*, *Paracoccus*, *Pseudomonas*, *Thermus*, *Azoarcus*, and the fungus, *Aspergillus*. Heterotrophic nitrification usually refers to the production of NO_2^- or NO_3^- either from NH_4^+ or from organic substrates by heterotrophic bacteria, and is best studied in a few denitrifiers where it is linked to aerobic denitrification (Stouthamer *et al.*, 1997). The enyzmology of the process is unknown (Nemergut and Schmidt, 2002) and its physiological role is not understood, as it usually cannot support growth and in fact, reduces growth yield compared to denitrification alone.

Liberation of NO_3^- from organic intermediates has also been reported for green algae (Spiller *et al.*, 1976) and N-fixing legumes (Hipkin *et al.*, 2004) but the relevance of these processes in the marine environment is unknown. Although the organisms performing them are autotrophic, the processes might be considered heterotrophic because the released N is derived from an organic intermediate.

It has been argued that heterotrophic nitrification involves enzyme systems that are quite different from those of the autotrophs (Wehrfritz *et al.*, 1993) and that heterotrophic nitrification cannot serve as an energy generating mechanism (Castignetti, 1990), as the autotrophic process does. In the aerobic denitrifiers, which are also capable of nitrification, the initial enzyme, AMO, appears to be quite similar to the enzyme in autotrophic nitrifiers. However, HAO differs significantly and in the heterotrophs, is a smaller, simpler enzyme that performs a two electron transfer (instead of the four electron transfer of the autotrophic HAO) and

releases nitroxyl as the product, rather than NO_2^- (Richardson *et al.*, 1998). Thus, no electrons are available for reverse electron transport in the heterotrophic system and the purpose of the process appears to be a means of disposing of excess reductant in times of redox stress, rather than harvesting that reductant for cellular energy.

In aquatic systems, the most important heterotrophic nitrifiers are thought to be a class of denitrifiers which are capable of aerobic denitrification, and which can also oxidize NH_3. The organism in which these physiologies were first described is now known as *Paracoccus pantatrophus* (formerly known as *Thiosphaera pantotropha*). *P. pantotrophus* oxidizes NH_3 to NO_2^- using an enzyme that exhibits important similarities and differences compared to AMO from autotrohpic nitrifiers (Moir *et al.*, 1996). The NO_2^- so generated can be released into the medium or denitrified to N_2. Denitrification of NO_2^- or NO_3^- can occur under atmospheric levels of oxygen (Robertson *et al.*, 1995). Aerobic denitrifiers have mostly been isolated from wastewater treatment systems, and their prevalence and ecological significance is unknown in natural aquatic systems.

Because autotrophic nitrification is such a hard way to make a living, it might seem curious that heterotrophic nitrification is not more common. The amounts of NO_2^-or NO_3^- formed are usually quite small compared to autotrophic nitrification, however, and the energetics are apparently even less favorable than for the autotrophic nitrifiers (Stouthamer *et al.*, 1997). There are no substantive reports of heterotrophic nitrification in the marine environment, despite its mention in anecdotal reports and suggestion of it as a possible explanation for curious observations (Hovanec and DeLong, 1996).

Thermophilic heterotrophic nitrifiers, capable of oxidizing NH_3 to NO_2^-, were isolated from several hydrothermal vent habitats (Mevel and Prieur, 1998). Most of the isolates were NO_3^- reducers or denitrifiers and exhibited a wide diversity related to the genera *Thermus* and *Bacillus*. Because they are able to ammonify, nitrify and reduce NO_3^-, they would seem to possess most of the physiologies of importance in the N cycle. Such organisms may be common in mesophilic aquatic habitats, but have not been quantitatively investigated.

Heterotrophic strains capable of oxidizing NO_2^- have also been reported. Sakai *et al.* (1996) described several classes of heterotrophic strains that oxidized NO_2^- to NO_3^- with variable amounts of NO_3^- accumulation, depending partly on the denitrification capabilities of the strains. Strains which were capable of both oxidation and reduction of N oxides were shown to switch between the two directions of conversion depending on the oxygen tension of the culture (Sakai *et al.*, 1997).

Heterotrophic nitrification has been studied in terrestrial systems, especially acid forest soils, where it has been difficult to document autotrophic nitrification. Experiments using isotopes to differentiate production of NO_3^- from inorganic and organic substrates in a forest system found that heterotrophic nitrification accounted for less than 10% of the total nitrification rate (Barraclough and Puri, 1995). No information of this sort is available on the occurrence or significance of heterotrophic nitrification in aquatic systems. The potential for NH_3 and NO_2^- oxidation by heterotrophic bacteria in aquatic systems warrants further exploration, and the capability may be present in many strains already in culture. If heterotrophic nitrification is common in nature, then a focus on autotrophic nitrification as the

model system and the basis for estimation of rates is too narrow and unrealistic. On a per cell basis, heterotrophic nitrification is much slower than is autotrophic nitrification, and the relative impact on N turnover must be greater by autotrophs due to their total dependence on N oxidation for energy. Nevertheless, widespread abundance of more numerous heterotrophic nitrifiers could compete in importance with the smaller number of slow growing autotrophs. Facultative nitrifiers that grow heterotrophically most of the time would seem to be an advantageous compromise, but mixotrophy is surprisingly uncommon in the microbial world (Whittenbury and Kelly, 1977). It is intriguing to wonder whether AOA will be an exception to this generalization. If heterotrophic nitrification were significant, it might not be detectable in the net stoichiometry of organic matter remineralization.

2.2. Anaerobic nitrification

The interest in anaerobic nitrification and aerobic denitrification arises mainly from the necessity to treat large volumes of wastewater to reduce N loading before release into natural waters. Classical nitrification and denitrification are environmentally incompatible processes, the first being obligately aerobic and the second induced only under conditions of anoxia. It is therefore usual to involve two steps in wastewater treatment, an aerobic step to convert NH_3 to NO_3^- and a subsequent anaerobic step, to convert the NO_3^- to N_2. If the two steps could be combined in one organism under either aerobic or anaerobic conditions, much time and money would be saved in wastewater treatment. And clearly, if a single organism is capable of combined nitrification and denitrification in a bioreactor or water treatment plant, such an organism could be of considerable importance in the natural environment as well.

The heterotrophic nitrifier mentioned earlier, *P. pantatrophus*, carries out at least part of both processes under aerobic conditions. *P. pantatrophus* was originally isolated from wastewater and its ability to denitrify aerobically, as well as this ability in several other conventional heterotrophic denitrifiers, has been confirmed (Robertson *et al.*, 1995).

Autotrophic nitrifying bacteria exhibit some abilities for anaerobic metabolism as well. Enrichment cultures under chemolithotrophic conditions and very low oxygen concentrations catalyzed the net removal of NH_4^+ as N_2 (Muller *et al.*, 1995). Bock and coworkers have shown that *Nitrosomonas eutropha* produces gaseous products, mainly NO and N_2, during growth on nitrogen dioxide gas (NO_2) and NH_3 (Schmidt and Bock, 1997). The process proceeds at a slower rate than NH_3 oxidation in the presence of a normal air atmosphere and supports cell growth. Additions of NO_2 and NO enhanced the complete removal of N in the form of NH_3 and organic N without the addition of organic carbon substrates (Zart and Bock, 1998).

A completely novel process in which NH_3 and NO_2^- are converted anaerobically to N_2 was reported several years ago (Mulder *et al.*, 1995; van de Graaf *et al.*, 1995) and the process has been quantitatively described (Jetten *et al.*, 1998; Strous *et al.*, 1999). The organisms responsible for this novel metabolism have been identified as *Planctomyces* (Strous *et al.*, 1999), and the genome of one strain has

been almost completely sequenced (Strous *et al.*, 2006). Referred to as "anammox" (anaerobic NH_4^+ oxidation), the process in wastewater involves a consortium of the planctomycete organism and an autotrophic NH_3 oxidizer such as *Nitrosomonas europaea* or *N. eutropha*. Ammonia is oxidized to NO_2^- by the autotroph under microaerophilic conditions. The NO_2^- so produced is reduced to N_2 by the planctomycete. Both oxygen and NO_2^- concentrations are maintained at nearly undetectable levels by the metabolism of the members of the consortium, and while both organisms grow quite slowly (generation times for the planctomycete of ≥ 11 days are reported), the net removal of NH_4^+ occurs at a rate 25 times faster than that reported for N removal by anaerobic autotrophic nitrification alone (Jetten *et al.*, 1998).

The anammox process was discovered and characterized in anaerobic wastewater treatment systems, and 16S rRNA sequences identified as belonging to the plancto-mycete member have been detected in several such systems. Research into the occurrence of the process and presence of the organisms in natural aquatic systems has proceeded rapidly in the last few years. Anammox has now been documented in estuarine (Risgaard-Petersen *et al.*, 2004a; Tal *et al.*, 2005; Trimmer *et al.*, 2003; Trimmer *et al.*, 2005) and marine (Dalsgaard and Thamdrup, 2002; Thamdrup and Dalsgaard, 2002) sediments and in the water column of the Black Sea (Kuypers *et al.*, 2003) and Golfo Duce, an enclosed Bay on the west coast of South America (Dalsgaard *et al.*, 2003) and most recently in the shelf waters of the Benguela upwelling zone (Kuypers *et al.*, 2005), and the OMZs of the eastern tropical South Pacific (Thamdrup *et al.*, 2006; Hamersly *et al.*, submitted for publication). Anammox is an oxidative process and there appear to be some enzymatic similarities between anammox and aerobic NH_3 oxidation (Strous *et al.*, 2006), the ecological significance of anammox is the same as denitrification, i.e., the loss of fixed N in anoxic environments. Therefore, for a full treatment of anammox, please see Chapter 6, Denitrification by Devol, this volume.

Nitrite oxizers are also reported to possess an anaerobic metabolism and even to grow under denitrifying conditions (Freitag *et al.*, 1987). Subsequent work showed that ATP was not produced during NO_2^- reduction (Freitag and Bock, 1990). Very little work has been done in this area with marine NO_2^- oxidizers, but NO_2^- oxidation has been reported in environments where very little oxygen is present (see later text).

In addition to the unconventional activities of conventional nitrifiers and deni-trifiers and the discovery of novel N metabolisms in new organisms, it has also been recently proposed that a short circuit of the nitrification/denitrification couple can also be accomplished abiotically. In marine sediments, which typically contain relatively high manganese levels, N_2 can be produced by the oxidation of NH_4^+ and organic N by manganese dioxide in air. The reduced Mn^{++} thus formed can be reoxidized by oxygen to continue the oxidation of NH_4^+, or can reduce NO_3^- to N_2 (Luther *et al.*, 1997). While the free energy of these coupled reactions is shown to be favorable, it remains to be seen whether the abiotic process can be unequivocably identified in natural systems and the degree to which it may compete with the biologically catalyzed processes. Hulth *et al.* (1999) detected anoxic production of both NO_2^- and NO_3^- in marine sediments, concurrent with the production of

reduced manganese. The NO_3^- production was directly proportional to the initial manganese oxide content, and the NO_3^- was subsequently depleted, apparently by denitrification. A series of linked redox cycles in which anoxic nitrification, coupled to manganese reduction, was linked in series to anoxic organic matter oxidation through several biogeochemical reductants, including iron and hydrogen sulfide, was proposed as the mechanism (Hulth *et al.*, 1999). These authors suggested that the lithotrophic nitrification they observed is biologically mediated and potentially of significance in the N cycle at sites where oxidized metals are reworked into anoxic sediments. Other authors have failed to detect significant coupling between Mn^{++} and NH_4^+ in anoxic sediments (Thamdrup and Dalsgaard, 2000). ^{15}N tracer experiments, including the kind used to demonstrate anammox (e.g., Dalsgaard and Thamdrup, 2002) have also shown that the anaerobic oxidation of NH_4^+ via manganese is not a significant flux, at least in some sediments (Risgaard-Petersen *et al.*, 2004a; Thamdrup and Dalsgaard, 2000).

Anoxic NH_3 oxidation, whether it results directly in N_2 formation (as in anammox) or in NO_3^- production (when linked to manganese reduction), would introduce new links into the aquatic and sediment N cycle. Failure to account for anoxic NH_3 oxidation might lead to an underestimate of NH_4^+ removal, because the products do not accumulate; they are either lost to the atmosphere immediately, or rapidly reduced by the next step in the anaerobic cycling of organic matter.

3. ROLE OF NITRIFICATION IN THE MARINE NITROGEN CYCLE

Many forms of organic and inorganic N can be utilized by phytoplankton, and the transformation of NH_4^+ into NO_3^- by nitrification does not change the absolute inventory of N available for algal nutrition. In soils, the different ionic properties of NH_4^+ and NO_3^- are important in determining inorganic N availability in the soil solution, but in aquatic systems, the properties of these ions are less important to their distributions. Because of the different chemical properties and varying preferences, abilities, and metabolic costs of utilizing NH_4^+ versus NO_3^-, and the role of NO_3^- as a substrate for denitrification, however, this transformation is very important in marine systems.

Because NH_4^+ contains N at the oxidation level of proteins, it is readily assimilated by both phytoplankton and bacteria, and is a preferred N source. Ammonia oxidizers may be in competition for NH_4^+ with other planktonic organisms. The different physiological requirements of phytoplankton and nitrifiers probably play a role in determining exactly where in the water column NH_4^+ assimilation and NH_4^+ oxidation occur. As explained below, most nitrification occurs within or near the base of the euphotic zone in the upper 100 or so meters of the ocean. However, there is usually very little NO_3^- in the surface ocean, due to utilization by phytoplankton, except in "high nutrient low chlorophyll" regions and when supplied by episodic events such as regional upwelling. The NO_3^- in the deep water of the oceans has accumulated from nitrification because phytoplankton assimilation is essentially zero below the euphotic zone. It is because of nitrifiers

that N accumulation in the deep waters is in the form of NO_3^-, rather than NH_4^+. The deep NO_3^- reservoir can be made available to phytoplankton by mixing, upwelling, and seasonal overturn. These physical processes bring cold deep nitrate-rich water up to the surface where, in the presence of light, phytoplankton can assimilate the NO_3^-. Thus, although NO_3^- is not usually abundant in surface waters, it is a very important N source for phytoplankton.

The NO_3^- that is produced by nitrification serves as a substrate for denitrification in low oxygen environments in both the water column and sediments (Devol, this volume). Although denitrification involves several semi-independent steps that need not function together, it is common for denitrifiers to begin the sequence with NO_3^- and to produce varying amounts of the other products depending upon the environmental conditions. Thus, although denitrifiers appear to have little in common with nitrifiers, the former are in fact dependent upon the latter – other than lightning and fertilizers, nitrifiers are the only significant source of NO_3^-. Similarly, NO_2^- and NO_3^- are the oxidants in the anaerobic oxidation of NH_4^+. While NO_2^- can be produced by either nitrification or denitrification, the production of the oxidized forms ultimately depends on aerobic autotrophic nitrification. Thus the role of nitrifiers in the N cycle of marine systems is to link the oxidizing and reducing processes of the N cycle by converting NH_4^+ to NO_3^-.

Nitrification can also be an important sink for oxygen in aquatic environments. NO_3^- is released through the aerobic oxidation of organic matter and nitrification according to the classic Redfield stoichiometry (Redfield *et al.*, 1963):

$$(CH_2O)x(NH_3)\gamma(H_3PO_4) + (x + 2\gamma)O_2 \rightarrow xCO_2$$
$$+ \gamma HNO_3^- + (x + \gamma)H_2O^-$$
where $x = 106$ and $\gamma = 16$. In this formulation, oxygen consumption should be inversely related to NO_3^- production with a slope of $138/16 = 8.6$. In fully oxygenated sediments (i.e., carbon loading is not sufficient to exhaust the available oxygen), such relationships are often found. Grundmanis and Murray (1982) and Jahnke *et al.* (1982) reported ratios of 10.1 and 7 respectively, and both state that these are in reasonable agreement with the predicted stoichiometry once differential diffusivities are taken in to account. Redfield stoichiometry implies that nitrification is responsible for $32/138 = 23\%$ of the total oxygen consumption associated with organic matter diagenesis. In environments where denitrification and anammox occur, the net O_2/NO_3 stoichiometries may vary (Devol, this volume).

3.1. Distribution and abundance of nitrifiers in the marine environment

Although most strains of NH_3-oxidizing and NO_2^--oxidizing bacteria have characteristic intracytoplasmic membrane structures, which can be visualized by electron microsocopy, it is not possible to distinguish the otherwise nondescript cells from other bacteria and archaea in water samples using standard microscopic techniques for cell enumeration, e.g., epifluorescence microscopy with DNA fluorochromes.

Most probable number (MPN) methods relying on the appearance or disappearance of NO_2^- in dilution media have been used to estimate the abundance of NH_3 oxidizers and NO_2^- oxidizers, respectively, in aquatic environments. MPN approaches are widely used to estimate abundances of nitrifying bacterial populations in soils, but there are very few modern reports using this technique in marine systems. Examples of data on nitrifying bacterial abundanced are provided in Table 5.1. Bianchi et al. (1999) estimated the abundance of both NH_3 and NO_2^- oxidizers in the water column of the Mediterranean Sea in the Rhone River plume using MPN. Maximum abundances of both types were found in surface water of the stations closest to the river and reached levels of 3.5×10^4 cells ml^{-1} for NH_3 oxidizers and 1.2×10^4 for NO_2^- oxidizers. Ammonia plus NO_2^- oxidizing cells averaged less than 2% of the total microbial abundance. McCaig et al. (1999) used MPN to estimate the abundance of NH_3 and NO_2^- oxidizers in polluted sediments underlying marine fish farms. In the sample from directly underneath the fish cage, NO_2^- oxidizers were abundant and NH_3-oxidizers were not detected. Farther away from the cage, NH_3 oxidizers were detected, but NO_2^- oxidizers were not present above detection level at these stations. Hall (1986) estimated from data in a number of lake studies that the efficiency of recovery for MPN was 0.05–0.001% for NH_3 oxidizers. He also concluded that MPN abundances showed little correlation with observed nitrifying activities. This technique should, however, yield isolates of the most abundant cell type present, assuming it can grow under the enrichment culture conditions. Phillips et al. (2000) compared MPN and a competitive PCR method for enumeration of NH_3-oxidizing bacteria in estuarine sediments and detected 1–3 orders of magnitude higher abundances using cPCR (on the order of $10^5 = 10^6$ cells g^{-1}).

Immunofluorescence (IF) was first applied to the study of nitrifying bacteria in soil and lake systems by Schmidt and coworkers (e.g., Fliermans et al., 1974; Schmidt, 1978; Smorczewski and Schmidt, 1991; Stanley et al., 1979) and the method was subsequently used by Ward and coworkers to enumerate nitrifiers in seawater (e.g., Ward and Carlucci, 1985; Ward and Perry, 1980). In a small survey of marine and estuarine sites, Ward (1982) reported that Nitrosomonas serotypes were more abundant than Nitrosococcus and that total abundance of NH_3 oxidizers (Nitrosomonas plus Nitrosococcus serotypes) ranged from 10^4 cells ml^{-1} in Chesapeake Bay to 10^2 cells ml^{-1} in inshore ocean waters and $10–10^2$ cells ml^{-1} offshore. Maximum abundances (10^6 cells l^{-1} for both NH_3 and NO_2^- oxidizers) occurred near the bottom of the photic zone in the vicinity of the primary NO_2^- maximum in the Peru upwelling system (Ward et al., 1989a) but such characteristic patterns are not always detected. Nitrosococcus oceanus abundance, determined by IF, was positively correlated with temperature, particulate organic carbon and N and total bacterial abundance, and negatively correlated with dissolved oxygen, in brackish Mediterranian lagoons (Zaccone et al., 1996). There was no relationship between IF and MPN counts over the 20 month sampling period of this study.

Immunofluroescence requires that the target organisms be cultivated so that antibodies can be produced against the cells to be enumerated. The antibodies responsible for the cell-staining reaction are those that interact with components of the outer cell membrane, and the reaction can be very specific (Ward and Carlucci, 1985). This is both a strength and a disadvantage of the method. It allows

Table 5.1 Abundances of Nitrifying Bacteria Reported from Aquatic Systems

Location	Depth (m)	AOB cell abundance	NOB cell abundance	Method	Reference
Sediments					
Freshwater lake sediments	Surficial sediments	$8–37 \times 10^5$ cells g^{-1}	$21–67 \times 10^5$ cells g^{-1}	MPN	Smorczewski and Schmidt, 1991
Sediments under marine fish farm cages	0.5 cm core top	Up to 0.2×10^6 cells m^{-2}	Up to 25×10^6 cells m^{-2}	MPN	McCaig et al., 1999
Marine (saline) Water column environments		Cells ml^{-1}	Cells ml^{-1}		
Lake Bonney (Antarctica)	Oxic water column	Nitrosomonas 2×10^3		IF	Voytek et al., 1998
	Oxic water column	Nitrosococcus 0.8×10^3		IF	Voytek et al., 1998
Mediterranean lagoon	Oxic water column	Nitrosococcus $1–10^3$		IF	Zaccone et al., 1996
Peru upwelling	Ave over water column	Nitrosomonas + Nitrosococcus 0.3×10^3	Nitrobacter + Nitrococcus 0.2×10^3	IF	Ward et al., 1989a
Southern California Coastal waters	Ave over water column	Nitrosomonas + Nitrosococcus 0.3×10^3	Nitrobacter + Nitrococcus 0.3×10^3	IF	Ward and Carlucci, 1985
Chesapeake Bay	Ave over water column	Nitrosomonas+Nitrosococcus 10^7		IF	Ward, 1982

AOB – Ammonia-oxidizing bacteria; NOB – Nitrite-oxidizing bacteria; IF – Immunofluorescence; MPN – Most Probable Number

strain or species specific detection, so that distribution patterns can be discerned for individual types, but therefore does not allow an enumeration of total abundance for all similar physiological types. The necessity for cultivation of the antigenic strain also guarantees that most of the strains that are important in the ocean cannot be tested for cross reactivity and it seems likely that they are not detected by these assays.

The molecular methods that have been used to detect and investigate the diversity of NH_3 oxidizers in the ocean have not been widely adapted for their quantitative analysis and enumeration. This is in great contrast to the study of AOB and NOB in soils and freshwater systems, particularly wastewater bioreactor and biofilm environments (reviewed by Schramm, 2003), where competitive and quantitative PCR assays based on both 16S rRNA and *amoA* genes that are specific for nitrifiers have been used to enumerate cells of various subgroups of nitrifiers. In a study designed to test the adaptation of fluorescence *in situ* hybridization (FISH) identification of specific cells to automated enumeration by flow cytometry, Sekar *et al.* (2004) detected both *Nitrosospira* and *Nitrosomonas* sequences in their 16S rRNA clone libraries. They subsequently used an enhanced sensitivity method (catalyzed reported deposition [CARD-FISH) to enumerate cells of both types in water samples from the coastal North Sea. Probes for *Nitrosospira* and *Nitrosomonas* detected 3.4% and 4.0% of the total DAPI-stained cells in a sample from March 2003, but the same probes did not detect any cells from samples taken in August, September, and November 2002 at the same site (Sekar *et al.*, 2004). Lam *et al.* (2004) enumerated betaproteobacterial AOB using FISH in and near neutrally buoyant plumes emanating from hydrothermal vents in the Endeavor segment of the Juan de Fuca Ridge. Along with many other reduced substrates, the plumes often contain high NH_4^+ concentrations and thus might be expected to provide an enriched environment for NH_3 oxidizers. AOB reached maximal abundances of $1–1.4 \times 10^4$ cells ml^{-1} in the plume itself and were present at much lower levels (minimum of 0.04×10^4 cells ml^{-1}) in background (non-plume) samples. The cells were preferentially associated with particles, constituting up to 51% of the total cells enumerated by DAPI in the >3 μm particle fraction, whereas AOB constitued up to 4.9% of the free living cells enumerated by DAPI (Lam *et al.*, 2004). These numbers are 10-fold higher than previous AOB counts obtained by immunofluorescence from shallower depths in the open and coastal ocean (Ward *et al.*, 1982, 1989a) and comparable to those from nutrient rich environments such as Chesapeake Bay (Ward, 1982), suggesting an important role for nitrifiers in this environment. Depending on the specificity of oligonucleotide probes, genetic methods should detect higher numbers than IF, because of the specificity and culturability issues mentioned earlier.

Clone libraries may give some indication of the relative abundance of target organisms. In this case, it would be instructive to know the percentage of a total bacterial 16S rRNA clones that were identified as AOB or NOB- like sequences. AOB sequences are easily retrieved when targeted directly with AOB-specific primers, but are very rare in total 16S rRNA libraries.

The results from FISH and IF measurements show that nitrifying bacteria generally contribute a minor fraction of the total microbial assemblage in natural waters, with estimates ranging from 0.1% to 7.5% of the total cell number in the

water column. This generalization is consistent with the autotrophic nature of nitrifiers, which requires that individual cells process relatively large amounts of N for minimal return in terms of carbon assimilation. The abundances estimated for the hydrothermal vent plumes are quite high (Lam *et al.*, 2004), but consistent with environmental parameters that favor the autotrophic NH_3 oxidizing metabolism. Abundance data for NO_2^- oxidizers are almost non-existent and for NH_3 oxidizers very sparse. This is an area in which quantitative PCR and enhanced sensitivity single cell detection methods (e.g., CARD-FISH) could be very usefully applied. FISH and quantitative PCR assays for 16S rRNA and *amoA* genes detected up to 1000 fold greater abundances of Crenarchaeota than AOB in coastal North Sea water (Wuchter *et al.*, 2006), indicating that unlike AOB, the AOA can be a major contribution to the total microbial assemblage.

3.2. Methods for measuring nitrification rates in water and sediments

As with most biogeochemically important processes, there is no perfect method for direct measurement of nitrification rates. Potential artifacts arise from the use of incubations, but incubation free methods can also be problematic.

3.2.1. Changes in din concentration and specific inhibitors

The easiest experimental design might be simply to incubate samples and measure the concentrations of NO_2^- or NO_3^- over time. This approach provided some of the earliest evidence for the occurrence of biologically mediated nitrification (Rakestraw, 1936; von Brand *et al.*, 1937). Vaccaro (1962) estimated nitrification rates by measuring changes in NO_2^- and NO_3^- in incubated samples, from depths up to 800 m in the Sargasso Sea, in the presence of added NH_4^+ or mixed whole plankton. He reported that both additions stimulated the net production rate of NO_2^- or NO_3^-. In such an experiment, accumulation of NO_2^- or NO_3^- indicates net nitrification. A decrease in the concentration over time could be observed, however, even when nitrification is occurring, if consumption of NO_3^- or NO_2^- exceeds production in the incubation bottle. This is likely to be the case in surface waters where the low concentration of fixed N relative to high biological demand means that large fluxes can be obscured by tight coupling between production and consumption terms.

The simple nutrient measurement approach can be modified by the use of specific inhibitors. Chemicals that specifically inhibit either NH_4^+ oxidation (e.g., acetylene, allylthiourea, methyl fluoride, N–serve) or NO_2^- oxidation (chlorate) are added to replicate incubation bottles (Bianchi *et al.*, 1997; Billen, 1976). The bottles must be incubated in the dark to prevent assimilation of by phytoplankton. A decrease in the concentration of NO_2^- over time in the bottles in which NH_4^+ oxidation was inhibited provides an estimate of the NO_2^- oxidation rate. The rate of NO_2^- increase in the bottles to which NO_2^- -oxidation inhibitor was added approximates the rate of NH_4^+ oxidation. Aside from the overall limitations of

bottle incubations, the potential artifacts associated with the inhibitor approach relate to the conditions of the incubation:

(1) Preventing production by phytoplankton probably has cascading effects on the activities of other microbes in the bottle, such that the rate of NH_4^+ mineralization is reduced, therefore changing the source term for the nitrification substrate.

(2) Incubating in the dark may release the nitrifiers from light inhibition such that the measured rate exceeds the *in situ* rate.

(3) Incubations typically last 48 h, which is sufficient to overcome the lag induced by light inhibition, but is also long enough to create quite unnatural conditions.

The search for precisely specific inhibitor compounds has been extensive and has resulted in a plethora of potentially useful compounds. Many are problematic for reasons not directly related to nitrification. For example, acetylene inhibits both nitrifiers and denitrifiers (Balderston *et al.*, 1976; Berg *et al.*, 1982). Thus its use to measure one process will also inhibit the other, and when one depends on the other (as is the case when denitrification depends upon nitrification for NO_3^-), both rates are affected and the independent measurement of one is not possible. It is reported that the length of exposure to acetylene can be optimized to differentiate between its affects on nitrification and denitrification (Kester *et al.*, 1996). N–serve is a commercial preparation that specifically inhibits NH_3-oxidizing bacteria (Goring, 1962) and it serves as the basis for the sensitive $^{14}CO_2$ method for measurement of nitrification rates. Being chemolithoautotrophs, nitrifiers fix CO_2 while oxidizing N. The amount of CO_2 fixation due to nitrifiers can be computed by difference between incubations with and without addition of an inhibitor that specifically removes the contribution of nitrifiers (Billen, 1976; Dore and Karl, 1996; Somville, 1978). Then a conversion factor is used to translate the CO_2 fixation into NH_4^+ and NO_2^- oxidation rates. This conversion factor has been shown to vary in the case of NH_3 oxidizers by a factor of five in pure cultures (Billen, 1976; Glover, 1985), and thus its use introduces some uncertainty, since the factor can only be directly determined in field samples if the ^{15}N methods are performed in parallel (see below).

To complicate matters further, N–serve is not soluble in water, so its addition to samples requires that it be dissolved in an organic solvent. This solvent can affect the other members of the community; e.g., ethanol stimulates dark CO_2 incorporation by heterotrophic bacteria (Owens, 1986; Ward, 1986). Thus in systems where heterotrophs are a large part of the overall assemblage, the N–serve plus solvent approach may over estimate the dark CO_2 incorporation due to nitrifiers (Priscu and Downes, 1985; Viner, 1990; Ward, 1986).

Inhibitor approaches similar to those described earlier for water samples have been used in sediments (Henricksen *et al.*, 1981; Miller *et al.*, 1993). The methyl–fluoride and difluoromethane methods (Caffrey and Miller, 1995; Miller *et al.*, 1993) seem particularly promising because the gases can diffuse thoroughly into the core with minimal disturbance of microzones and gradients. These NH_4^+ oxidation inhibitors are added to cores and the accumulation of NH_4^+ over time is assumed to represent the net rate of nitrification. Other processes that consume NH_4^+ would lead to an underestimate of the rate. De Bie *et al.* (2002) found that both

acetylene and methyl fluoride stimulated dark $^{14}CO_2$ fixation in estuarine sediments. They concluded that methyl fluoride could not be used to estimate nitrification from this approach in natural samples although NO_2^- production was inhibited by 95% in pure cultures of *Nitrosomonas europaea* by both of these inhibitors. CO_2 fixation is an indirect estimate of nitrification and may reflect activities of many other kinds of metabolism. Measurement of NH_4^+ accumulation in conjunction with specific inhibitors is more direct, but still subject to interference from other processes that produce and consume NH_4^+ in natural samples.

To overcome the bias resulting from uneven dispersal of tracer or inhibitor, sediment rate measurements are often made in slurries, which destroy the gradient structure of sediments, which is essential to the *in situ* fluxes. Slurries may provide useful information on potential rates, but not *in situ* rates. Potential nitrification rates and rates measured in intact cores were not correlated in estuarine sediments (Caffrey *et al.*, 2003). The lack of correlation was explained by the inclusion of variable amounts of anoxic sediments in the slurries from which the potential rates were derived.

3.2.2. Isotopic incubation methods

The direct radioisotope tracer method, in which the accumulation of radiolabeled product from added radiolabeled substrate over time yields a rate estimate, is not very practical for measuring rates of nitrification in the environment. Capone *et al.* (1990) were able to quantify nitrification rates using ^{13}N, but the isotope is so short-lived (10 min half-life) that its use is usually impractical.

The other main approach to measuring nitrification rates directly is to use the stable isotope, ^{15}N, as a tracer (Olson, 1981a; Ward *et al.*, 1984). The signal of transfer of the tracer from substrate to product pool (e.g., $^{15}NH_4^+$ to $^{15}NO_2^-$) can be detected regardless of what other processes are occurring in the incubation (so *in situ* light conditions can be used) and no assumptions of steady state need be made. The major drawback of this method is the necessity to add a tracer, sometimes in excess of the natural concentration of substrate. In culture, AOB and NOB respond to increased substrate concentrations by increasing oxidation rates (Carlucci and Strickland, 1968; Suzuki *et al.*, 1976; Ward, 1987a), suggesting that addition of non-tracer levels of isotopically labeled substrate should artificially enhance measured oxidation rates. Such an enhancement is not generally observed in the case of NH_3 oxidation, however, suggesting that natural nitrifier assemblages are not substrate limited at *in situ* levels (Olson, 1981a, Ward, 1990).

The problem of excess substrate addition in tracer experiments has been largely overcome by the advent of more sensitive mass spectrometers, however, and estimates obtained under conditions approaching *in situ* are possible. Owing to the great sensitivity of isotope ratio mass spectrometry, much shorter incubations (compared to the inhibitor and inventory methods) are possible (a few hours to 24 h are commonly used). Although they have not yet been widely applied for this purpose, the recently introduced sensitive isotope methods for determination of ^{15}N content of NO_2^- and NO_3^- (McIlvin and Altabet, 2005; Sigman *et al.*, 2001) should make true tracer level incubations possible. Details on the most commonly used isotope tracer methods for

measurement of nitrification can be found in work by Ward and O'Mullan (2005) and in the Chapter by Lipschultz (this volume).

The ^{15}N approach is most useful in water samples because complete mixing of the tracer is possible. In sediments, rate measurements are constrained by the inhomogeneous nature of the sample and the dependence of rates on the structure of the environment. In this situation, fluxes between overlying water and sediment cores can be analyzed to obtain areal rates. In conjunction with ^{15}N tracer addition, estimates of nitrification rates can be obtained from the dilution of NO_2^- or NO_3^- in the overlying water due to its production in the sediments (Capone et al., 1992). The isotope pairing method for measurement of denitrification (Nielsen, 1992; Rysgaard et al., 1993) is essentially an isotope dilution approach from which both nitrification and denitrification rates can be calculated.

Even if rate measurements in sediments are made using whole core incubations, e.g., when the inhibitor is a gas, it is still difficult to obtain a depth distribution of the rate (usually, an areal rate is obtained). A sophisticated measurement and model based system that avoids direct rate measurements has been used to overcome this problem. Microelectrodes, which have very high vertical resolution, are used to measure the fine scale distribution of oxygen and NO_3^- in freshwater sediments. By assuming that the observed vertical gradients represent a steady state condition, reaction–diffusion models can then be used to estimate the rates of nitrification, denitrification and aerobic respiration and to compute the location of the rate processes in relation to the chemical profiles (e.g., Binnerup et al., 1992; Jensen et al., 1994; Meyer et al., 2001; Rysgaard et al., 1994). Recent advances and details of the microelectrode approach can be found in the Chapter by Joye and Anderson (this volume).

Comparison of incubation methods: The inhibitor methods using ^{14}C have advantages in higher sensitivity, smaller sample volume, easier analysis and therefore greater throughput than the ^{15}N tracer approaches. Therefore, in spite of the potential artifacts mentioned above, the inhibitor approach remains attractive to some investigators. Incubations of 24 h up to 12 days were used to compare the ^{14}C inhibitor, $^{15}NH_4^+$ oxidation and $^{15}NO_3^-$ dilution methods to estimate nitrification rates in the water column of the Baltic Sea (Enoksson, 1986). Artifacts associated with elevated substrate additions and long incubations were identified. The $^{15}NO_3^-$ dilution method was not recommended due to sensitivity problems. Andersson et al. (2006) suggested a formal distinction between nitrification activity as measured by ^{15}N and nitrifier growth as measured by specific inhibition and $^{14}CO_2$ incorporation. The ratio of the two rates was found to vary as a function of temperature and oxygen concentration, and the necessity to exclude phytoplankton $^{14}CO_2$ uptake by performing incubations in the dark was seen as unacceptably artifactual (Andersson et al., 2006). Gundersen (1966) had long ago reported that the ratio of N oxidized to C fixed decreased at low oxygen concentrations relative to air.

Incubation methods, whether enclosing water in a bottle or bag or sediment in a coring tube, may introduce unavoidable artifacts. Even the act of sampling introduces artifacts; in the case of water sampling, larger sinking particles are usually not included in bottle incubations, so the metabolism associated with such particles is not represented in incubations. Approaches that avoid incubations altogether are therefore attractive, but they are largely limited to measuring changes in chemical

concentrations over time, and therefore can detect net transformation rates only. The compromise made by most investigators is to maximize the size and minimize the length of incubations in order to minimize artifacts associated with wall growth or preferential inclusion or exclusion of grazers.

3.2.3. Geochemical constraints to estimate nitrification rates

Stable isotope signatures and distributions in constituents of the N cycle can be used to identify rate processes and potentially to constrain their rates. Because nitrification is often closely coupled to the processes that produce and consume its substrates and products, nitrification would not be expected to leave a clear signature in many environments. Ammonia oxidizing bacteria in culture, however, exhibit relatively large enrichment factors (Casciotti *et al.*, 2003; Delwiche and Steyn, 1970; Mariotti *et al.*, 1981), leaving behind isotopically enriched NH_4^+ and producing isotopically depleted NO_2^-. The fractionation associated with NO_2^- oxidation to NO_3^- has not been directly determined in culture, due to the difficulty of separating NO_2^- and NO_3^- for independent isotopic analysis (Delwiche *et al.*, 1970). It is assumed, however, that the ^{15}N of the NO_3^- produced is depleted relative to the NH_4^+ from which it derived, as is the oxygen in NO_3^- relative to that in NO_2^- and water from which it is derived. Because NO_2^- rarely accumulates, most of the fractionation due to nitrification probably happens at the rate limiting NH_3 oxidation step (Kendall, 1998). Isotopically light NO_3^- in the surface water of the eastern tropical North Pacific was attributed to nitrification, and direct measurements of nitrification using ^{15}N tracer techniques substantiated the distribution of the process in the euphotic zone (Sutka *et al.*, 2004).

Sutka *et al.* (2006) investigated the potential for intramolecular isotopic (isotopomer) distributions to identify the source of nitrous oxide in the environment. Ammonia-oxidizing bacteria, methane-oxidizing bacteria (which can also oxidize NH_4^+ and hydroxylamine) and denitrifiers can all produce N_2O in the laboratory and are all potential sources of N_2O in the marine environment. Methanotrophs and AOB had indistinguishable site preferences for ^{15}N in N_2O produced from NH_3 or hydroxylamine (Sutka *et al.*, 2003, 2006). AOB can produce N_2O by two pathways; one by oxidation of hydroxylamine and one by reduction of NO_2^-. The NO_2^- reduction pathway in nitrifiers – nitrifier denitrification – is homologous with that of denitrifiers (Casciotti and Ward, 2001, 2005) and showed the same site preference in N_2O as found in denitrifiers (Sutka *et al.*, 2006). Thus the isotopomer approach cannot distinguish between the oxidative production of N_2O by methanotrophs vs. AOB, nor can it distinguish between canonical heterotrophic denitrification and nitrifier denitrification. However, the oxidative and reductive pathways to N_2O production did have significantly different isotopomer signatures. In order to use isotopomers to identify the source of N_2O in the ocean, we need to know which of the two possible pathways AOB use to produce N_2O. It may be important that the isotopomer studies mentioned above did not test marine nitrifiers – the observed isotopic fractionation and functional gene sequences indicate that there may be biochemical differences among the genera of AOB, and of course the most abundant AOB and AOA have not been cultured or tested for these pathways. The capacity for nitrifier denitrification may be ubiquitous among AOB (Casciotti and Ward, 2005;

Shaw *et al.*, 2006) and even some of the genome of the crenarchaeal relative of the cultivated AOA possesses the genes that encode the pathway (Hallam *et al.*, 2006).

On a basin or areal scale, the expected rates of nitrification can be estimated from other biogeochemical distributions and rates. Dore and Karl (1996) compared nitrification rates measured using the ^{14}C inhibitor approach to the estimated fluxes of N_2O, assuming a very high N_2O yield from nitrification. Although they reported broad agreement, both rate estimates are very poorly constrained. Ward and Zafiriou (1988) measured NH_3 oxidation rates as deep as 3000 m using the [15]NH_4^+ oxidation method and noticed that the rate decayed rapidly with depth (Fig. 5.3). They compared the integrated nitrification rate in the eastern tropical North Pacific to the predicted N mineralization rate derived from sediment trap fluxes in the same area (Martin *et al.*, 1987). The integrated trap flux and nitrification rates differed by about a factor of 2, suggesting broad agreement and implying that nitrification is coupled to mineralization of sinking particles, but that the nitrification process occurs not on the particles themselves, but in the water captured in the incubation.

Berelson used the equation of Martin *et al.* (1987) to compare mineralization rates at the 17 stations from the regional JGOFS studies and found that the stations varied by only a factor of two in the magnitude of the fitting parameter, b (Berelson, 2001). The greater the value of b, the more rapid the decrease in flux with increasing depth, implying greater mineralization activity at shallower depths. The curvature was correlated with the magnitude of the flux, which varied by a factor of $\sim$20 among the 17 stations. The linear relationship between b and POC flux can be used to constrain mineralization, and thus nitrification, rates, assuming most mineralization occurs in the water column and that the NH_4^+ released is completely nitrified. For POC fluxes ranging from 1.3 mmol C m^{-2} day^{-1} (the lowest equatorial Pacific station) to 24.9 mmol C m^{-2} day^{-1} (the North Atlantic Bloom Experiment), PON fluxes of 0.133–.167 to 2.9–3.6 mmol N m^{-2} day^{-1} can be computed (assuming a C/N ratio of the particles of 8 or 10, respectively; Antia, 2005). The integrated nitrification rates reported by Ward and Zafiriou (1988) for the eastern tropical North Pacific are about the only data suitable for comparison over this vertical extent, and they ranged from 1.1–2.7 mmol N m^{-2} day^{-1}.

The fundamental agreement between these estimates of integrated PON flux (i.e., mineralization rates due to PON loss) and observed nitrification rates has important biogeochemcal implications. Firstly, nitrification is coupled to mineralization and the rate decreases dramatically with increasing depth. This is consistent with incubation rate measurements that usually detect highest rates within the top 100 m of the water column. Most of the nitrification required to balance mineralization over the water column occurs in the planktonic phase or on particles that can be captured in bottles, rather than on rapidly sinking particles, suggesting that mineralization leads to the break up of particles and the release of dissolved NH_4^+ that is subsequently nitrified. Such rate estimates are an important constraint on inferences of microbial metabolic activities: regardless of the phylogenetic identify of the nitrifiers, they can't be growing or nitrifying very rapidly over most of the deep ocean. Even if 40% of the microbial cells in the deep ocean are chrenarchaeota with the capacity for NH_3 oxidation, their livelihood, whether it be NH_3 oxidation or organoheterotrophy, is fundamentally constrained by substrate supply, which decreases greatly with depth.

The distribution of nitrous oxide may provide a further geochemical constraint on nitrification rates and distributions. Using a global dataset of N_2O distributions, Nevison *et al.* (2003) derived a parameterization for the instantaneous production by nitrification of N_2O per mole of O_2 consumed as a function of O_2 concentration and depth. Assuming that NH_3 oxidizers produce N_2O in increasing proportion to NO_2^- as O_2 concentration decreases (as previously reported; Goreau *et al.*, 1980), an annual N_2O production rate of $\sim 5.8 \pm 2$ Tg N year^{-1} was estimated (Nevison *et al.*, 2003). It is not a simple calculation to derive a total nitrification rate from this result because of the nonlinear relationship between O_2 concentration, nitrification rate and the proportion of NH_4^+ that is lost as N_2O. Nevertheless, it might be possible to estimate a global nitrification rate with vertical flux data as discussed above, which would also be constrained by the global ocean N_2O flux calculations.

3.3. Distribution of nitrification in water and sediments

When Kaplan reviewed the status of nitrification in the marine environment in 1983, direct measurements of nitrification rates in water column and sediment environments were few and far between. The proliferation of inhibitor approaches, plus increased accessibility and sensitivity of mass and emission spectrometers has allowed great progress in this area. In 1983, Kaplan was unable to make many generalizations about major patterns in the rate and distribution of nitrification. Since that time, advances in experimental data and conceptual frameworks have elucidated the following patterns:

1. Nitrification rates in oxygenated water columns show typical depth distributions with maximum rates near the bottom of the euphotic zone and a rapidly declining rate with increasing depth below that.
2. Nitrification in the water column is tightly coupled with NH_4^+ regeneration, such that NO_3^-, not NH_4^+, accumulates in the deep sea.
3. Nitrification rates are often low in the well lit surface waters of the ocean, probably due to light inhibition and competition for NH_4^+ with phytoplankton and heterotrophic bacteria.
4. Nitrification is ubiquitous in surface sediments and is often tightly coupled to denitrification in the sediment redox gradient.

3.3.1. Nitrification in the water column

The major N product of organic matter decomposition in seawater is NH_4^+, but NH_4^+ is present at trace or undetectable levels in the huge volume of the deep ocean. Rather, deep water contains NO_3^- at 20–40 μM concentrations, which would seem to imply that nitrification occurs mainly in the deep ocean. Nitrate concentrations in the surface ocean are usually maintained at low levels because phytoplankton assimilate NO_3^- more rapidly than it can be supplied by mixing or diffusion from the deep NO_3^- reservoir. Ammonium, which is produced in the photic zone by heterotrophic processes, is also usually immediately assimilated by phytoplankton and heterotrophic bacteria before it can be nitrified. The important physical and biological differences in the source functions of NH_4^+ and NO_3^- are

the basis of the new production paradigm (Dugdale and Goering, 1967; Eppley and Peterson, 1979) as a framework to understand phytoplankton N demand and growth in the surface ocean, and the subsequent flux of N to the deep sea and ocean floor (Fig. 5.1A).

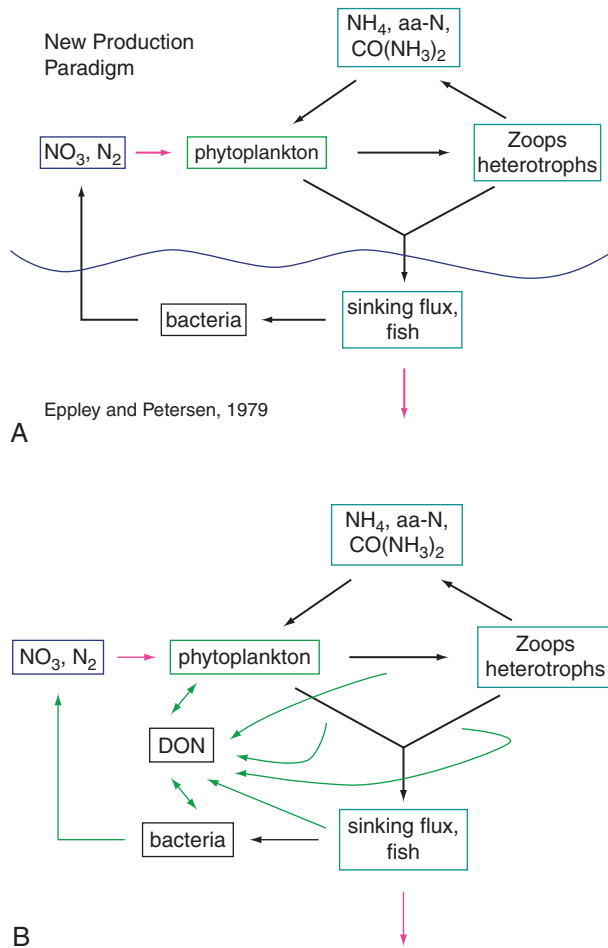
Ammonium is considered a ''regenerated'' source of N, because it is produced *in situ*, in the euphotic zone, from ammonification of organic matter. The N in


Figure 5.1 (A) The New Production Paradigm, redrawn from Eppley and Petersen, 1979, representing nitrogen transformations in the surface layer of the ocean. N assimilation by phytoplankton is derived from either "new" (NO_3, N_2) or regenerated (NH4, amino acids, urea) nitrogen. In the first panel is the original view of Eppley and Petersen, in which nitrification occurs only below the euphotic zone such that nitrate is a "new" nutrient. The two red arrows are equivalent because "new production" is balanced by the export flux from the euphotic zone. (B) In the second panel, nitrification, as well as various production and consumption terms involving dissolved inorganic nitrogen (DON), occurs in the euphotic zone. Nitrate is thus at least partially a "regenerated" nutrient, and the flux through the labile portion of the DON pool can be rapid and linked to other euphotic zone processes.

NH_4^+ is recycled rapidly and repeatedly between living biomass (phytoplankton, the zooplankton that graze on them, protozoans, bacteria and archaea) and the inorganic nutrient form, which is released from heterotrophic metabolism and grazing. Nitrate, on the other hand, is "new" N because it is virtually absent from the euphotic zone most of the time and must be transported into the system by physical means—mixing or upwelling from deep waters or falling in rain – in order for phytoplankton to use it. The rate of NO_3^- supply can be equated with the steady state rate of export production, primary production based on NO_3^- as a N source (Eppley and Peterson, 1979). This equality between supply and export makes it possible to measure "new production," and by inference, the sinking flux of N, by measuring the assimilation of NO_3^- in incubated samples. In this scenario, nitrification is responsible for the production of NO_3^- in the deep water, from whence it is transported to the surface layer; nitrification is explicitly absent from the euphotic zone itself.

Depth distribution of nitrification rates: Actual measurements of the depth distribution and rate of nitrification show, however, that NO_3^- production and consumption are not in fact so completely or conveniently separated in space. The highest nitrification rates, both NH_4^+ oxidation and NO_2^- oxidation, occur not in the deep ocean, but in a region near the bottom of the euphotic zone. In this depth interval, the light intensity is very reduced and phytoplankton are light limited, and their rates of nutrient assimilation are therefore reduced. It is in this interval that nitrifying bacteria can compete with phytoplankton for NH_4^+; a sharp peak is often observed in the nitrification rate at a depth in the water column where the light intensity is 5–10% of surface light intensity or in the vicinity of the deep chlorophyll maximum, when it occurs (Lipschultz *et al.*, 1990; Sutka *et al.*, 2004; Ward, 1987b; Ward *et al.*, 1984) (Fig. 5.2).

Rates of nitrification reported for the open ocean are in the range of a few to a few hundred nanomolar per day, and have been detected as deep as 3000 m (Ward and Zafiriou, 1988). Most of the data discussed here are NH_4^+ oxidation rates. Nitrite oxidation rate methods are more prone to experimental artifacts; many fewer results have been published and many of the high rates reported are probably overestimates. Rates of nitrification reported in various aquatic environments are presented in Table 5.2. Where profiles extending to a depth of several hundred to a few thousand meters are available, the main pattern that emerges is the association of the highest rates of NH_3 oxidation with the lower region of the euphotic zone (Fig. 5.3). In the eastern tropical North Pacific, NH_3 oxidation rates at the maximum were no more than 20 nM day^{-1} (Ward and Zafiriou, 1988). In the Peru upwelling region, a maximum rate of 747 nM day^{-1} was reported (Lipschultz *et al.*, 1990). In the temperate eastern Pacific Ocean off western North America, maximum rates of 45 nM day^{-1} were reported (Ward, 1987b). Nitrite oxidation shows a less predictable distribution with depth, probably due to methodological problems; in the Peru upwelling system, maximum rates of 600 nM day^{-1} were observed near the lower boundary of the euphotic zone, but high rates (e.g., nearly 300 nM day^{-1}) were observed within the oxygen minimum zone (Lipschultz *et al.*, 1990).

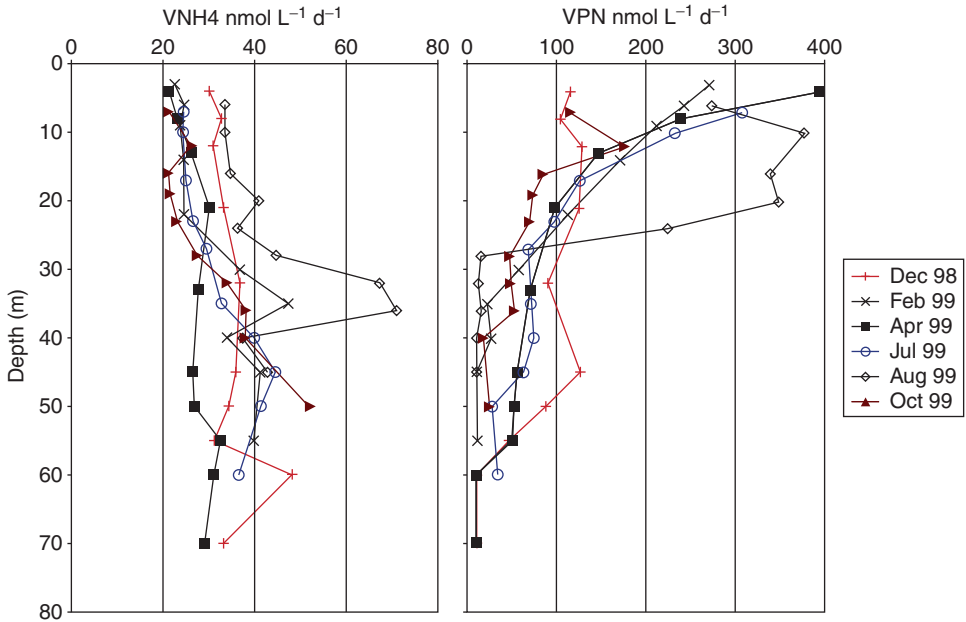
Several studies of nitrification rates have focused on the primary NO_2^- maximum, rather than attempting complete depth profiles. Dore and Karl (1996) reported a few


Figure 5.2 Depth distribution of ammonia oxidation rate (VNH4) and ammonium assimilation rate (VPN) in the surface layer in Monterey Bay, CA. Data were obtained from ^{15}N-NH$_4$ tracer incubations at simulated in situ light intensities. (From Ward 2005)

rate measurements based on inhibitor experiments from the central Pacific Ocean and calculated rates up to 137.4 and 138 nM day^{-1} for NH$_4^+$ and NO$_2^-$ oxidation, respectively. Rates 10-fold lower were reported for the same station using ^{15}N tracer methods (Sutka *et al.*, 2004). Ammonium and NO$_2^-$ oxidation rates were usually comparable, and were maximal just below the primary NO$_2^-$ maximum. Bianchi *et al.* (1994) reported nitrification rates up to 1–2 μM day^{-1} in the Rhone River Plume, with rates decreasing to the usual oceanic levels with increasing distance from shore in the Mediterranean Sea. In a recent compilation of nitrification rate measurements, Yool *et al.* (2007), a great range of rates in the upper 250 m of open ocean environments. Using a specific nitrification rate (d-1) they did not detect consistent depth patterns, but did document nitrification within the photic zone. Clearly the simple model that distinguishes NO$_3^-$ as a new nutrient should be modified (Fig. 5.1B); nitrate produced from nitrification in the eupotic zone is often sufficient to meet phytoplankton demand in the same depth interval.

The rate of nitrification in deep ocean water is minimal, due to the decreasing flux of NH$_4^+$ from organic matter decomposition with increasing depth. Thus in many parts of the world ocean, the typical depth distribution of nitrification shows a subsurface maximum which occurs near the bottom of the euphotic zone, and very low rates persisting to great depths. The great accumulation of NO$_3^-$ in the deep sea is therefore due to a small production term and a lack of any significant consumption terms. An exception to this deep sea condition is found in the vicinity of

hydrothermal vent plumes, where NH_4^+ concentrations are elevated to hundreds of nM (Lilley *et al.*, 1993) and oxidation rates (up to 91 nM day^{-1}) on the same order as those detected in surface water have been reported (Lam *et al.*, 2004).

Based partly on anecdotal evidence from culture work, observations in waste water treatment systems with very high particulate loads, the tendency of nitrifiers to grow in aggregates in bioreactor biofilms, and the prevalence of small particles in natural waters, it has been suggested that nitrification occurs mainly on particles and is mediated by particle–attached bacteria (Hagopian and Riley, 1998). Nitrifier sequences were found both associated with particles and in the bulk seawater phase in the northwestern Mediterranean Sea. In the clone library of 16S rRNA sequences, *Nitrosomonas*-like sequences were preferentially associated with particles and *Nitrosospira*-like sequences dominated in clones from the planktonic phase (Phillips *et al.*, 1999). This may indicate niche preference by the different groups on the basis of attachment to particles, substrate concentration or other physical/

chemical parameters of particle surfaces (Prosser and Embley, 2002). Karl *et al.* (1984) reported high numbers of AOB associated with particles caught in sediment traps and attributed high rates of chemoautotrophy to the particle-associated assemblages. The relative contribution to nitrification rates by particle-associated vs. truly planktonic nitrifying bacteria or those associated with smaller suspended particles is difficult to assess. The distribution of rates as a function of depth indicates that rapidly sinking, i.e., large, particles cannot be the main site of the process (see above, geochemical constraints); nitrification associated with suspended small particles could be consistent with the typical subsurface rate maximum and depth profile that is characteristic of oceanic waters. Nitrifiers appear to escape predation by protozoans by aggregating into particles that are too large to be grazed (Lavrentyev *et al.*, 1997). Thus a trophic effect on nitrification is implied, which also has ramifications for the planktonic vs. particle-associated question.

3.3.2. Nitrification in sediments

The magnitude of nitrification rates in sediments can be much higher, and is certainly more variable, than that reported from water column measurements (Table 5.2). The variability arises not only from the small scale heterogeneity inherent in sediments (partly due also to bioturbation and association of nitrification with the walls of faunal tubes in the sediments), but from the wide range in the level of organic matter input to sediments in shallow water. Very high NO_2^- and NO_3^- fluxes to the water column from sediments, including coral reefs (Capone *et al.*, 1990; Webb and Weibe, 1975) and sponge dominated reef surfaces (Diaz and Ward, 1997), have been attributed to nitrification associated with invertebrates and biotic sediments. Welsh and Castadelli (2004) showed that nitrification activity was associated with the tissues, as well as the external shell surfaces, of filter feeding bivalves. They suggested that nitrifying bacteria may colonize invertebrates and establish specific biological relationships with them (Welsh and Castadelli, 2004), as was suggested by the high nitrification rates observed in sponges (Diaz and Ward, 1997) and the detection of AOB sequences in sponge tissues. High rates have also been reported from the shallow waters of sediment dominated systems such as mangrove forests (Dham *et al.*, 2002) Nitrification in the shallow water column of the mangrove forest was highly seasonal and strongly coupled with NH_4^+ regeneration and NO_2^- assimilation rates (Dham *et al.*, 2002). In contrast, nitrification rates were very low in the sediments of a coastal lagoon where uptake of DIN by seagrass dominated the N cycle (Rysgaard *et al.*, 1996).

Irrigation by worm tubes and sediment infauna has been shown to increase nitrification rates by increasing oxygen availability (Pelegri *et al.*, 1994; Pelegri and Blackburn, 1996; Svensson, 1998). The presence of worm tubes, which are actively irrigated by the invertebrate inhabitants, introduces small scale spatial variability into the oxygen distribution in sediments. Nielsen *et al.* (2004) used microelectrodes to measure small scale distributions of oxygen and NO_3^- around individual worm tubes and found that nitrification and NO_3^- reduction (denitrification plus NO_3^- reduction to NH_4^+) were spatially separated: nitrification was restricted to the oxic zone (up to 1.5 mm) around the tubes, while NO_3^- reduction occurred in the adjacent anoxic zone. Both processes were stimulated by the addition of NH_4^+ indicating that NO_3^- produced by nitrification limited the rate of denitrification. Webb and Eyre

(2004) found that the presence of burrowing shrimp (*Trypaea australiensis*) increased denitrification rates by fivefold compared to unoccupied sediments, while oxygen consumption increased by 81%. Most of the increased oxygen demand was attributed to microbial respiration and oxidation processes (rather than to respiration by the shrimp itself), implying that the increased denitrification was coupled to increased nitrification resulting from increased organic matter decomposition (Webb and Eyre, 2004). Gilbert *et al.* (2003) investigated the relationship between coupled nitrification/denitrification rates and the density of macrofaunal burrow spacing using simulated burrows and reaction-diffusion models. Nitrification rates were maximal at an intermediate tube density, and denitrification varied in direct proportion to nitrification, indicating the importance of the coupling of the two processes through *in situ* NO_3^- production. The main controls on nitrification rate were the supply of oxygen and NH_4^+, and competition for oxygen by other reductants. Dollhopf *et al.* (2005) found that coupled potential rates of nitrification and denitrification in salt marsh sediments were positively correlated with each other and with macrofaunal burrow abundance and attributed this effect to enhanced oxygen availability due to bioirrigation. Nitrification potential, measured using chlorate inhibition, was positively correlated with the occurrence of macrofaunal structures in estuarine sediments (Mayer *et al.*, 1995). Local sediment conditions are likely to be important in determining the degree of coupling and net rates of nitrification and denitrification. In a bay in southern Australia, denitrification rates were not related to bioirrigation and it was suggested that high irrigation rates removed NH_4^+ that was regenerated in anoxic regions of the sediments too fast for it to be nitrified and recycled (Berelson *et al.*, 1998). Any variability among nitrifier community composition between aerated and non-aerated sites would introduce complexity into the community response, perhaps shifting the optimum to slightly different length and packing scales, but probably not changing the nature of the relationships and the coupling between nitrification and denitrification.

Nitrifiers living in marine sediments that are periodically or persistently exposed to anoxic conditions would need to be able to survive periods of inactivity or even serious inhibition in order to recover when conditions improved. The physiological basis of this survival or tolerance of anoxic conditions is unknown, and the degree to which nitrifiers can recover from serious anoxia is questionable. In microcosm studies with estuarine sediments, nitrification was almost completely inhibited by sulfide, the end product of bacterial sulfate reduction that occurs widely in anoxic marine sediments (Joye and Hollibaugh, 1995). A pulse of sulfide, which was detectable in the sediments for only a few hours, inhibited nitrification for at least 24 h. Thus in marine sediments where sulfate reduction occurs, the ability of nitrifiers to respond to daily oxygen fluctuations may be impeded. Even when the oxygen-sulfide interface deepens during the day, nitrifiers may be unable to recover from the sulfide poisoning. In that case, both nitrification and denitrification (which is partially dependent upon NO_3^- supply from nitrification) may occur at slower rates than would be predicted for similar environments in freshwater sediments (where sulfate, and therefore sulfide release from sulfate reduction, is much less prevalent). In contrast, Jensen *et al.* (1993) reported that nitrification could be stimulated essentially instantaneously by addition of oxygen to sulfidic freshwater sediments. Using microelectrodes to measure oxygen and NO_3^-

profiles in a sediment core, Jensen *et al.* (1993) detected an almost immediate increase in nitrification rate when anaerobic sediments were aerated, implying that nitrifiers are inhibited but not poisoned by sulfide. When sediments were allowed to equilibrate with overlying water of differing oxygen concentrations, the zones of nitrification and denitrification stabilized at greater depths with increasing oxygen concentration, reflecting oxygen penetration into the core (Fig. 6, Jensen *et al.*, 1994). This difference may reflect the different community composition of freshwater and marine nitrifying bacteria, or it may be related somehow to salinity and its effect on nitrifiers.

In both deep and shallow sediments, nitrification can be one of the main sinks for oxygen (Blackburn and Blackburn, 1993; Grundmanis and Murray, 1977). Nitrification accounted for up to 50% of the oxygen demand in the Mississippi River plume at intermediate salinities (Pakulski *et al.*, 1995) but was much less important in the nearby Atchafalaya River, which is dominated by heterotrophic processes (Pakulski *et al.*, 2000). In continental shelf sediments, nitrification and denitrification are often closely linked. Coupled nitrification/denitrification is invoked to explain the observation that the rate of N_2 flux out of sediments can greatly exceed the diffusive flux of NO_3^- into the sediments (Devol and Christensen, 1993). Ammonium, produced during aerobic and anaerobic organic matter mineralization, is oxidized to NO_3^- and subsequently reduced to N_2. Anaerobic oxidation of the regenerated NH_4^+ could also be a factor in the otherwise lack balance between NO_3^- supply and consumption. Nitrification can supply up to 100% of the NO_3^- consumed by denitrification (Laursen and Seitzinger, 2002; Lehmann *et al.*, 2004). In deep sea sediments, denitrification may not be detected in the upper 30–50 cm, and NO_3^- accumulates in near Redfield stoichiometry due to nitrification of regenerated NH_4^+ during organic matter diagenesis (Grundmanis and Murray, 1982).

Although oxygen and NH_4^+ conditions likely differ between planktonic and sediment environments, there is no clear evidence from clone libraries that water column and sediment nitrifying communities are significantly different in composition and regulation. The most extensive comparisons are possible on the basis of *amoA* clone libraries from Chesapeake Bay sediments (Francis *et al.*, 2003) and the Monterey Bay water column (O'Mullan and Ward, 2005). Although unique sequences were found in both environments, it was more common to find the sequences from different environments clustering together, and with representatives from both planktonic and sediment sequences from other studies. Thus on the basis of functional genes alone, it is not possible to distinguish major sediment vs planktonic strains. 16S rRNA sequences that were 96–98% identical with known betaproteobacterial nitrifying isolates were obtained in clone libraries from anoxic sediments in a marine Loch (Freitag and Prosser, 2003). The sedimentation rate at this site implied that the sediments from which the sequences originated had been buried for about 100 years, implying the long term viability of nitrifying bacteria in anoxic environments. The same authors did not detect gammaproteobacterial or anammox type planctomycetes-like sequences, and concluded that some groups of betaproteobacterial AOB might be capable of growing and perhaps nitrifying under anoxic conditions. Mortimer *et al.* (2002, 2004)

detected a sharp peak of NO_3^- in pore water profiles from the sediment environment, and were able to detect low NH_3 oxidation rates at the depth (20 cm) of the NO_3^- peak, and also documented the presence of both *Nitrosospira-* and *Nitrosomonas*-like 16S rRNA sequences in the sediments. It was concluded that the buried NO_3^- peak was due to slumping of the coastal sediments and represented a non steady state feature, rather than a long term result of anoxic NH_3 oxidation. The ability of AOB to persist for long periods in unfavorable conditions is well known, but the continued activity of conventional aerobic AOB in anoxic sediments is doubtful.

4. Environmental Variables Affecting Nitrification Rates and Distributions

It is clear from the discussion of the depth distribution of nitrification rates that variables such as light intensity and substrate concentration are important determinants of the magnitude and location of nitrification in the water column, as they are for much of the biogeochemical cycling in the environment. Their effects have been studied in both laboratory culture experiments and in field samples, using incubations and measurements of natural assemblages. Culture studies have so far been restricted to bacterial nitrifiers, so regulation inferred from studies of AOB may not apply to archaeal ammonia oxidizers. On the other hand, rate measurements from environmental samples reflect the ecological properties of the natural assemblages, regardless of their phylogentic composition. Thus environmental effects inferred from field samples may provide insight into the physiology of uncultivated organisms involved in the processes.

4.1. Temperature

The effect of temperature is of potential importance in wastewater systems where nitrifying bacteria are cultured under artificial conditions, or in terrestrial environments or shallow marine systems where temperature changes on short time scales. Temperature was a significant regulator of nitrification rates in the shallow water column of mangrove forests (Dham *et al.*, 2002), although oxygen and NH_4^+ concentrations were more important. Different temperature optima are reported for strains isolated from different kinds of terrestrial environments (Golovacheva, 1976; Jiang and Bakken, 1999). A marine betaproteobacterial AOB species with a temperature tolerance between $-5°C$ and nearly $29°C$ was isolated from Alaskan shelf sediments (Jones *et al.*, 1988). In the oceanic environment, however, temperature is not generally considered to be an important variable for nitrification because bacterial populations are generally adapted to the temperature of their environments. Thus, one can demonstrate a classical dependence of the rate of nitrification on temperature in any particular environment, but temperature is not generally the limiting factor *in situ*. Nitrifiers adapted to low temperature can nitrify under low temperature conditions at rates comparable to the rates attained by nitrifiers adapted to higher

temperatures living under high temperature conditions. Nitrification rate was highly adapted to temperature in arctic sediments, with temperature optima ranging from 14 to 40°C, depending on the temperature of the environment (Thamdrup and Fleischer, 1998). While temperature is an important master variable for biological processes, nitrification is if anything less sensitive to regulation by temperature than other processes, and is usually regulated in the environment by some other variable.

4.2. Salinity

Because salinity in the open ocean does not vary on scales that are important to physiological response in bacteria, sensitivity to salinity changes is not an important variable in determining nitrification rates or nitrifying bacterial community composition in the ocean. It appears, however, that salinity is a very important, perhaps dominant, variable in regulating nitrification in riverine and estuarine environments. Highest nitrification rates were associated with low to moderate salinities in the Mississippi (7 psu) and Atchafalaya (8 psu) River plumes (Pakulski et al., 2000), but turbidity and competition with phytoplankton and other bacteria also played a role in determining the distribution of nitrification. An earlier study in the Mississippi River plume had detected highest nitrification rates at higher salinities (27 psu) (Pakulski et al., 1995).

Using the N-serve inhibition method with $^{14}CO_2$ uptake to estimate nitrification, Somville (1984) showed that salinity was an important variable in determining nitrification rates in the Schelde estuary in The Netherlands. She concluded that nitrifier populations were adapted to their in situ salinities and suggested that community composition – and salt tolerance – varied along the estuarine gradient. Large shifts in the composition of 16S rRNA clone libraries representing AOB communities were subsequently found along the salinity gradient from 0 to 15 psu in the Schelde estuary (Bollman and Laanbroek, 2002; de Bie et al., 2001). The Schelde libraries were dominated by Nitrosomonas-like sequences, but two different groups switched dominance in the clone libraries between about 3 and 5 psu. Nitrosospira-like sequences were detected only rarely and mostly at the highest salinity station. Sequences representing both the uncultivated marine Nitrosospira clade and the marine Nitrososmonas clade were found in clone libraries from Chesapeake Bay sediments (Francis et al., 2003). The level of amoA sequence diversity within samples from Chesapeake Bay was compared to the pairwise differences in environmental parameters (e.g., salinity, oxygen, temperature, NO_3^- and NH_4^+ concentrations) between stations. Difference in salinity was the dominant variable and accounted for 62% of the variation in pairwise sequence dissimilarity between stations. Ammonia concentration, the next most important variable, explained only an additional 2.7%. The greatest diversity in AOB clone libraries occurred in the freshwater end member stations, and these libraries were also most different in composition from all the other samples, indicating that different organisms perform the nitrification function in different parts of the bay, depending on salinity. Members of the uncultivated Nitrosopira clade dominated the clone libraries from higher salinity stations. In a study that included three estuarine stations with salinities ranging from 8.7 to 31.7, different and temporally stable

AOB communities were detected by terminal restriction fragment analysis of *amoA* genes (Bernhard *et al.*, 2005). *Nitrosospira*-like sequences were also identified as the seawater dominants in this environment.

Using sediments collected from the middle of the estuarine salinity gradient in the Douro estuary (Portugal), manipulation of salinity in the overlying water was used to test the effect of salinity on nitrification and denitrification (Magalhaes *et al.*, 2005). Denitrification rates did not vary in response to salinities of 0 and 35 psu, but nitrification was optimal at 15 psu. This may indicate the presence of a halotolerant denitrifier assemblage, while the nitrifier assemblage was adapted to its *in situ* salinity and was inhibited by both lower and higher salinity. In the Rhone river estuary, highest nitrification rates were found in the surface low salinity layer, but both NH_3 and NO_2^- oxidation rates were correlated primarily with NH_4^+ concentration, and influenced by temperature, rather than salinity directly (Bianchi *et al.*, 1999).

Rysgaard *et al.* (1999) tested the effect of salinity on nitrification in a Danish estuary to determine whether the increased desorption of NH_4^+ from sediments was responsible for the decreasing nitrification rates at high salinity. They concluded that salinity influenced nitrification rates independently of NH_4^+ concentrations and suggested that some physiological factor must be involved.

Many authors have described the salinity tolerances of nitrifying bacterial cultures (Macfarlane and Herbert, 1984; Stehr *et al.*, 1995) and it is clear that halotolerance is not the rule among AOB. Seven strains of *Nitrosomonas* isolated from different regions of the Elbe showed different ranges of salinity tolerance (Stehr *et al.*, 1995). *Nitrosococcus halophilus*, one of two known species in the gammaproteobacterial AOB, has a higher salinity optimum and upper limit than does *N. oceani*, the strain detected widely in the open ocean (Koops *et al.*, 1990). The salt requirements of cultivated AOB are summarized by Koops *et al.* (2003). Salinity may restrict the distribution of nitrifying strains and help determine nitrifier community composition, but as with temperature, appropriately adapted communities minimize the variability in nitrification rates as a function of salinity. The apparent dominance of AOA over AOB abundance in seawater is consistent with strong selection by salinity in favor of AOA. AOA have also been detected in terrestrial (Leininger *et al.*, 2006) and wastewater (Park *et al.*, 2006) environments, however, and salinity as a variable in the overall ecology of AOA remains to be investigated.

4.3. Inhibitory compounds

Both NH_3 oxidizers and NO_2^- oxidizers, but especially the former, are susceptible to inhibition by a wide range of compounds, and several different modes of action have been documented (Bedard and Knowles, 1989). The two most common modes of inhibition are: (1) interference with the active site of the primary enzyme (i.e., NH_3 monooxygenase in AOB; NO_2^- oxidoreductase in NOB) by compounds that share structural homology with NH_3 or NO_2^- and (2) metal binding compounds, which interfere with the action or availability of copper in the NH_3-oxidizing enzymes. In both NH_3- and NO_2^--oxidizers, the susceptibility to inhibitors by key enzymes forms the basis of some methods used to measure the rate of nitrification in the environment (see above).

In terrestrial systems, the presence of certain organic compounds (e.g., mono-terpenes produced by plants) has been proposed to limit the rate of nitrification and the inhibition of nitrification in acid soils has long been of concern. The potential of naturally occurring organic compounds to inhibit nitrification in seawater has not been considered very much. Inhibition by organosulfur compounds has been demonstrated in cultured marine NH_3 oxidizers (Ly et al., 1993) and the inhibitory effect of sulfide on nitrification is thought to limit nitrification and coupled nitrifi-cation/denitrification in marine sediments (see below; Joye and Hollibaugh, 1995). While naturally occurring organic compounds have not been investigated as poten-tial inhibitors in seawater, the product of their photodecomposition, carbon monoxide, has been implicated (Jones and Morita, 1984). While CO, like methane, acts as a substrate analog or a suicide inhibitor for NH_3 oxidizers, the direct inhibitory effect of light on nitrifiers (see below) is considered to outweigh the potential effect of CO inhibition in surface waters. As a substrate analog, CO can be oxidized by NH_3–oxidizing bacteria, and Jones (1992) proposed to exploit this capability as a method for quantification of NH_3 oxidation rates in natural systems. Like methane oxidation (Ward, 1987b), however, the rate of CO oxidation by nitrifiers depends on the relative concentration of alternative substrates, which may cause artifacts in relating overall rates of CO oxidation to nitrification. The susceptibility of AOA to the known suite of nitrification inhibitors remains to be investigated.

4.4. Light

The inhibitory effect of light was reported by German researchers in the 1960s (Muller-Neugluck and Engel, 1961; Muller-Nugluck and Engle, 1961; Schon and Engel, 1962), verified in enrichment cultures in seawater (Horrigan et al., 1981) and later described in more detail (e.g., Vanzella et al., 1989). Even in enrichment cultures of nitrifiers derived from the sea surface film, nitrification was severely inhibited by light, such that periods of more than 12 h darkness were necessary to allow net nitrification to occur over a 24 h period (Horrigan et al., 1981). Vanzella et al. (1989) found evidence that NO_2^- oxidizers were more sensitive to sunlight than were NH_3 oxidizers, based on single culture studies, but Guerrero and Jones (1996a) showed that species specific responses may obscure any generalizations among major groups. Light at near UV wavelengths of 300–375 nm, as well as in the visible range (<500 nm), was inhibitory for the cultures tested, and sunlight caused almost complete inhibition within 2 hr of the AOB tested, and 67% and 17% inhibition for the two NOB tested (Guerrero and Jones, 1996a). Many biological molecules such as DNA and proteins, quinones, flavins, NADH and other molecules involved in electron transport activity absorb primarily in the near UV wavelengths. Bock (1965) showed that light caused the oxidation of cytochrome c in both AOB and NOB, and suggested that photoinhibition resulted from damage to the electron transport system. The specific phototargets involved in light inhibition have not been thoroughly investigated, but photosensitivity is consistent with the potential for photodamage of these essential molecules in microbes living in near surface waters. Horrigan and Springer (1990) reported that oceanic strains of NH_3 oxidizers were generally more sensitive to light inhibition than were estuarine strains. Degree

of inhibition was inversely correlated with NH_3 oxidation rate, but the mechanism of this relationship could not be determined. Horrigan and Springer (1990) argued that the greater sensitivity of oceanic NH_3 oxidizers might be responsible for the generally lower rates of NH_3 oxidation observed in oceanic vs. river or estuarine environments, but the complex of other factors such as overall rates of material processing could not be independently evaluated.

There is abundant evidence from culture studies that both AOB and NOB are photosensitive. It is a high priority to investigate the photosensitivity of AOA. Even if all nitrifiers exhibit photoinhibiton in some form, however, the direct and indirect ecological implications of this physiology for the rates and distributions of nitrification in the environment are not easily predicted. Dissolved organic matter in seawater, as well as turbidity due to sediments or phytoplankton, might all provide photoprotection in surface waters, and regulation of nitrification by other factors discussed in this section may be much more important in many environments.

Ammonia and NO_2^- oxidation rates are often reported to be highly coupled and to occur at about the same rate. This coupling would be consistent with the observation that neither NH_4^+ nor NO_2^- accumulates to high levels in most natural waters. For NO_2^-, the exceptions to this rule are the primary NO_2^- maximum of near surface waters and the secondary NO_2^- maximum characteristic of oxygen minimum zones. The surface water feature has been attributed to two main processes. Because the primary NO_2^- maximum is usually associated with low light intensities at the bottom of the euphotic zone, some interaction between biological processes and light is suspected. In one scenario, phytoplankton are responsible: assimilation of NO_3^- (via reduction to NO_2^- and then to NH_4^+) requires energy, especially the step at which NO_2^- is reduced to NH_4^+. Under low light intensity, phytoplankton might not have enough energy to reduce the NO_3^- completely, and some of the intermediate NO_2^- is allowed to leak out of the cell. In the alternative scenario (Olson, 1981b), nitrifying bacteria are responsible: on the basis of information then available (Bock, 1965; Muller-Neugluck and Engel, 1961; Schon and Engel, 1962), Olson hypothesized that NO_2^- oxidizers are more sensitive to light inhibition than are NH_3 oxidizers. Therefore, NH_3 oxidizers are active at slightly shallower depths in the water column than are NO_2^- oxidizers. This leads to an accumulation of NO_2^- in the interval between the depths at which NH_3- and NO_2^--oxidizers are released from light inhibition. Guerrero and Jones (1996a) had reported that AOB were more sensitive to light inhibition than were NOB, but found that NOB required longer recovery times than AOB (Guerrero and Jones, 1996b). Thus differential recovery time, rather than differential light inhibition, could explain the formation of the primary NO_2^- maximum by nitrification.

Several studies of nitrification rates in surface seawaters from various geographical regions show profiles that are consistent with light inhibition of both NH_3 and NO_2^- oxidation (Lipschultz et al., 1990; Ward and Carlucci, 1985; Ward and Kilpatrick, 1991; Ward, 1987a; Ward et al., 1984). Simulated in situ rate measurements (i.e., measured under realistic light conditions) show a clear negative relationship with ambient light intensity (Ward et al., 1984). Nitrifiers may be somewhat protected from light inhibition in surface waters by the presence of absorbant organic compounds in seawater and by mixing, which prevents long intense

exposure at the surface. However, the data from simulated *in situ* rate measurements are consistent with light inhibition in surface waters, and the well verified sensitivity of nitrifiers in culture strongly suggests an influence of light in the environment. In two year study of NH_4^+ oxidation in the surface layer the highest rates were usually associated with lowest light intensity, but low rates occurred at all intensities (Fig. 5.4), implying a role for additional factors. Dore and Karl (1996) did not directly assess the effect of light on nitrification rates (all rates were measured in the dark) but they attributed two distinct features within the primary NO_2^- maximum to phytoplanton (the upper primary NO_2^- maximum) and nitrifiers (the lower primary NO_2^- maximum). After a comprehensive review of previous models for the formation of the primary NO_2^- maximum, and the distributions of chlorophyll, NO_2^- and NO_3^- in the Sargasso Sea, Lomas and Lipschultz (2006) concluded that phytoplankton NO_2^- release was the dominant factor in creating and maintaining the primary NO_2^- maximum, with a secondary role in some seasons for nitrification.

Lipschultz *et al.* (1985) documented the light inhibition of NH_3 oxidation in the Delaware River and concluded that this effect influenced the spatial distribution of nitrification in the estuary. Depending on their depth, light is not usually a problem for nitrification in sediments. In shallow sediments, light may have an indirect positive effect on nitrification rates by increasing photosynthesis, and thus increasing oxygen supply to the sediments (Lorenzen *et al.*, 1998).

The fact that nitrification rates are often maximal in the vicinity of the bottom of the euphotic zone has important implications for our understanding of N supply for primary production. The important distinction made in the new production paradigm (see above), between NH_4^+, which is the "regenerated" nutrient and NO_3^-, the "new" nutrient, is the basis of ^{15}N-tracer methods to assess new and regenerated primary production. However, if nitrification occurs in the same depth interval where nitrate assimilation occurs, then nitrate too is a "regenerated" nutrient.
Figure 5.4 Relationship between ammonia oxidation rate and simulated in situ incubation light intensity. Data are shown for approximately 220 ^{15}N-NH_4 tracer incubations performed over the course of 2 years in Monterey Bay, CA. (From Ward, 2005)

Then, total NO_3^- assimilation would depend on a combination of NO_3^- supplied by nitrification, plus that supplied by mixing from the deep reservoir. Several studies have addressed the question of whether significant nitrification occurs in the euphotic zone, and have concluded that *in situ* nitrification could supply 100% or more of the phytoplankton NO_3^- demand (Bianchi *et al.*, 1997; Dore and Karl, 1996; Ward *et al.*, 1989b). A large role for *in situ* nitrification to supply the phytoplankton NO_3^- demand is also supported by biogeochemical models (Mongin *et al.*, 2003). Estimated vertical fluxes of NO_3^- via eddy pumping were also not sufficient to support the observed primary production in the Sargasso Sea (Martin and Pondhaven, 2003). Thus nitrification and NO_3^- assimilation by phytoplankton can be closely coupled, even though the two processes are favored by quite different environmental conditions. Nitrate must be considered a regenerated nutrient in some cases, and estimates of new primary production in the euphotic zone on the assumption that NO_3^- is supplied only as a new nutrient from outside the system is not valid (Yool *et al.*, 2007).

Even in coastal systems where allocthanous nutrient supply can be very large, nitrification and be an important source of NO_3^-. Dham *et al.* (2002) measured very high nitrification rates in the summer in the shallow water of mangrove forests. The rates were highly correlated with both NH_4^+ and NO_3^- concentrations and could supply the entire phytoplankton NO_3^- demand in summer.

4.5. Substrate concentration

The influence of light may be compounded by the necessity for NH_3 oxidizers to utilize NH_4^+, which is in short supply in those depth intervals in the water column where light is most intense. When NH_4^+ assimilation and NH_4^+ oxidation are measured in the same incubation, it is seen that assimilation is more important in the upper portion of the euphotic zone and nitrification in the lower portion (Fig. 5.3 and Ward, 1987a). This pattern suggests that in the well lit upper waters, phytoplankton are able to assimilate NH_4^+ but nitrifiers are either unable to compete for NH_4^+ in the presence of phytoplankton or else, light inhibition prevents them from utilizing NH_4^+ in that environment. In the lower portion of the euphotic zone, phytoplankton may be light limited and less able to assimilate NH_4^+, whereas nitrifiers are released from light inhibition and better able to utilize the NH_4^+ being released by mineralization or N_2 fixation in that interval. There is no direct evidence that nitrifiers are poor competitors with phytoplankton in the lower euphotic zone, but direct tests of this hypothesis in shallow sediments confirm that benthic algae are superior competitors for NH_4^+ relative to benthic AOB communities (Risgaard-Petersen *et al.*, 2004b). The analogous situation in the surface ocean is certainly consistent with observed rate and biomass distributions. Incubation experiments under various conditions of light and NH_4^+ additions could be used to differentiate the effects of light and substrate competition. It would be especially important to impose true tracer level substrate additions and very sensitive isotope determinations to avoid even minor perturbations caused by additions of substrate and product.

In cultures of nitrifying bacteria, the dependence of nitrification rate on substrate concentration is first order at low concentrations (10–100 μM; these

concentrations are low for culture conditions and some sediments, but very high compared to surface seawater). The instantaneous rate of NH_4^+ oxidation or NO_2^- oxidation increases predictably with increasing NH_4^+ or NO_2^- concentration until some, often very high, inhibitory level is reached. However, researchers often have been unable to demonstrate consistent substrate dependence for NH_3 oxidizers in natural assemblages. A general relationship between measured NH_4^+ oxidation rate and ambient NH_4^+ concentration supports the importance of substrate concentration. Early studies (Vaccaro, 1962) showed that net NO_2^- and NO_3^- accumulation in samples from the Gulf of Mexico was stimulated by the addition of NH_4^+. In ^{15}N tracer experiments on water samples when substrate additions are made at the micromolar level representative of the environment, NH_4^+ oxidation is usually independent of substrate concentration. Lack of response to substrate perturbation (e.g., Olson, 1981a; Ward and Kilpatrick, 1990) has led to speculation that the affinity of NH_3 -oxidizers for NH_4^+ may be so great that current experimental methods cannot detect a response to enhanced substrate concentrations. In contrast to NH_3 oxidation, NO_2^- oxidation in natural samples usually shows a more conventional response to added substrate (e.g., Olson, 1981a), but this second step in the nitrification process has received less attention. If AOA dominate the NH_3 oxidizing assemblage of seawater, then the substrate affinity arguments above apply to AOA, but their substrate affinity and kinetics in culture have not been studied.

Nitrification in sandy sediments and in biofilms on rocky substrates in a Portuguese estuary was stimulated by increased NH_4^+ concentration, up to thresholds greater than 100 μM, above which higher concentrations became inhibitory (Magalhaes et al., 2005). Considering measurements from several marine and estuarine environments, Caffrey et al. (2003) found that potential nitrification rates were positively correlated with ambient NH_4^+ concentration when oxygen was available. Very high NH_4^+ concentrations were associated with anoxic sediments, however, where no nitrification occurred. Availability of NH_4^+ in sediments is expected to be influenced by ionic strength, because NH_4^+ ions are displaced from sediment adsorption sites by other cations at high salinity. The idea that the salinity effect on nitrification could be explained by the interaction with NH_4^+ availability (Gardner et al., 1991; Seitzinger et al., 1991) does not appear to be the case (see salinity section above).

4.6. Oxygen concentration

Nitrifying bacteria are traditionally considered to be obligate aerobes; they require molecular oxygen for reactions in the N oxidation pathways and for respiration. They are reputed to be microaerophiles, however, who thrive best under relatively low oxygen conditions. Microaerophily may be important in interface environments such as the sediment water interface and in the oxygen minimum zones of the ocean. The role of oxygen in sedimentary nitrification and coupled nitrification/denitrification is discussed above in the section on nitrification in sediments.

While net nitrification and growth at the expense of inorganic N occurs only under aerobic conditions in autotrophic nitrifiers, both NH_3- and NO_2^--oxidizing

nitrifiers are apparently capable of partial or even complete denitrification. Loss of fixed N has been observed in cultures of nitrifying bacteria growing at reduced oxygen tension. *Nitrosomonas* sp. marine in a lithotrophic medium (no added organics) grew best under an oxygen concentration of 1% in the headspace (compared to 20% in air) (Goreau *et al.*, 1980) and they also produced the greatest amount of nitrous oxide relative to NO_2^- under those conditions. Production of nitrous oxide, nitric oxide and N_2 was reported for *Nitrosomonas* growing in the presence of organic compounds in the absence of oxygen (Stuven *et al.*, 1992). *Nitrosomonas* could also grow using hydrogen as an electron donor and NO_2^- as its electron acceptor (Bock *et al.*, 1995). NO_2^- oxidizers can grow via dissimilatory NO_3^- reduction in the presence of organic matter and the absence of oxygen (Freitag *et al.*, 1987).

The potential ecological impact of this physiological versatility in nitrifying bacteria has not been widely investigated in natural systems. The anaerobic capabilities of nitrifiers have received much more attention in connection with sewage and wastewater treatment, where there is economic incentive to enhance the conversion of NH_4^+ to N_2 under totally anaerobic or totally aerobic conditions. The conditions that are conducive to denitrification by nitrifying bacteria are the same ones that induce denitrification in classical denitrifying bacteria. It is conceivable that both metabolic types are involved in the production and consumption of trace gases in the same environment. Both N_2O and NO are involved in important atmospheric processes; they contribute to greenhouse warming and to catalytic destruction of stratospheric ozone. Thus, understanding which processes are responsible for their production could prove to be important for understanding or potentially regulating their fluxes.

A significant positive correlation between apparent oxygen utilization (AOU) and N_2O accumulation is often observed in marine systems (Cohen and Gordon, 1978; Nevison *et al.*, 2003; Yoshinari, 1976). The relationship implies that nitrification is responsible for N_2O accumulation in oxic waters where it is released as a byproduct of mineralization going to completion via nitrification. The relationship breaks down at very low oxygen concentrations ($\sim 6\ \mu M$, Nevison *et al.*, 2003), where N_2O is usually below atmospheric saturation due to consumption by denitrification. The lack of correlation between N_2O accumulation and N-star (an indicator of N cycle stoichiometry; Deutsch *et al.*, 2001) is additional support for the conclusion that most of the N_2O in the ocean is derived from nitrification rather than denitrification (Nevison *et al.*, 2003). In a few special places in the open ocean, oxygen concentration is depleted to a level low enough to allow net denitrification to occur in the water column. These regions, referred to as oxygen deficient zones, occur in the eastern tropical South Pacific (off the coast of Peru), in the Arabian Sea and the eastern tropical North Pacific Ocean (off the west coast of Mexico). The coupling between nitrification and denitrification has also been studied in these systems, which are essentially analogous to the sediment environments described above, except that the oxygen and NO_3^- gradients extend over tens to hundreds of meters. Suboxic and anoxic waters and sediments tend to have large fluxes, and sometimes large accumulations, of the gaseous intermediates of nitrification and denitrification. This is probably due to the sensitivity of the various organisms and enzymes involved in their production and consumption to oxygen concentration in the local environment of the microorganism.

In studies of N cycling in oxygen deficient zones, nitrification and denitrification appear to be linked, as might be expected from analogy with sediment systems. Ammonium oxidation typically is maximal near the bottom of the euphotic zone close to the upper boundary of the oxygen minimum zone, but NO_2^- oxidation is detected within the oxygen minimum zone itself (Lipschultz *et al.*, 1990). This finding is consistent with the ability of NO_2^- oxidizers to persist and metabolize at very low or zero oxygen conditions, but their metabolism under these conditions would be expected to be dissimilatory rather than oxidative. The nitrous oxide that typically accumulates in the suboxic (low but not zero oxygen concentrations) regions of the oxygen minimum zones is thought to be due to nitrification (via NO_2^- reduction by AOB under low oxygen conditions), because nitrous oxide is depleted in the core of the oxygen minimum zone where denitrification rates are thought to be greatest. A direct tracer confirmation of this pathway in nature has not yet been accomplished. Stable isotope measurement of nitrous oxide from oxygen depleted waters in the Arabian Sea imply that both nitrification and denitrification may contribute to the signal (Naqvi *et al.*, 1998; Ward and Zafiriou, 1988). Ward and Zafiriou (1988) attributed the nitric oxide production they observed in the oxygen minimum zone of the eastern tropical North Pacific to nitrification and found that it was equivalent to 18% of the total NH_3 oxidation rate.

5. NITRIFICATION AND METHANE OXIDATION

As mentioned above in connection with the physiology of nitrifying bacteria, the NH_3 oxidizers and the methanotrophs have important biochemical similarities. These similarities extend to the nature of the primary enzyme in the NH_3 and methane oxidation pathways, the sensitivity of the enzymes to a wide range of metabolic inhibitors, the metabolic capabilities of the cell and to the ultrastructure of the cell (Bedard and Knowles, 1989). Methanotrophs, like NH_3 oxidizers, depend on two substrates with generally opposite sources. Methane, like NH_4^+, accumulates in anoxic habitats where it is produced by strictly anaerobic methanogens. Oxygen diffuses into surface waters or surface sediments from the overlying oxygenated habitats. The classical environment for significant contributions by methanotrophs to system–wide carbon cycling is stratified lakes, in which a large fraction of the annual carbon fixation is cycled through methanogenesis and methane oxidation. The methanotrophic activity is highest at the interface where oxygen and methane coincide. As described above for sediments, such an interface would also be an interface for NH_4^+ and oxygen and might be expected to harbor high nitrification activity as well.

Owing to the presence of high sulfate concentrations in seawater, methanogenesis is not as important in marine sediments and seawater as it is in freshwater systems. Nevertheless, there are a few marine environments where methane is found. The situation in Scan Bay or Cape Lookout Bight sediments, or in the water column of the Black Sea or the Cariaco Basin, is largely analogous to that in stratified lakes.

The observation from culture studies that methane oxidizers are capable of oxidizing NH_3 (Dalton, 1977) and that NH_3 oxidizers are capable of oxidizing

methane (Jones and Morita, 1983; Ward, 1987a), has led to uncertainty about which organisms are responsible for observed methane and NH_4^+ fluxes in nature. Although both groups of microorganisms show similar regulation by environmental variables and similar sensitivities to a variety of inhibitors (Bedard and Knowles, 1989), the possibility for differential regulation based on substrate affinity or competition suggested that ''cross oxidation'' might have important implications for the rate of NH_4^+ or methane oxidation in nature. Based on a combination of simulated *in situ* rate measurements, inhibitor studies and kinetic experiments with natural assemblages, it has been concluded largely that methanotrophs are mostly responsible for methane oxidation and nitrifiers for NH_4^+ oxidation in both freshwater and marine environments (Ward and Kilpatrick, 1990; Bedard and Knowles, 1997; Carini *et al.*, 2003). These conclusions do not rule out a role for cross oxidation or participation by both groups in some environments, and the two processes remain problematic to separate entirely in the environment.

6. Future Directions

Our understanding of the biogeochemistry of nitrification has advanced greatly in the past two decades. The basic patterns of distributions and rates have been discovered and are largely understood in terms of the characteristics of the organisms believed to be responsible for the process and their interactions with other components of the ocean's physical and biological systems. Unpredictable surprise discoveries that change our view of the N cycle are likely to appear, as they have done in recent years. Nevertheless, there are some avenues of future discovery that are more easily predictable on the basis of current research.

1. Two recent discoveries are presently causing major reevaluation of our understanding of the N cycle. The anammox process was first described in 1995 (Mulder *et al.*, 1995; van de Graaf *et al.*, 1995) and is reviewed elsewhere in this volume (chapter by Devol). In the time between the first draft of this review and its final revision, the NH_3 oxidizing archaea have been cultivated (Konnecke *et al.*, 2005), shown to be both ubiquitous (Francis *et al.*, 2005; Leininger *et al.*, 2006) and abundant (Wuchter *et al.*, 2006) in both aquatic and terrestrial environments. At this point, it is entirely unclear how extensively the discovery of the AOA will change our understanding of nitrification in the ocean. There are several obvious high priority questions that should be addressed immediately:
    i. What fraction of the ubiquitous Crenarchaeota in the ocean are AOA?
    ii. Are the marine AOA predominantly autotrophic or do they have a facultative or mixotrophic metabolism that allows them to utilize alternative energy generation modes?
    iii. What are the pathways of NH_3 oxidation in AOA? Are they homologous with those of AOB? Do AOA possess a microaerophilic or anaerobic metabolism similar to the nitrifier denitrification pathway of AOB?

iv. How do the physiological characteristics of the AOA compare with those of the AOB in terms of substrate affinity, light sensitivity, growth rates, oxygen requirements, N_2O production, etc.? I.e., are AOA and AOB regulated in the environment by similar factors?

v. What fraction of NH_3 oxidation in the ocean is due to AOA vs. AOB?

It would be very surprising if AOA turn out to have metabolisms and physiological characteristics quite different from those of the AOB, because the knowledge summarized above about nitrification in the environment obviously includes the influence of AOA. That is, conclusions about the distribution and environmental regulation of nitrification rates are derived from samples that contained the natural assemblage of AOA as well as AOB and NOB. What is still missing is the thorough characterization of organismal biochemistry from culture work, or from *in situ* characterizations using molecular methodology such as qPCR to evaluate gene expression and activities in response to environmental variables.

The discovery of AOA does not change the magnitude or distribution of nitrification rates. It may that AOA, rather than AOB, are predominantly responsible for the measured rates, but that does not alter the rates. Thus the *in situ* abundance and activities of AOA, when determined, must be compatible with the biogeochemical constraints discussed above.

Are AOA involved in N_2O production? Preliminary information from soil Archaeal metagenomic fragments reveal a *nirK* homolog similar to that found in *Nitrosomonas europaea* (Treusch *et al.*, 2005). The *nirK* of *N. europaea* is quite distinct from that found in conventional denitrifiers and from the closely related marine clades of AOB (Casciotti and Ward, 2001). The protein encoded by this type of *nirK* apparently is not involved in NO production leading to N_2O from NO_2^- (Beaumont *et al.*, 2002), but may play a role in NO_2^- detoxification or some more general electron transport function. The genome of *C. symbiosum* also contains elements of the NH_3 oxidation pathway, but it appears to be incomplete (Hallam *et al.*, 2006). There is no homolog for the second critical enzyme, hydroxylamine oxidoreductase, and again, the *nirK* homolog is not the type usually recognized as involved in NO_2^- reduction to NO. The pathways involved in NH_3 oxidation and the potential for nitrifier denitrification in AOA are likely to be resolved soon, and they will provide much insight in to the role of AOA in marine N cycling.

Why have AOA never been cultivated before? Although AOB were never thought to be abundant in seawater, extrapolation from *in situ* numbers and rates estimated from cultures usually resulted in a rough match such that no huge missing nitrification flux was identified. Such estimates and extrapolations are very poorly constrained, however, because even the most important/abundant AOB in seawater (the marine *Nitrosospira* type) have not been cultivated and therefore extrapolations from culture to environment could be wildly incorrect. Abundance estimates based on FISH indicate that AOA outnumber AOB in the open ocean by as much as 1000-fold (Wuchter *et al.*, 2006). Nevertheless, AOB have been cultivated from locations all over the world, even though they are notoriously difficult to cultivate and fastidious in culture. The evidence that AOA have only once been obtained in culture, and that from a marine aquarium (Konnecke *et al.*, 2005) suggests that AOA

have some fundamentally different metabolic requirements than AOB. The explanation could be the same that applied to *Pelagibacter ubique*, identified in 16S rRNA clone libraries as SAR11. Although ubiquitous in clone libraries, *P. ubique* was never cultivated until very low substrate clean culture techniques were applied (Rappe *et al.*, 2002). *P. ubique* and its close relatives are estimated to contribute up to 50% of the surface ocean microbial communities, yet it does not grow under standard rich media conditions. Perhaps AOB are the weeds of the marine nitrifiers and AOA are the ever present dominant assemblage that is important in normal—low substrate clean—environmental conditions, the *P. ubique* of NH_3 oxidizers. Alternatively, perhaps most AOA use NH_3 oxidation only as a background or support metabolism and therefore do not compete well in the obligately autotrophic conditions usually employed to enrich for nitrifiers. The only cultivated AOA appears to be obligately autotrophic, but the uncultivated marine Crenarchaeota assimilate organic compounds (Ouverney and Fuhrman, 2000), indicating that a more versatile metabolism may prevail in the AOA that dominate the marine environment.

Are NOA waiting to be discovered? Even less is known about the abundance and growth characteristics of important marine NOB than the AOB; it is entirely possible that NOA are also present. On the other hand, NO_2^- does not accumulate in most of the world's ocean, specifically in the deep ocean where the Crenarchaeota, suspected to be AOA, constitute up to 40% of the microbial cells. If AOA are abundant and active, the resident NO_2^- oxidizing assemblage is clearly capable of keeping up with them. On balance, this argues that most of that 40% of cells is not very active in NH_3 oxidation, or another 40% of the assemblage would be required to consume the NO_2^-.

2. Molecular ecological research has arisen as a powerful research tool and has led to major new ecological insights in recent years. As is the case for every process that has been investigated, this approach has led to the discovery of immense diversity at the genetic level among organisms involved in nitrification. The degree to which this genetic diversity in relation to distribution or regulation of biogeochemical reaction rates is the focus of much current research. Cultivated nitrifiers and rates measured in natural samples make it clear that different strains of nitrifiers have different physiological optima and are thus likely to inhabit different ecological niches. Although so far untested, this statement probably applies to AOA as well as AOB and NOB. Does the variety of physiological types ensure that ecosystem function is maintained in widely different environmental conditions by the activity of different assemblages under different conditions? What is the time scale for change in the microbial assemblage in response to environmental change? Which environmental changes are most likely to affect nitrification rates? A combination of biogeochemical and molecular methods can address these questions.

3. Our understanding of the biochemistry of nitrification is based largely on insights from cultivated strains. Molecular data obtained from clone libraries indicate that the most important AOB in the ocean are not represented in the culture collection. The same is probably true for NOB, but much less molecular information is available for these organisms. At this stage, the most

important AOA have not been identified even in clone libraries, but they certainly are not in culture. Because pure cultures are such a powerful way to investigate the biochemistry and regulation of microbial biogeochemistry, every effort should be made to cultivate both AOA and the so far uncultivated important AOB clades. It is clear that innovative cultivation techniques will be required, perhaps on the *P. ubique* model.

4. Rising CO_2 in the atmosphere or purposeful deep ocean CO_2 disposal may lead to decreases in oceanic pH. pH was not even considered as a factor that influences nitrification rate in the list of potential factors mentioned earlier, because ocean pH is reliably invariant over most of the ocean in today's world. But changes of 1–2 pH units in response to CO_2 increases could inhibit nitrification rates by up to 90% (Huesemann *et al.*, 2002). Long term inhibition of nitrification may lead to the accumulation of NH_4^+ in the oxic waters, decreases in NO_3^- available for denitrification, and changes in phytoplankton community composition as a result of nutrient preferences and competition.

5. Nitrifiers are responsible for the accumulations of N_2O that typically occur at the upper boundaries of OMZ regions. It has been suggested (Fuhrman and Capone, 1991; Jin and Gruber, 2003; Law and Ling, 2001) that increased productivity in the surface ocean, leading to increased organic flux to deeper waters, could increase the total volume of suboxic water, and thence to enhanced N_2O fluxes to the atmosphere. Global warming due to increased atmospheric inventories of greenhouse gases may cause increasingly stable thermal stratification, which could in turn lead to further enlargement of the major oxygen minimum zones of the world ocean. Increased stratification due to atmospheric warming might lead to increased N_2O fluxes to the atmosphere from this source, thus compounding the greenhouse warming effect of CO_2. These possibilities for changes in N_2O dynamics point to the necessity to understand factors that regulate trace gas metabolism by nitrifiers, as well as denitrifiers. The most likely avenues of progress in this area are through stable isotope analyses, including isotopomer approaches (Popp *et al.*, 2002; Sutka *et al.*, 2004), and through genomics. The former can elucidate the biochemical pathways responsible for the formation of compounds with multiple potential sources. Genomics can provide insights into the genetic capabilities, pathways and regulation of metabolic processes that result in trace gas production consumption. Genetic data provide the information necessary to develop specific probes and assays to identify which organisms are involved in particular transformations in particular times and places.

6. Better rate measurements: Although the currently available methods for direct assessment of nitrification rates and the geochemical constraints provide internally consistent estimates of the overall rates and distributions of nitrification, improvements in direct rate methods are sorely needed to investigate the effects of environmental variables on rates under realistic conditions. These improvements will likely come with the application of even greater sensitivity isotope tracer methods, which require less substrate perturbation for detection of signal in the product pool. In addition, stable isotope methods that do not require tracer addition may possess the sensitivity to detect small fractionation

changes in incubated samples. It is particularly important to apply these efforts to the measurement of NO_2^- oxidation rates. Nitrite oxidation rates have only rarely been measured and have suffered from methdological artifacts. Direct rate measurements would be useful in investigating the actual degree of coupling between the two steps in nitrification.

7. Nitrite oxidation and NO_2^- oxidizing bacteria have not received the attention accorded to the first half of the nitrification process. The discovery of AOA raises even more questions about the abundance and activity of NO_2^- oxidizers. With the publication of several NOB genomes (Starkenburg *et al.*, 2006; 2008), new tools are also at hand for the molecular ecological study of NOB to address the parallel questions of diversity and abundance raised by recent findings on the AOB and AOA. Finally, are the NOB responsible for the consumption of NO_2^- generated by AOB and AOA or are NOA awaiting discovery?

Denitrification including Anammox

Allan H. Devol

Contents

1. Introduction

Denitrification is the process by which combined nitrogen is reduced to gaseous end products; combined nitrogen being nitrogen combined with any element other than itself, e.g., nitrate, ammonium or organic ammines. Originally "denitrification" referred to the phenomenon of loss of nitrogen from a microbial community, but the term was adopted by Kluyver and Donker (1926) when they defined denitrification as a metabolic pathway that allowed respiratory metabolism in the absence of oxygen. Canonical denitrification is a heterotrophic process in which nitrogen oxides serve as the terminal electron acceptor for organic carbon metabolism (Codispoti *et al.*, 2001). However, from a biogeochemical perspective any process that results in loss of combined nitrogen from the biosphere is a denitrifying process. Thus, metabolisms such as the newly discovered anammox reaction, an autotrophic metabolism (Strous *et al.*, 1999), as well as purely inorganic reactions between metal oxides and ammonium that may produce nitrogen

gas would also be denitrifying processes. This is the definition of denitrification adopted here.

In the oceans canonical denitrification takes place when dissolved oxygen concentrations are reduced to zero, or nearly so. At this point, a series of suboxic respiratory processes is initiated through which alternate electron acceptors are utilized during the oxidation of organic matter. These electron acceptors include NO_3^-, IO_3^-, Mn (III, IV) oxides, and Fe (III) oxides (Farrenkopf et al., 1997; Luther et al., 1997; Nealson and Saffarani, 1994). In the oceans the dominant of these electron acceptors is nitrate. Thermodynamic calculations suggest that oxidation of typical "Redfieldian" organic matter with NO_3^-, IO_3^-, or Mn (IV) all yield similar amounts of free energy, all of which are somewhat less than O_2, while Fe (III) oxidation yields are substantially less (Farrenkoph et al., 1997; Froelich et al., 1979; Hulth et al., 1999; Murray et al., 1995). Chemical distributions of oxidized and reduced species in the water column and sedimentary pore waters suggests that the sequence of electron acceptor utilization generally follows the thermodynamic energy yield, i.e., $O_2 > NO_3^- \cong IO_3^- \cong Mn(IV) > Fe(III) > SO_4^=$ (Farrenkoph et al., 1997; Froelich et al., 1979; Luther et al., 1998; Murray et al., 1995; King and Nedwell, 1985).

Nearly all heterotrophic denitrifiers are facultative anaerobes (Tiedje, 1988). Although various workers defined suboxia differently, the upper limit of oxygen concentration for the occurrence of denitrification is probably 5 µM, with quantitatively most denitrification in the marine environment taking place below about 2 µM (Cline and Richards, 1972; Codispoti et al., 2005; Devol, 1978; Murray et al., 1995). The ability to denitrify is not limited to the bacteria, archea and even some fungi are capable of denitrification (Knowles, 1996; Zumft and Körner, 1997).

Suboxic environments are found throughout the oceans. Three large water column suboxic zones are found in the modern ocean: one in the eastern tropical North Pacific off the west coasts of Mexico and Guatemala, one in the eastern tropical South Pacific off Peru and Chile, and one in the northern Arabian Sea (Codispoti et al., 2001). Suboxic zones are also found in marine sediments, primarily shelf and slope sediments, where dissolved oxygen is depleted relatively quickly below the sediment–water interface (Aller et al., 1985; Blackburn, 1987; Blackburn et al., 1996; Devol and Hartnett, 2001; Jørgensen and Sørensen, 1985; Lomstein et al., 1989; Reimers et al., 1992; Seitzinger and Giblin, 1996). Likewise, anoxic basins and fjords such as the Black Sea, Cariaco Trench, and Saanich Inlet contain a suboxic zone between the upper oxic layer and the lower sulfidic layer (Anderson and Devol, 1973; Murray and Yakushev, 2006; Richards, 1975; Thunell et al., 2004). Finally, the lower water column over productive shelf areas sometimes becomes suboxic. This situation is a persistent natural phenomenon off south west Africa (Kuypers et al., 2005; Tyrrell and Lucas, 2002), occurs ephemerally on others (Dugdale et al., 1977) and, due to anthropogenic stimulation of productivity, has become a problem on the shelf surrounding the Mississippi River delta (Rabalais et al., 1996) and on the continental shelf off the north west coast of India (Naqvi et al., 2000).

This review will cover various pathways of denitrification, important oceanic sites of denitrification, isotopic consequences of denitrification, and the role of

denitrification in the marine combined nitrogen budget. A detailed recent review of the metabolic pathways and cell biology of denitrification is given by Zumft (1997) and the ecology of denitrification was reviewed by Tiedje (1988).

2. Pathways and Controls of Nitrogen Oxide Reduction and Denitrification

2.1. Canonical or respiratory denitrification

Canonical denitrification is carried out by heterotrophic bacteria during which nitrate (or nitrite) serves as the terminal electron acceptor for organic matter oxidation and the nitrogen oxides are reduced mainly to nitrogen (some nitrous oxide may be formed). The characteristic feature of canonical denitrification is that the reduction of N-oxides is coupled to electron transport phosphorylation (Knowles, 1982, 1996; Koike and Hattori, 1975). The capacity for respiratory denitrification is widespread among bacteria and is distributed across various taxonomic subclasses, mainly within the Proteobacteria (Zumft, 1997).

   The N-oxide reduction pathway during canonical denitrification has been well worked out and involves the sequential reduction of nitrate to nitrite, followed by nitric oxide, nitrous oxide and finally to nitrogen gas (Fig. 6.1). This sequential reduction is facilitated by four well-studied enzyme systems, nitrate reductase, nitrite reductase, nitric oxide reductase and nitrous oxide reductase (Zumft and Körner, 1997). The intermediate, NO_2^-, is known to escape the cell and is frequently found in denitrifying environments under certain conditions; likewise, N_2O also can accumulate externally (Codispoti et al., 2005; Tiedje, 1988). In denitrification favorable environments local maxima in both intermediates tend to occur near the boundaries of a suboxic zone. Interestingly, NO_2^- and N_2O are also intermediates that accumulate in the environment during nitrification (Betlach and Tiedje, 1981; Codispoti et al., 1992; Naqvi and Noronha, 1991), frequently complicating interpretation of oceanographic profile data (Yoshinari et al., 1997). As NO is actually a free radical and, thus, very reactive, and highly toxic to most bacteria including denitrifiers (Zumft, 1997), nitrite reductase and nitric oxide reductase are controlled interdependently at both the transcriptional and enzyme activity levels in order to minimize the accumulation of NO (Ferguson, 1994; Zumft, 1997). Although the distribution of NO in the environment has not been well-studied, it is generally undetectable in aerobic water columns but it has been detected at low levels in oxygen deficient waters (≤ 0.5 nM; Ward and Zafario, 1988).

$$NO_3^- \xrightarrow{\text{Nitrate reductase}} NO_2^- \xrightarrow{\text{Nitrite reductase}} NO \xrightarrow{\text{Nitric oxide reductase}} N_2O \xrightarrow{\text{Nitrous oxide reductase}} N_2$$

Figure 6.1 Denitrification pathway involved in canonical denitrification. The four enzymes involved in the sequential reduction of nitrate are show.

2.2. Chemodentirification and chemotrophic denitrification

In addition to canonical heterotrophic denitrification there are a number of reactions between inorganic and organic compounds and N-oxides that produce N_2 and yield significant free energy. Some of these reactions are known to be catalyzed by microbes, while others have been proposed to occur spontaneously. Under acidic conditions, pH ≤ 5, the acid catalyzed reduction of NO_2^- can become important (Broadbent and Clark, 1965; Van Cleemput et al., 1976). Another related reaction is a Van Slyke type reaction (Van Slyke, 1911), whereby organic ammines are oxidized by NO_2^- to form N_2. This reaction is also favored under mild acidic conditions and has been shown to be important in frozen soils where NO_2^- is concentrated by the salting out effect (King and Nedwell, 1985). However, due to the well-buffered nature of seawater these reactions are not thought to be important in the oceans (Cline and Richards, 1972; Richards, 1965). It is well documented that reduced sulfur compounds (*Beggiatoa*, *Thiobacilus*) and H_2 also (*Pseudomonas*) also support chemotrophic bacterial denitrification (Tiedje, 1988; Zumft, 1997).

Much attention has recently been focused on interactions between various manganese and nitrogen species because solute profiles through the suboxic zones of anoxic basins such as of the Black Sea and marine sediments suggest that reactions involving these two species may be occurring (Murray et al., 1995; Luther et al., 1997, 1998). Luther et al. (1997, 1998) have proposed two reactions with manganese that result in denitrification:

$$15MnO + 6HNO_3^- \rightarrow 15MnO_2 + 3N_2 + 3H_20 \qquad (6.1)$$

$$15MnO_2 + 10NH_3 \rightarrow 15MnO + 5N_2 + 15H_20 \qquad (6.2)$$
Interestingly, if the two reactions are coupled, the overall result is:

$$6HNO_3^- + 10NH_3 \rightarrow 8N_2 + 18H_2O. \qquad (6.3)$$
Similar reactions can be written for Fe and N, but the free energy yields are not as large and the Fe^{2+} oxidation coupled to NO_3^- reduction to N_2 is not favorable at typical seawater pH (Luther et al., 1997). Reaction 2 has been shown to proceed under laboratory conditions (Luther et al., 1997; Straub et al., 1996) and has been proposed to explain sediment pore-water distributions in the Laurentian Trough (Anschutz et al., 2000), but it would seem likely that any such reactions in the natural environment are microbially catalyzed.

2.3. Anammox

Canonical denitrifiers are mainly facultative anaerobes that can modify their electron transport system to accommodate N-oxides as the terminal electron acceptor for organic carbon oxidation. However, commitment with the oxidation of proteins to CO_2 and H_2O is the liberation of the amino group as NH_4^+. Thus, canonical denitrification should be accompanied by the build up of NH_4^+ concentrations, but

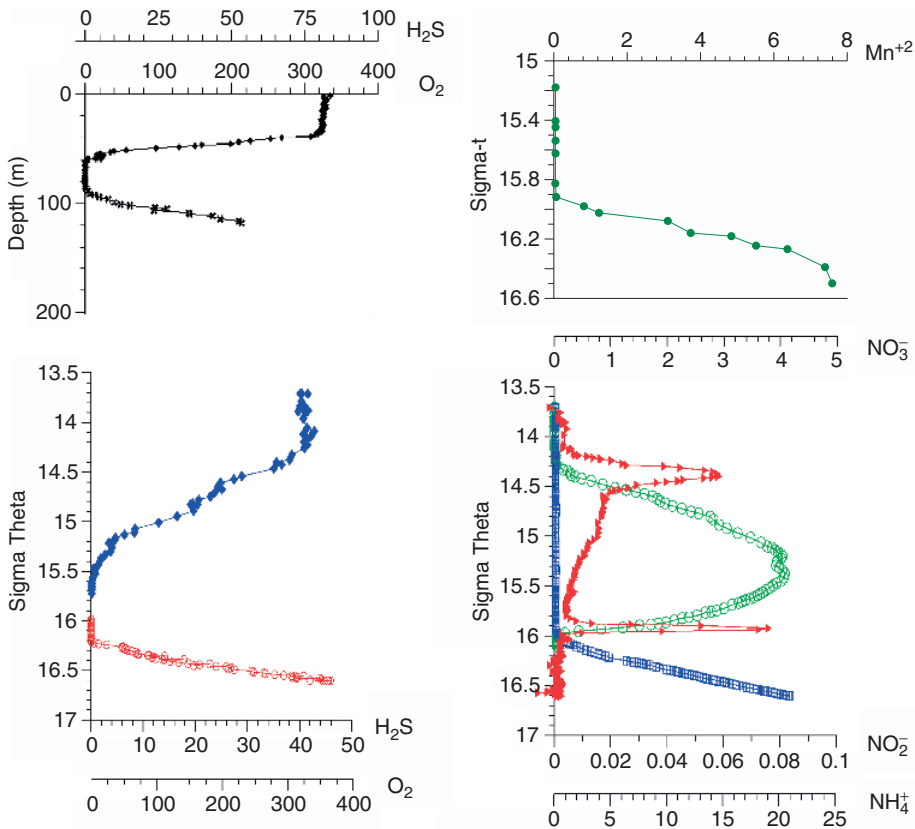
significant NH_4^+ accumulation is not observed in the water column of open-ocean denitrification zones (Codispoti, 1973). Similar observations led Richards (1965) and Cline and Richards (1972) to propose that a Van Slyke like reaction was responsible for the anaerobic oxidation of ammonium (similar to the reaction given in Eq. (6.3) above but with amino acids as the electron donor). Likewise, interpretation of solute profiles in sediments lead several groups to propose anaerobic ammonium oxidation there (Bender et al., 1989; Emerson et al., 1980), as well as in the water column of the Black Sea (Murray et al., 1995). The Black Sea data are perhaps the most compelling (Fig. 6.2). Here dissolved oxygen is depleted at a depth of about 60 m ($\sigma_\theta = 15.7$), whereas nitrate is depleted somewhat deeper at about 80 m ($\sigma_\theta = 15.95$). Ammonium is generated at depth via sulfate reduction and it is in high concentration there. As one moves upward these high ammonium concentrations decrease until they


Figure 6.2 Water-column profiles from the western gyre of the Black Sea, 2003: Upper left— dissolved oxygen (diamonds) and hydrogen sulfide (x) versus depth; Upper right—dissolved Mn (II) versus sigma theta; Lower left—dissolved oxygen and hydrogen sulfide versus sigma theta; (lower right), Nitrate (open circles), nitrite (triangles), and ammonium (open squares) versus sigma theta. (Composite redrawn from Murray and Yakushev, 2006. Data are from the same station but different hydrocasts.).

reach zero very near the depth at which NO_3^- and NO_2^- reach zero. These gradients imply a flux of NO_3^- and NO_2^- downward and a flux of NH_4^+ upward into a zone where they are both consumed. However, as noted by Broda (1977) the organism that could carryout this reaction seemed to be "missing in Nature." In 1999, a Plancto-mycetes microbe capable of the "anammox" reaction, i.e., Eq. (6.3), except with NO_2^- substituted for NO_3^-, was isolated from a fluidized bed reactor (Strous *et al.*, 1999), and shortly thereafter other genetically similar organisms were identified in natural environments where the anammox reaction was shown to take place, includ-ing the Black Sea suboxic zone (Dalsgaard and Thamdrup, 2002; Jetten *et al.*, 2003; Kuypers *et al.*, 2003; Risgaard-Petersen *et al.*, 2004a). Although three genera of anammox organisms have been isolated so far—*Candidatus*, *Kuenenia*, and *Scalin-dua*—only *Scalindua* has been found in environmental samples to date.

Anammox bacteria are chemoautotrophic bacteria that fix CO_2 using NO_2^- as the electron donor (Güven *et al.*, 2005) and they are thought to be strict anaerobes. All anammox species found too date have evolved a membrane-bound intracyto-plasmic compartment called the anammoxasome. The anammoxasome membrane is made up of high-density lipids, called ladderanes because of their ladder-like struc-ture, that are thought to be specific to anammox bacteria. The proposed mechanism of anammox involves a hydrazine hydrolase, which catalyzes the combination of hydroxyl ammine and ammonium to form hydrazine. The hydrazine is subsequently oxidized to N_2 by a hydrazine-oxidizing enzyme (Fig. 6.3; Jetten *et al.*, 2003; van Niftrik *et al.*, 2004). The ladderane-lipid membrane is thought to act as a barrier to diffusion thus isolating the toxic intermediates of the anammox reaction within the anammoxasome. It is also believed that the anammoxasome helps create a proton motive force that is coupled with ATP production (van Niftrik *et al.*, 2004).

Anammox bacteria were originally thought to be specialists catalyzing only the oxidation anaerobic oxidation of NH_4^+. They were also considered slow growing organisms (Dalsgaard *et al.*, 2005). Recent evidence has changed this view some-what. It has been suggested that anammox bacteria are able to grow at much more rapid rates, doubling every 1.8 days versus the 11 day doubling time originally
Figure 6.3 (Right) Schematic depiction of anammox cell showing the anammoxozome and nucleoid. (Left) Postulated pathway of anaerobic ammonium oxidation coupled to the ana-mmoxosome membrane resulting in a proton motive force and ATP synthesis via membrane-bound ATPases. determined (Isaka *et al.*, 2005). More importantly, examination of the genome of *K. stuttgartiensis* revealed anammox bacteria to be much more metabolically versatile previously thought (Strous *et al.*, 2006). They are able to oxidize low molecular weight organic acids to CO_2 using NO_3^- or NO_2^- as the electron acceptor, while simultaneously carrying out the anammox reaction (Güven *et al.*, 2005). Kartal *et al.* (2007) went one step further. In incubations of *K. stuttgartiensis* that were given ^{13}C–formate as a energy source and $^{15}NO_3^-$ as an electron acceptor the main products of nitrate reduction were $^{13}CO_2$ and $^{15}N^{15}N$. In these experiments N_2 did not start to evolve until after a lag phase of several hours, during which $^{15}NO_2^-$ accumulated as an intermediate. They were able to show *K. stuttgartiensis* reduced NO_3^- to NH_4^+ with NO_2^- as an intermediate and that the NH_4^+ and NO_2^- produced were subsequently converted to N_2 via the anammox reaction.

2.4. Dissimilatory nitrate reduction

There are two types of dissimilatory denitrification that are considered here. The first is denitrification that takes place during the chemoautotrophic process of nitrification. Nitrification is the sequential oxidation of NH_4^+ to NO_2^-, which is followed by the oxidation of NO_2^- to NO_3^- (see Chapter 11 by Ward, this volume). These two steps are accomplished by two distinct microbes of the *Nitroso* and *Nitro* groups, respectively. Although it would seem that this obligately aerobic process would not be simultaneously a denitrifying process, a common byproduct of nitrification is N_2O (Tiedje, 1988). Originally, it was thought that this N_2O was produced during the oxidation of ammonium, but Poth (1986) and Poth and Focth (1985) used ^{15}N isotope tracers to show that N_2O was produced from NO_2^- by *Nitrosomonas europaea* and a *Nitrosomonas* sp.

A copper containing nitrite reductase was also isolated from *Nitrosomonas europaea* at about the same time (DiSpirito *et al.*, 1985). More recently, Casciotti and Ward isolated a copper containing nitrate reductase gene, *nirK* (Casciotti and Ward, 2001), as well as a nitric oxide reductase gene, *norB* (Casciotti and Ward, 2004), from several strains of nitrifying bacteria that were homologous to those of denitrifying organisms. Bock *et al.* (1995) showed that *N. europaea* and *N. eutropha* were able to nitrify and denitrify at the same time when grown under oxygen limitation (0.2 and 0.4 mg L^{-1}) and anaerobically. Under oxygen limitation, oxygen and nitrite served simultaneously as electron acceptors and both N_2 and N_2O were produced, whereas under anaerobic conditions N_2 was the predominant end product. (See also Schmidt and Bock, 1997 and Zart and Bock, 1998.) This type of nitrification–denitrification pathway may help explain why ammonium oxidizers remain totally active in nearly suboxic environments and the observation that the N_2O production is stimulated at reduced oxygen concentrations (Blackmer *et al.*, 1980; Goreau *et al.*, 1980). Furthermore, it may help explain the ^{15}N depleted N_2O found in some environmental samples (Dore *et al.*, 1998; Yoshida, 1988). The ability of nitrifiers to thrive at near suboxic oxygen concentrations and the common intermediates (NO_3^-, NO_2^-, NO, and N_2O) with canonical denitrification creates the potential for coupling between the two process at suboxic transition in the

water column and sediments and for a possible coupling of nitrifier-dentirification and anammox (Lam *et al.*, 2007; Schmidt *et al.*, 2002).

Although not strictly denitrification by the definition used here, the process of anaerobic dissimilatory nitrate reduction to ammonium, also known as nitrate fermentation, is worth mention. The reaction has been reported for anoxic sediments (Boon *et al.*, 1986; Kaspar, 1983; Sørensen, 1978) and sediments with substantial free sulfide, possibly due to sulfide inhibition of nitrification and denitrification (An and Gardner, 2002). Suboxic NO_3^- reduction to ammonium appears to occurr in environments where there is excess available carbon, such as estuarine sediments (Rysgaard *et al.*, 1996) and under fish culture net pens (Christensen *et al.*, 2000). Perhaps more important are the nitrate fermenting organisms such as *Thioploca* and *Thiomargarita*, that are found in sediments underlying the major suboxic-denitrifying water columns of the Arabian sea, eastern Tropical Pacific and Namibia (Farrias, 1998; Fossing *et al.*, 1995; Jørgensen and Gallardo, 1999; Schmaljohann *et al.*, 2001; Thamdrup and Canfield, 1996; Devol, unpublished data). These organisms are able to couple the reduction of NO_3^- to ammonium with the oxidation of reduced sulfur compounds. Both *Thioploca* and *Thiomargarita* are able to concentrate NO_3^- at up to 500 mM levels in large vacuoles within their cells for subsequent sulfide oxidation (Fossing *et al.*, 1995; Schulz *et al.*, 1999). *Thiomargarita*, the largest known bacteria, is actually visible with the naked eye (Schulz *et al.*, 1999). Although, the reduction of NO_3^- to NH_4^+ in these environments is not denitrification per se, because these environments underlie suboxic waters, when the ammonia produced by these organisms diffuses up to the denitrification zone it may well be oxidized to N_2 by anammox bacteria at the sediment–water interface or in the overlying suboxic-denitrifying water column (Codispoti *et al.*, 2001, 2005).

2.5. Environmental controls on denitrification

The two necessary requirements for denitrification in the environment appear to be low dissolved oxygen concentrations and the availability of N-oxides. Indeed, the inhibitory effects of oxygen were first reported by Gayon and Dupetit, 1882. The effect of oxygen on denitrification is usually described as an oxygen threshold below which denitrification is initiated, and the sharpness of this transition in the ocean's major oxygen deficient zones (ODZs) is clearly evident in high quality hydrographical data. When the concentration of the denitrification intermediate NO_2^- is plotted against dissolved oxygen, it is seen that NO_2^- does not appear in the water columns of the eastern tropical North Pacific or Arabian Sea until oxygen concentrations are reduced below about 2 μM (Fig. 6.4A and B). Interestingly, when a similar plot is made for data from the intermittently anoxic fjord Saanich Inlet (British Columbia, Canada) the oxygen threshold for NO_2^- accumulation is ~4 μM (Fig. 6.4C). This apparently elevated threshold for denitrification was interpreted as a response by the microbial population to the more transient suboxic environment in the coastal inlet (Devol, 1978). Ferguson (1974) suggested aerobic denitrification might be advantageous to populations growing in near suboxic conditions. Although it has long been known that oxygen represses synthesis and activity of denitrifying enzymes (Tiedje, 1988), denitrification in the presence of
Figure 6.4 Dissolved oxygen versus nitrite concentration for the waters of the ODZ ($<20\,\mu M\,O_2$); the eastern tropical North Pacific (upper, redrawn from Cline and Richards, 1972), the Arabian Sea (center, redrawn after Morrison *et al.*, 1999), and Saanich Inlet (lower, redrawn from Devol, 1975). Note, axes are different on each plot. Vertical lines denote possible denitrification thresholds for each area.

oxygen has been observed in the laboratory (Bell and Ferguson, 1991; Lloyd, 1993; Yoshinari and Koike, 1994). Interestingly, although it is clear that low oxygen concentrations are a prerequisite for denitrification in both the water column (Fig. 6.4) and sediments (Rysgaard *et al.*, 1994), at least in the water column, the denitrification rate is likely controlled by the availability of oxidizable carbon (Lipschultz *et al.*, 1990).

3. Sites of Marine Denitrification

3.1. Water-column denitrification

3.1.1. Locations of pelagic water-column denitrification

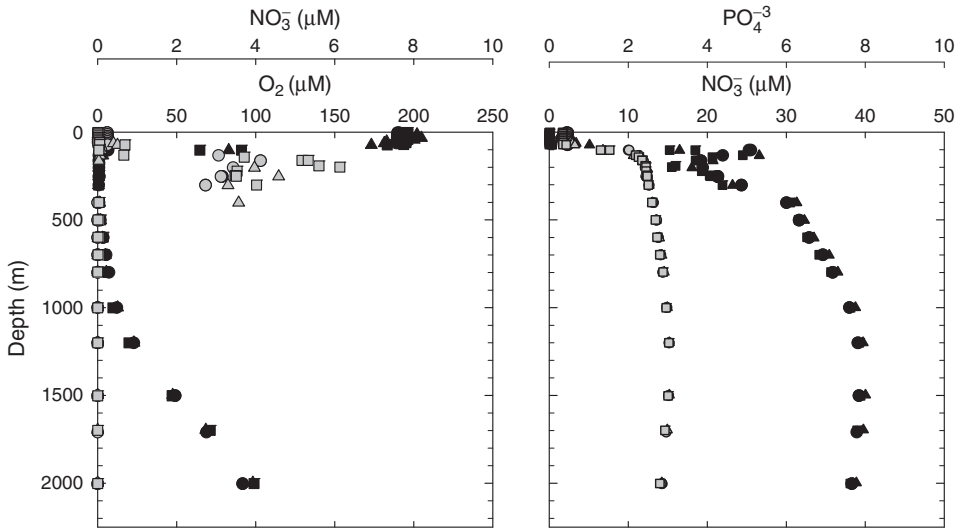
Somewhat less than half the current marine denitrification is thought to occur in the three main pelagic ODZs that are located in the eastern tropical North Pacific (ETNP), the eastern tropical South Pacific (ETSP) and the northern Arabian Sea (Fig. 6.5). These zones occur in the intermediate waters (~150–1000 m) in locations where the ventilation rate is not great enough to meet the oxygen demand. In the Arabian Sea the ventilation of the intermediate waters is not particularly sluggish (Morrison *et al.*, 1999; Naqvi and Shailaja, 1993; Olson *et al.*, 1993). However, high primary productivity during both the Southeast Monsoon and the Northwest Monsoon (Barber *et al.*, 2001) results in a correspondingly elevated organic matter rain rate to the ODZ, which drives these waters to denitrification (see Chapter 14 by Naqvi, this volume). Off western Mexico the situation is reversed. Although primary productivity is only moderate in this area (Longhurst *et al.*, 1995), residence times of ODZ waters have been estimated at about 10 years based on geostrophic calculations (Codispoti, 1973) and CFC ages in the ODZ are the oldest on those
Figure 6.5 Dissolved oxygen on the 26.5 sigma theta surface. Note the three main pelagic water column ODZs, the eastern tropical North Pacific, the eastern tropical South Pacific and the Arabian Sea. Althouth oxygen levels are very low in the Bay of Bengal, this area does not appear to be a location of water column denitrification (Rao *et al.*, 1994).


Figure 6.6 Dissolved oxygen nitrate, nitrite and phosphate in through the ODZ of the Arabian sea. Left—dissolved oxygen (solid black symbols) and nitrite (solid gray symbols). Right—Nitrate (solid black symbols) and phosphate (solid gray symbols). Data are from USJGOFS station M1 during cruises TGT O43 (circles), TGT 045 (triangles) and TGT 050 (squares).

density surfaces in the North Pacific (WOCE Electronic Atlas; www.awi. bremerhaven.de/eWOCE/gallery/index.html). Although a significant ODZ has been reported off south West Africa (Calvert and Price, 1971) little is known about denitrification in this area (except see Section 2.3).

In the ETNP and Arabian Sea dissolved oxygen is reduced to detection levels at about 150–180 m and remains so until about 800 m (Fig. 6.6), while in off Peru waters suboxic waters can be found as shallow as 50 m. Within the upper oxycline both nitrate and phosphate increase dramatically. In the depth zone of vanishingly low oxygen, phosphate concentrations continue to increase to maximal values more or less in the middle of the ODZ. The nitrate profile, however, exhibits a local minimum or ''divot'' in the ODZ where nitrate concentrations actually decline while phosphate increases. This ''divot'' has classically been interpreted as the consequence of canonical denitrification (Codispoti and Christensen, 1985; Codispoti and Richards, 1976; Codispoti and Packard, 1980; Fiadeiro and Strickland, 1968; Naqvi, 1987). Usually coincident with the divot in the nitrate profile is a local maximum in NO_2^- concentration, typically on the order of 2–4 μM. This local maximum is called the secondary nitrate maximum, SNM. Its association with low oxygen waters of the eastern tropical North Pacific was first noted by Gilson in 1937 and represents an accumulation of this intermediate in the denitrification process (Brandhorst, 1959; Codispoti and Richards, 1976; Naqvi, 1987; Thomas, 1966). (The primary NO_2^- maximum is located at the base of the euphotic zone in oxygenated water and is associated with the nitrification process.)
Figure 6.7 Dissolved oxygen (line), nitrite (gray squares) and nitrous oxide (profiles black circles) through the ODZ in the Arabian sea (redrawn from Devol *et al.*, 2007).

Nitrous oxide, the other accumulating intermediate during denitrification, typically displays a profile with two local maxima, one coincident with the base of the oxycline and the second, deeper local maxima near the lower transition from suboxic back to oxic conditions (Fig. 6.7). Concentrations of N_2O at these maxima are frequently an order of magnitude above saturation Below this deeper maximum, N_2O concentrations fall steadily with depth but remain well above saturation. Between the local maxima, N_2O concentrations decrease to extremely low values, presumably due to consumption during denitrification (see Chapter 2 by Bange, this volume; Bange *et al.*, 1996; Bange *et al.*, 2000; Codispoti and Christensen, 1985; Codispoti *et al.*, 1992; Cohen and Gordon, 1978; Naqvi and Noronha, 1991; Naqvi *et al.*, 1998a,b; Yoshinari *et al.*, 1997).

3.1.2. Rates of water-column denitrification
Various methods have been used to estimate water–column denitrification rates including stoichiometric relationships, measurements of the enzymatic activity of the electron transport system (ETS), and $^{15}NO_3^-$ incubation experiments. In combination with residence times or mass transport calculations these measurements yield areal denitrification rates.

Stoichiometric estimations involve calculation of the NO_3^- concentration in a parcel of ODZ water expected before denitrification takes place, i.e., the "expected NO_3^-" (*sensu* Codispoti and Richards, 1976). Given an expected NO_3^-, $^{exp}NO_3^-$, concentration and an analytical determination of the actual inorganic nitrogen concentration ($IN = NO_3^- + NO_2^- + NH_4^+$), the measured value can be subtracted from the expected to give a "NO_3^- deficit" or the amount of NO_3^- removed by denitrification, viz.,

$$^{def}NO_3^- = IN - {}^{exp}NO_3^-. \tag{6.4}$$

Three primary methods have been used to calculate expected NO_3^- and all are based on Redfieldian stoichiometry.

The first quantitative estimates of denitrification in the eastern tropical North Pacific were made by Codispoti and Richards (1976). Codispoti and Richards used apparent oxygen utilization, AOU, and phosphate data to stoichiometrically extrapolate back to the nitrate concentration present when a given water mass was previously at the surface. In this way they were able to develop a relationship between $^{exp}NO_3^-$ and sigma-*t* for waters of the ETNP-ODZ, from which they calculated nitrate deficit as outlined in Eq. (6.4).

A second method used to calculate nitrate deficit takes advantage of the "semi-conservative" water-mass tracer "*NO*" (Broecker, 1974). Stoichiometrically, every mole of O_2 respired will remineralize approximately 1/9 of a mole of NO_3^- so that *NO*, defined as

$$NO = [O_2] + 9.1[NO_3^-], \tag{6.5}$$

should be a conservative property in most water masses. Then, given *NO* in any particular water mass, the amount of NO_3^- expected can be calculated by rearranging the above equation to the following:

$$^{exp}NO_3^- = (NO - O_2)/9.1. \tag{6.6}$$

Again, one can then calculate the nitrate deficit from Eq. (6.4). This method has been used primarily to estimate denitrification rates in the Arabian Sea (Howell *et al.*, 1997; Mantoura *et al.*, 1993; Naqvi, 1987).

Yet another stoichiometric method involves the quantitiy N$\star$ (Deutsch *et al.*, 2001; Gruber and Sarmiento, 1997; Gruber and Sarmiento, 2002). Gruber and Sarmiento used high quality JGOFS or GEOSECS data to develop a general relationship between combined inorganic nitrogen, IN, and PO4 for the world's oceans. The relationship as given in Deutsch *et al.* (2001) is

$$N^* = IN - 16P + 2.90. \tag{6.7}$$

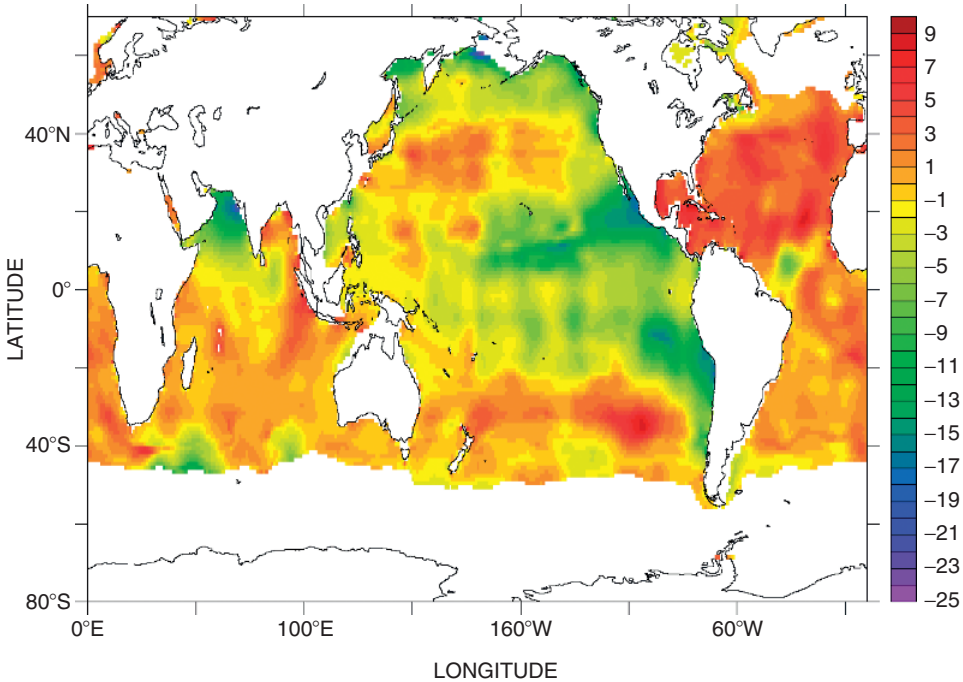
Here N$\star$ is the deviation from the amount of IN predicted stoichiometrically from phosphate and the world-ocean N:P regression relationship. Negative values of N$\star$ are interpreted to show net denitrification whereas positive values show net


Figure 6.8 N⋆ as defined by Deutsch *et al.* (2001) on the 26.5 sigma theta surface. Note the large negative N⋆ values in the eastern tropical North Pacific, the eastern tropical South Pacific and the Arabian Sea. Also note the lack of negative N⋆ in the Bay of Bengal despite its low oxygen (c.f. Fig. 6.5).

nitrogen fixation. N⋆ contours on specific density surfaces clearly show the large pelagic ODZs along with several other possible denitrification features. For example, in Fig. 6.8, the large negative N⋆ values associated with the ETNP, ETSP, and Arabian Sea denitrification zones are clearly evident. Also evident are relatively highly negative N⋆ values in the deep Bering Sea. Indeed, Broecker and Peng (1982) noticed low N–P relationships in deep Bering Sea water and suggested denitrification as the source, and this has since been confirmed by Lehmann *et al.* (2005).

Although N⋆ is useful to demonstrate general patterns of oceanic N-cycling, as Gruber and Sarmiento (1997) point out, N⋆ only show net N-cycling relative to the general oceanic mean. To overcome this shortcoming and to quantitatively estimate nitrate deficits in the Arabian Sea, Codispoti *et al.* (2002) develop a N⋆-type relationship specific to the Arabian Sea from the high-quality JGOFS nutrient data. They utilized a Type II linear regressions of reactive phosphate (PO_4^{3-}) vs inorganic nitrogen ($IN = NO_3^- + NO_2^- + NH_4^+$) on samples from depths between 100 and 1500 db, with oxygen concentrations >65 μM/l to determine the N–P relationship for the intermediate water before the onset of denitrification. The resulting equation was:

$$N_{deficit} = [14.89PO_4^{3-} - 0.28) - IN] \mu M \times 0.86 (r^2 = 0.998), \quad (6.8)$$

where $N_{deficit}$ is the estimate of the inorganic nitrogen removed from a water parcel by denitrification, $14.89 = \Delta IN/\Delta PO_4^{3-}$ (by atoms), 0.28 is the PO_4^{3-} intercept at IN, and 0.86 accounts for the PO_4^{3-} released by the organic material re-mineralized by denitrification assuming that N/P in local organic matter is 14.89, and that consumption of 94.4 NO_3^- by denitrification releases one PO_4^{3-} (Froelich *et al.*, 1979; Richards, 1965). Partially because this equation is independent of dissolved oxygen, it does not result in large negative nitrate deficits in the surface layer (Fig. 6.9). The maximum predicted deficit is about 30% larger (12 vs 9 μM) and remains and extends about 1000 m deeper than the deficits calculated from NO–θ relationships. The observation that the denitrification signal penetrates well below the ODZ, to almost 2000 m is supported by isotopic data (see isotopic section).

Measurement of the enzyme activity of the respiratory electron transport system (ETS activity) has also been used to estimate denitrification rates in the Arabian Sea (Naqvi and Shailaja, 1993) and eastern tropical South Pacific (Codispoti and Packard, 1980) denitrification zones. To measure the ETS activity a crude enzyme extract is made by grinding filtered seawater samples in a buffered medium to liberate the enzymes, after which the ETS substrates NADH+ and NADPH+ along with tetrazolium salt are added as an artificial electron acceptor. Samples are then incubated for a
Figure 6.9 Nitrate deficit in the ODZ of the Arabian Sea. Solid cricles are Codispoti *et al.* (2001) modified N⋆ calculation, while the open circles are calculated from sigma theta relationships of Naqvi and Sen Gupta (1985). Shaded zone approximates the depth zone of the ODZ. (Redrawn from Devol *et al.*, (2007).

short time during which electrons are transferred from the substrates to the electron acceptor by the ETS system reducing the tetrazolium salt to a colored end product, which is quantified and from which the rate of electron transfer can be calculated and used to estimate denitrification rates (Devol, 1975; Codispoti and Packard, 1980; Packard, 1971). In both the Arabian Sea and eastern tropical South Pacific, rates estimated by ETS activity were in general agreement with those estimated by stoichiometric methods.

Recently, Devol et al. (2006) have used on-deck and in situ incubation of water samples with added $^{15}NO_3^-$ to determine the rate of denitrification by measuring the rate of $^{29}N_2$ production. Although these were not true tracer experiments, as the in vitro NO_3^- concentrations were increased 5 µM over the in situ concentration of 25 µM, it is likely that rates were not stimulated by the amendment. In the Arabian Sea ODZ the $\delta^{15}N$ of the N_2 typically increased by 0.4–0.8‰. The average denitrification rate for the ODZ waters they determined was 8.8 ± 3.8 (s.d.) nmol N l^{-1} d^{-1}. Although not directly comparable because of different time scales (days vs years), these rates are in general agreement with those estimated from nitrate deficits and residence times. Rates measured in suboxic shelf waters were moderately higher averaging 28.5 ± 48.9 (s.d).

Devol et al. (2006) were also able to determine the profile of excess N_2 gas throughout the Arabian Sea ODZ. They did this by measuring the N_2:Ar ratio using high precision isotope ratio. Mass spectrometry: The amount of excess N_2 was then computed from the increase in the N_2:Ar over that present in the source waters as measured south of the ODZ. Nitrogen excess gas measurements predicted a larger nitrogen anomaly than that estimated by nitrate deficit, maximum anomaly $=$ 23 µg-at N l^{-1} versus 13 µg-at N l^{-1}, respectively (Fig. 6.10). It was suggested that the mismatch may have resulted from incorrect assumptions of Redfield stoichiometry inherent in the nitrate deficit calculation (Van Mooy et al., 2002), inputs of new nitrogen through N-fixation, N_2 contributions from sedimentary denitrification along continental margins, the anammox reaction, or metal catalyzed denitrification reactions. Regardless, the data suggested that denitrification in the Arabian Sea may have previously been underestimated.

3.2. Sedimentary denitrification

3.2.1. Sites of sedimentary denitrification

Another place where oxygen is typically depleted and denitrification takes place is in marine sediments, especially continental margin and hemipelagic sediments. This is because the source of nitrate, and other respiratory electron acceptors, is the local overlying water, while the respiratory processes within the sediments act as sinks. The sedimentary pore-water profiles reflect the balance between sources and sinks, and the transport mechanism of electron acceptors into the sediment is either molecular diffusion or molecular diffusion plus macrobenthic irrigation. Thus, sedimentary pore-water profiles generally show the vertical zonation of respiratory modes according to the thermodynamic yield outlined previously. Going down core, oxygen is depleted first followed by nitrate, after which reduced manganese appears, followed by reduced iron and finally sulfate declines (Fig. 6.11). In most
Figure 6.10 Excess nitrogen gas in the Arabian Sea. Excess N_2 gas values are presented in units of μg-at l^{-1} so there is a 1:1 stoichiometry with nitrate anomaly. Compare the maximum values presented here, $\sim$25 μg-at l^{-1} with the values of about 13 μg-at l^{-1} derived from nitrate deficit calculations shown in Fig. 6.9. (Redrawn from Devol *et al.*, 2007).
Figure 6.11 Schematic representation of the vertical zonation of electron acceptors in sediments. The highest energy yeilding acceptors are used first, thus oxygen is depleted before nitrate is depleted. Manganese oxide(s) reduction occurs next as shown by the appearance of reduced manganese followed by Iron oxide(s) reduction. Finally, Sulfate is reduced. Mehthanogenesis is not shown but it occurs deeper than sulfate reduction (after Froelich *et al.*, 1979).

continental shelf sediments oxygen penetrates to less than 1 cm below the sediment–water interface and even in most deep-sea sediment oxygen penetration is restricted to the upper 10 cm or so. Thus, there exist ample environments for denitrification in marine sediments.

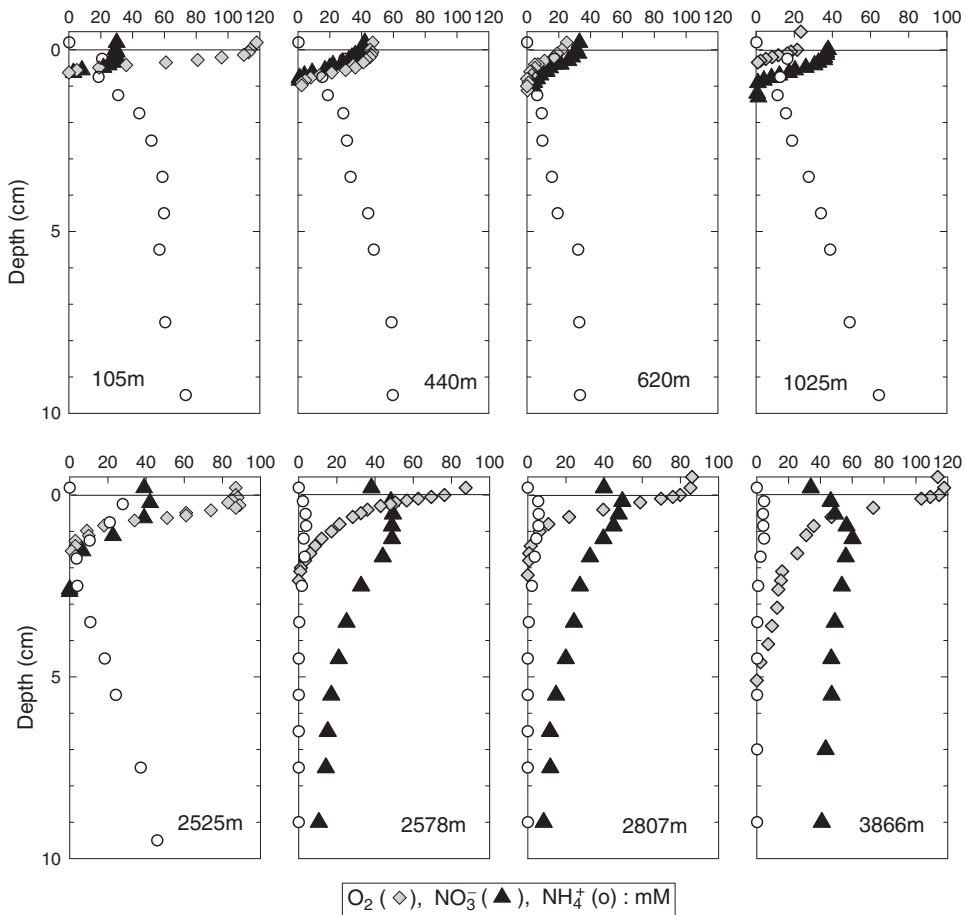
Pore-water nitrate profiles in marine sediments typically show one of three profile shapes. In sediment with rapid rates of organic matter oxidation relative to rates of solute supply from the overlying water, both oxygen and nitrate concentrations decrease more or less exponentially from overlying water concentrations at the sediment–water interface to zero, with oxygen depletion preceding or simultaneous with nitrate depletion at shallow sediment depth (see 105 m and 440 m profiles in Fig. 6.12). These types of profiles are common in continental shelf and upper slope sediments, and are due to relatively large carbon rain to the sediments (relatively


Figure 6.12 Pore-water profiles of oxygen, nitrate and ammonium along a zonal section off the Washington State continental margin at approximatly 47°N latitude extending 650 km offshore. Data from Hartnett and Devol (2003) and Emerson and Devol unpublished.

high shelf productivity and short travel time to sediments; e.g., Brandes and Devol, 1995; Glud *et al.*, 1998; Hartnett and Devol, 2003; Jørgensen and Sørensen, 1985; Kristensen *et al.* 1999; Reimers *et al.*, 1992). When organic matter degradation is less rapid relative to solute supply a subsurface nitrate maximum typically develops (2578 m and 2807 m profiles in Fig. 6.12). This is the result of nitrification in the oxygenated zone of the sediments. These profile shapes are commonly found in hemi–pelagic sediments (Hartnett and Devol, 2003; Reimers *et al.*, 1992). In sediments with very slow rates of organic matter respiration, nitrate profiles increase due to nitrification, but do not decrease because oxidizable organic matter is consumed before the oxygen supply is depleted (this situation is approached in the 3886 m profile in Fig. 6.12). Such profiles are found in deep-sea sediments and under oligotrophic conditions. Continental margins will typically show a progression from very shallow nitrate penetration depth to deeper penetration to a subsurface nitrate maximum that deepens going even further off-shore (Fig. 6.12).

3.2.2. Rates of sedimentary denitrification

Sedimentary denitrification rates have been estimated from measured pore-water solute profiles using diagenetic models, determined directly via sediment incubation both on deck and in situ, and determined from ^{15}N-incubation techniques. Sedimentary diagenetic process can be thought of as a simple reaction–diffusion–transport system (Berner, 1980; Boudreau, 1997). In a simple fine-grained sediment system, transport is via molecular diffusion and the diagenetic equation describing this system can be expressed as:

$$dN/dt = \rho D_s(\partial N/\partial z) - R_{NO_3} + P_{NO_3}, \qquad (6.8)$$

where *N* is nitrate concentration, ρ is sediment porosity, D_s is the sediment diffusion coefficient is depth, *R* is nitrate consumption rate (denitrification) and *P* is nitrate production rate (nitrification). Also note that the flux into the denitrification zone from the top must equal the integrated denitrification rate within the zone or on an areal basis:

$$\text{Flux in} = \int R_{NO_3} dz = \rho D_s(\partial N/\partial z_m), \qquad (6.9)$$

where ∂z_m is the maximum negative N gradient. Thus, given vertical stratification in the zones of oxygen consumption and denitrification, the areal denitrification rate can be calculated from the steepest part of the nitrate gradient.

Early examples of the use of the diagenetic equation are given in Jahnke *et al.* (1982) and Galloway and Bender (1982). Because nitrification is dependent on ammonium produced during oxic degradation of carbon there is a relationship between oxygen consumption and denitrification inherent in these models. Indeed, in a purely diffusive environment it is possible to predict the maximum amount of carbon that can be oxidized by denitrification, C_N, relative to that oxidized by oxygen, C_O. In the pelagic Pacific $C_N:C_O$ can theoretically reach about 0.33, while

in the pelagic Atlantic it can only be 0.13 at maximum (Jahnke *et al.*, 1982). This is because of the higher bottom water nitrate and lower bottom water oxygen in the Pacific than the Atlantic.

Although the simple advection diffusion model works well in open-ocean pelagic sediments, this is not where the majority of sedimentary denitrification occurs; rather it occurs in shallow, shelf and upper margin sediments. About 30% of shallow sediments are fine grained with the remander being sandy (Rao *et al.*, 2007). In these sediments there is rarely a subsurface nitrate maximum and solute transport due to the activities of benthic macrofauna and/or pore-water advection is important if not dominant (Aller *et al.*, 1998; Archer and Devol, 1992; Devol and Christensen, 1993; Glud *et al.*, 2003; Huettel and Rusch, 2000; Janssen *et al.*, 2005a and 2005b; Kristensen and Blackburn, 1987; Kristensen *et al.*, 1991). In shallow fine-grained sediments pore-water advection is not important and the diffusive supply of nitrate for denitrification can be calculated from the pore-water gradient, however the component due to macrobenthic activities, or "irrigation," must also be modeled. Typically this is done with a "biodiffusion" term or a non-local source function (Berner, 1980; Boudreau, 1997). Martin and Banta (1992) investigated the magnitude of macrobenthic irrigation by including a non-local source term of the form $\alpha(C_o-C)$ in the reaction-diffusion equation (here α is an exchange coefficient, cm s^{-1}, C is the concentration at a depth, z, and C_o is the concentration in the overlying water). They modeled both the penetration of added bromine in sediment core incubations and the natural deficit of ^{222}Rn for Long Island Sound sediments. Martin and Banta found that the flux of a given solute into the sediment due to irrigation was equal to that of molecular diffusion or up to several times greater than the molecular diffusive flux. In a more recent study they were able to show that irrigation increased the denitrification rate by about 50% at a upper continental slope site in the mid-Atlantic Bight (Martin and Sayles, 2004).

Devol and Christensen (1993) used a different approach to determine the importance of irrigation in fine-grained Washington State continental shelf sediments. They used in situ benthic flux chambers to measure the net flux of nitrate into the sediments and they also determined pore-water nitrate profiles. By comparing the total nitrate flux into the sediment with the purely diffusive flux calculated from the pore-water profiles, they were able to show that the irrigation flux could be as great as 3 times the molecular flux (this was also true for oxygen and silica fluxes). In addition to benthic nitrate fluxes into the sediment, Devol and Christensen (1993) also measured the flux of N_2 gas out of the sediments. For sediments at their study site the flux of N_2 out of the sediments was about twice the flux of NO_3^- into the sediments. The extra N_2 was attributed to coupled nitrification–denitrification, i.e., within sediment nitrification of NH_4^+ regenerated during organic matter oxidation coupled to subsequent denitrification. This conclusion was supported by a sedimentary nitrogen budget that showed that up to 75% of the regenerated NH_4^+ was nitrified (Devol and Christensen, 1993). The importance of irrigation and within-sediment nitrification as a supply of nitrate for denitrification has been shown by many workers (Christensen *et al.*, 1987; Devol *et al.*, 1997; Glud *et al.*, 1998; Howe *et al.*, 2004; Hulth *et al.*, 1996; Jenkins and Kemp, 1984; Lehmann *et al.*, 2004; Kristensen and Blackburn, 1987; Kristensen *et al.*, 1991).

In general it appears that the rate of sedimentary dentirificaiton is related to the rate of sediment oxygen consumption (Christensen, 1994; Laursen and Seitzinger, 2002; Seitzinger and Giblin, 1996).

Workers who use the nitrogen isotope pairing technique are able to quantitatively partition denitrification into that supplied by nitrification and that supplied by the flux from the overlying water (Christensen *et al.*, 2000; Jensen *et al.*, 1996; Loshe *et al.*, 1996; Nielsen, 1992; Risgaard-Petersen *et al.*, 1998; Wang *et al.*, 2003). However, depending on the degree to which anammox is present, the isotope pairing technique would overestimate canonical denitrification, although this would not be a large problem in sediments where anammox is a minor component of the N-cycling (Risgaard-Petersen *et al.*, 2004b; see following section).

Interestingly, in fine-grained sediments off the west coast of Mexico where the ODZ impinges upon the continental margin denitrification rates are a little less than half those of the Washington margin even though pore-water profiles are about the same (Hartnett and Devol, 2003). Apparently, the lack of dissolved oxygen in the overlying waters precludes macrobenthic organisms and thus pore water irrigation. Lack of oxygen and irrigation prevents both enhanced exchange of overlying-water nitrate into the sediments via macrobentihc irrigation and the possibility of within sediment nitrification and coupled denitrification. This results in the rather counter intuitive observation that denitrification rates are actually decreased by a lack of oxygen in the overlying waters (Hartnett and Devol, 2003).

Though sediments are generally treated as vertically zoned, this may not be the case for all situations. Brandes and Devol (1995) presented pore-water profiles from shallow, rapidly respiring sediments of Washington State and the Chukchi Sea that show oxygen depletion and nitrate depletion at the same depth. Additionally, when both solutes were normalized to their overlying water values, the profiles were nearly identical as were their first derivatives. Brandes and Devol proposed the existence highly respiring microsites within the sediments and they were able to successfully model their data with a microsite model. One of the consequences of this model is that concentrations of both nitrate and oxygen at the microsite are very small and, thus the isotopic fractionation of both solutes should be very much smaller than the observed biological fractionation (Brandes and Devol, 1995). Indeed, subsequent studies have found near zero isotopic fractionation for dissolved oxygen, nitrate and nitrogen gas in sediment incubations Brandes and Devol, 1997; Lehmann *et al.*, 2005; Sigman *et al.*, 2003).

In sandy sediments pressure gradients caused by waves and flow over irregular topography (sand waves or mounds) can force an advective flow of pore water through sediments (Huettel *et al.*, 1998; Precht and Huettel, 2003). Although it is well documented that pore-water advective flow through coarse-grained sediments increases sedimentary oxygen consumption (Huettel and Rusch 2000; Reimers *et al.*, 2004), little is known about its effect on sedimentary denitrification. However, Rao *et al.* (2007) investigated denitrification rates in sandy sediments from the South Atlantic Bight. Their experiments were done by pumping water through natural sediment cores at environmentally determined rates and measuring the nitrate and

nitrogen gas differences between the inflow and outflow. Measured rates were similar to those typically found in fined grained sediments.

3.3. Sites and rates of anammox

Like canonical denitrification anammox favorable conditions are those where oxygen has been depleted, and, like canonical denitrification, anammox has been found both in marine sediments and within the water column. Nitrogen stable isotope incubations are commonly used to distinguish between anammox and canonical denitrification. Typically, additions of $^{15}NH_4^+$, $^{15}NH_4^+ + {}^{14}NO_3^-$, and $^{15}NO_3^-$ are made to anaerobic samples that are then incubated for hours to several days, after which the samples are sacrificed and the isotopic composition of N_2 is determined. If $^{29}N_2$ is formed during the incubations with added $^{15}NH_4^+$ this is taken as evidence of anammox, whereas formation of $^{30}N_2$ in the $^{15}NO_3^-$ treatment is indicative of canonical denitrification. The treatment with both $^{15}NH_4^+ + {}^{14}NO_3^-$ is used to detect anammox in samples with little or no ambient NO_3 or samples that have been preincubated to remove traces of O_2 and NO_3^-. That NO_2^- rather than NO_3^- is the electron acceptor during anammox has been confirmed by the isotopic composition of N_2 at the end of the experiment. With $^{15}NO_3^-$ as the electron acceptor, the reaction stoichiometry would be

$$5{}^{15}NO_3^- + 3{}^{14}NH_4^+ = 4N_2 + H^+ + H_2O, \qquad (6.10)$$
whereas, with 15 NH_4^+ and $^{14}NO_2^-$ as the electron acceptor the stoichiometry would be

$$^{14}NO_2^- + {}^{15}NH_4^+ = N_2 + H_2O. \qquad (6.11)$$
The former stoichiometry would yield 75% $^{29}N_2$ and 25% $^{30}N_2$ while the latter would yield 100% $^{29}N_2$. As 100% $^{29}N_2$ is typically found experimentally in relatively pure anammox cultures, NO_2^- appears to be the oxidant for anammox (Dalsgaard et al., 2005).

In the oceans anammox has been found to occur in the sediments and in the water column, as well as in Arctic Sea ice (Kuypers et al., 2003; Rysgaard and Glud, 2004; Thamdrup and Dalsgaard, 2002). Anammox was first observed in sediments from the Skagerrak and Arahus Bay by Thamdrup and Dalsgaard (2002). It was discovered through ^{15}N-isotope paring experiments such as those described above, and from the relative yields of $^{29}N_2$ and $^{30}N_2$ in the different incubations it was concluded that 24% and 67% of the total N_2 produced at two continental margin sites (Skagerrak) was attributable to anammox, but anammox was insignificant in Arahus bay. Subsequently, anammox has been reported from sediments in the Thames estuary, United Kingdom (Trimmer et al., 2003), Arctic sediments around Svalbard (Rysgaard et al., 2004), several Swedish fjords and Long Island Sound, New York (Engström et al., 2005) and Boston Harbor, Massachusetts (Tal et al., 2005). The range of rates reported by Egström et al. of between 0.14 and
Figure 6.13 Relative rate of N_2 production from anammox as a percentage of the total N_2 production rate as determined from ^{15}N incubation experiments described in text. Although the relative rate of anammox increases with water depth, the ablsolute rate of N_2 production generally decreases with increasing water depth. (Redrawn from Dalsgaard *et al.*, 2005).

16 μM N_2 h^{-1}, more or less brackets the entire reported range sedimentary anammox, as does their range of importance of anammox relative to total N_2 production of 4%–79%. Although, the study of anammox in marine sediments is in its infancy, it appears that the relative importance of anammox increases as overlying water depth increases (Fig. 6.13).

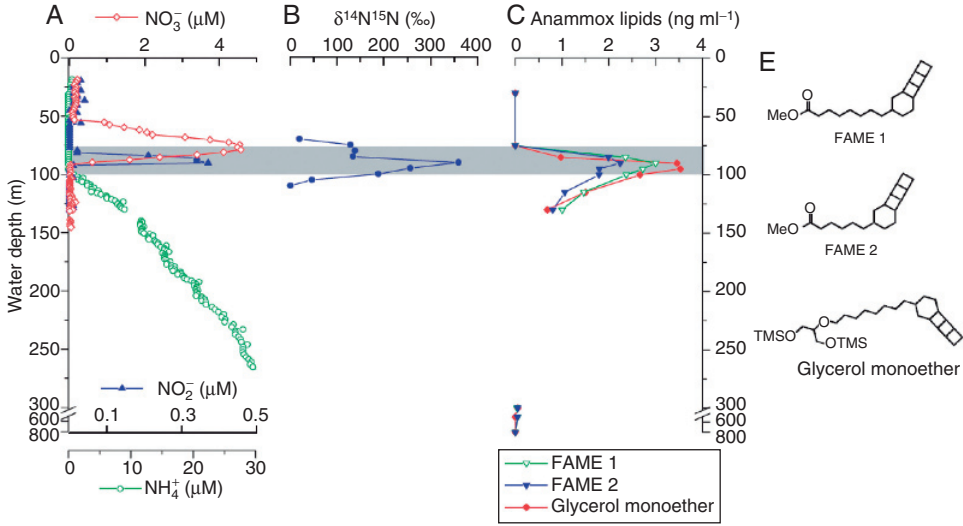
Anammox has also been reported to occur in the water columns of the Gulfo Dulce, Costa Rica (Dalsgaard *et al.*, 2003), the Black Sea (Kuypers *et al.*, 2003), and in the bottom waters over the Namibian shelf (Kuypers *et al.*, 2005). To see if the anammox organism in the Black Sea was similar to well–characterized Planctomycetes isolated from the fluidized bed reactors, Kuypers *et al.* looked for the characteristic ladderane lipid signatures of anammox bacteria and found that ladderane lipid distributions in the water column closely mirrored the anammox reaction as indicated by the isotope labeling experiments. Additionally, molecular DNA analysis showed that organisms closely related to known anammox bacteria were also present at this depth (Fig. 6.14). Taken together, this was striking confirmation of the anammox process in the Black Sea. Subsequently Kuypers *et al.* have also demonstrated anammox in the suboxic bottom waters of the Nambian shelf, this time occurring at very low but measurable oxygen concentration (Kuypers *et al.*, 2005). In fact, at the time of their observations, anammox was the only process responsible for


Figure 6.14 Anammox indicators in the suboxic transition of the Black Sea. (A) Nitrate (red) nitrite (blue) and ammonia (green) concentrations, (B) the dirtribution of $^{15}N^{14}N$ produced in incubation experiments similar to those described in the text, and (C) distributions of the three ladderane lipids Fame 1, Fame 2 and glycerol monoether. The suboxic transition zone is shown as the gray shaded area. The molecular structures of the three ladderane lipids are also shown on the right. (Redrawn from Kuypers *et al.*, 2003).

N_2 production in the oxygen depleted waters over the shelf, canonical denitrification was not detectable.

Thamdrup *et al.* (2006) investigated denitrification and anammox in the oxygen deficient waters of the ETSP using the ^{15}N labeling technique and found that anammox was by far the dominant the N_2 production mechanism with canonical denitrification playing only a minor role. They postulated that during the time they were there organic matter decomposition was proceeding mainly through nitrate reduction to nitrite and that anammox converted the remineralized NH_4^+ to N_2. However, given a Redfield stoichiometry for organic matter decomposition this could only be a transient situation because with the estimated nitrate deficit the nitrite concentration would need to be much greater than observed. In contrast to the ETSP, Nicholls *et al.* (2007) found little evidence for anammox in the Arabian Sea ODZ based on conversion of $^{15}NH_4^+$ to $^{29}N_2$. They also concluded that denitrification could not be the only source of N_2 production because if that were the case the percentage of ^{15}N label found as $^{29}N_2$ in the N_2 pool should equal the percentage of label found as $^{15}N_2O$ in the N_2O pool and that was not what they observed in their incubations.

Up until a few years ago the general understanding was that in the world's oxygen deficient zones, heterotrophic denitrification was the sole mechanism of N_2 production and NO_3^- was the sole electron acceptor. Given the results of

the recent incubation work with ^{15}N tracers it appears that our understanding of the processes producing N_2 in the world's ODZ is not really all that well understood.

4. Isotopic Consequences of Denitrification

Two stable isotopes of nitrogen exist, ^{14}N (99.634%) and ^{15}N (0.366%). Because of this mass difference the heavier isotope reacts at a slightly slower rate, producing a kinetic isotope fractionation in many biological reactions. The increase in the $^{15}N/^{14}N$ in the reaction products is typically expressed as the parts per thousand change in the ratio relative to that of a standard (air), or the del change, $\delta^{15}N‰$. With respect to denitrification, the change in isotopic composition or ''fractionation'' that occurs during canonical denitrification is relatively well-studied, both in the water column and sediments, while those of other denitrifying processes, anammox, chemodenitirification and nitrifier denitrification, are virtually unknown.

Early studies with cultures of heterotrophic denitrifiers suggested fraction factors, ε, of 17–30‰ (Delwiche and Steyn, 1970; Mariotti *et al.*, 1981: $\varepsilon = 1000[\alpha-1]$, where $\alpha =$ ratio of the rate constants for the light and heavy isotopes, respectively). These have been confirmed by a recent study in which fractionation by steady-state cultures of *Paracoccus dentirificans* was investigated at oxygen concentrations between 0 and 1.2 μM (Barford *et al.*, 1999). Barford *et al.* found that the overall ε for denitrification was 28.6‰ and that it was independent of oxygen concentration. They were also able to determine the fractionation associated with the $N_2O \rightarrow N_2$ step of denitrification and it was 12.9‰. This results in the N_2O formed during denitrification being about 15‰ lighter than the nitrate from which it was produced and about 13‰ heavier than the N_2 that is produced.

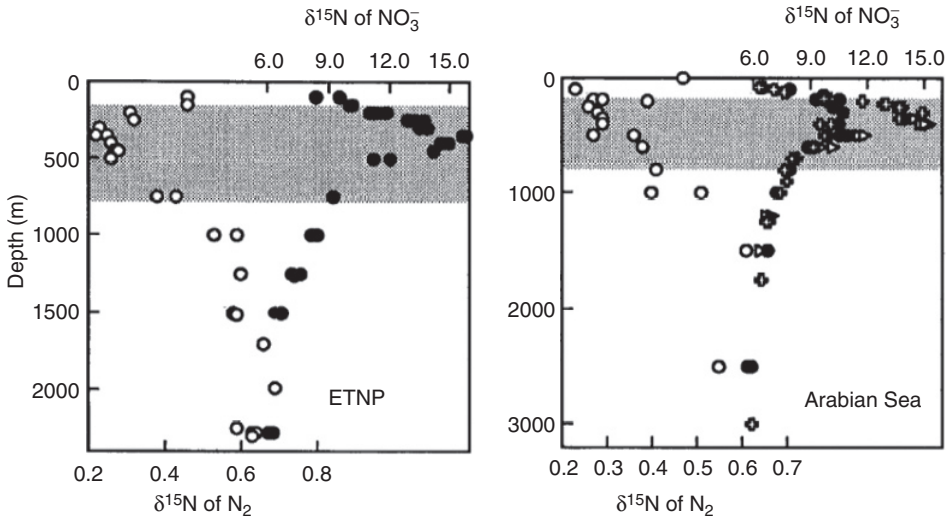
The isotopic fractionation is easily seen in $\delta^{15}NO_3^-$ and $\delta^{15}N_2$ distributions in the major open-ocean denitrification zones (Altabet *et al.*, 1999; Brandes *et al.*, 1998; Cline and Kaplan, 1975). Typical open ocean values of sub-euphotic zone nitrate are about 5‰ (Lehmann *et al.*, 2005; Sigman *et al.*, 2000; Wu *et al.*, 1997) but within the ODZ they climb to upwards of 15‰. Concomitant with this increase is a decrease in the $\delta^{15}N_2$ from about 0.6‰ to 0.2‰ (Fig. 6.15). The large enrichment of $^{15}N-NO_3^-$ and the mirror image decrease in $^{15}N-N_2$ is undoubtedly due to fractionation during denitrification. It is also possible to derive a fraction factor, ε, from the isotope distributions in the ODZ if one makes some assumption about the amount of nitrate that has been removed by denitrification, i.e., the nitrate deficit. For the eastern tropical North Pacific Brandes *et al.* (1998) assumed a Raleigh fraction mechanism and both open (advection-reaction) and closed (diffusion-reaction) systems to derive fractionation factors from the data. in Fig. 6.15. (Raleigh fractionation; $\delta^{15}NO_3^- = 10^{3(\alpha-1)}f_{NO3}$, where $\delta^{15}NO_3^-$ is the isotopic composition of the fraction, f, of nitrate remaining after denitrification.) Brandes *et al.*, found that ε was between 22‰ (Arabian Sea closed system model) and 30‰ (eastern tropical North Pacific open-system model). Altabet *et al.* (1999), Cline and Kaplan (1975),


Figure 6.15 Profiles of del ^{15}N of N_2 and NO_3^- through the oxygen deficient water of the eastern tropical North Pacific (left) and Arabian Sea (right). The shaded area represents the oxygen deficient zone. Redrawn from Brandes *et al.*, 1998.

Sigman *et al.* (2003), and Voss *et al.* (2001) have similarly used observed isotopic values and nitrate deficits to estimate ε from ODZs (Fig. 6.16) and all of these estimates cluster around an ε of 25‰.

In sediments the situation is much different. Brandes and Devol (1997) measured the isotopic change in NO_3^-, N_2 and O_2 in the overlying water of benthic flux chambers. While NO_3^- and O_2 decreased and N_2 increased within the flux chamber during the incubation the isotopic concentrations of all three remained virtually constant. This implied that there was near zero net isotopic fractionation during sedimentary denitrification and oxygen consumption. This was a surprising result because given the large biological isotope fractionation associated with both denitrification and oxygen consumption (ε for O_2 uptake ∼20‰; Kiddon *et al.*, 1993) and a reaction diffusion system such as that given by Eq. (6.8), the observed fractionation in the overlying water theoretically should be half that of the true biological fractionation or 12.5‰ (Bender, 1990). This apparent lack of fractionation has since been confirmed by observations in the Santa Barbara Basin (Sigman *et al.*, 2003), the deep Bering Sea (Lehman *et al.*, in press), as well as the freshwater lake sediment (Lehmann *et al.*, 2003).

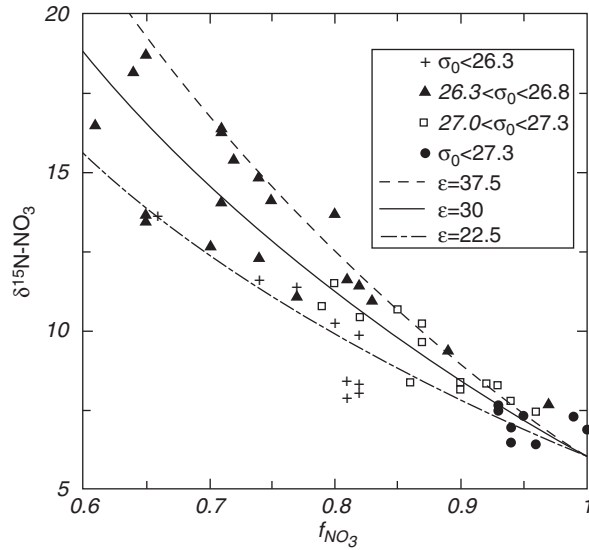
The small isotopic effect expressed during sedimentary denitrification could be due to diffusion limitation as proposed by Brandes and Devol (1997), but it could also result from a balance between the isotopic effects of denitrification being offset by an input of low $^{15}N/^{14}N$ NO_3^- from sedimentary nitrification. However in an elegant study of the isotopic effects of denitrification during benthic flux chamber deployments, Lehmann *et al.* (2004) were able to show that not only was there little N-fractionation, there was also little O-fractionation in the residual NO_3^-. Because


Figure 6.16 Solutions to a horizontal ventilation model of denitrification for waters of the eastern tropical North Pacific for $\delta^{15}NO_3$ vs f, the fraction of nitrate remaining, i.e., the measured nitrate minus the nitrate deficit. Nitrate deficit was calculated as $NO_{3(deficit)} = 14.8 \times PO_4 - NO_3$, 'where NO_3 and PO_4 are the measured concentrations. The two equations describing the steady-state nitrate isotope distribution are: $\partial[^{14}NO_3]/\partial t - J[^{14}NO_3] + A\partial^2[^{14}NO_3]/\partial x^2$ and $\partial[^{15}NO_3]/\partial t - \alpha QJ[^{14}NO_3] + A\partial^2[^{15}NO_3]/\partial x^2$, where A is the eddy diffusion coefficient in the x direction, J is the denitrification rate, α is the fraction factor, and Q is a $^{15}N{:}^{14}N$ ratio that makes the system non-linear. (See Voss *et al.*, 2001 for solution details). Solutions for three different values of ε are given ($\varepsilon = [1-\alpha] \times 1000$).

the ratio of N and O isotopic fractionation seems to be close to unity for denitrification in seawater (Casciotti *et al.*, 2002; Sigman *et al.*, 2003) and because sedimentary nitrification should actually enrich ^{18}O in the nitrate produced (Lehmann *et al.*, 2004), the near lack of fractionation in both N and O isotopes strongly suggested that the isotopic fractionation specifically associated with sedimentary denitrification was, indeed, small. That water-column and sedimentary denitrification have different apparent fractionation factors provides a valuable constraint on the relative rates of the two processes globally.

5. DENITRIFICATION AND THE MARINE COMBINED NITROGEN BUDGET

Nearly all quantitative estimates of open-ocean water column denitrification are based on some type of nitrate deficit calculation. In the Arabian Sea, Naqvi (1987) have used nutrient-potential temperature relationships to estimate a denitrification rate of ~30 Tg/y. In a later study Naqvi and Shailaja (1993) arrived at a

similar value, $\sim$33 Tg/y, based on denitrification rates estimated enzymatically from electron transport system activity. Howell *et al.*, 1997, likewise, used nutrient-temperature relationships in their estimate of $\sim$22 Tg/y for the Arabian Sea. However, as as noted above Codispoti *et al.*'s (2002) N$\star$ relationship predicts nitrate deficit values about 30% larger than those predicted from nutrient-potential temperature relationships, so it is likely that the denitrification rate in the Arabian Sea is similarly greater. Because they are based on nitrate deficit, these rates are strictly for canonical denitrification (N$_2$ produced from NO$_3^-$) but new information suggests that such estimates may be too low due to inappropriate stoichiometries (Van Mooy *et al.*, 2002) and under-appreciated pathways, such as anammox (Codispoti *et al.*, 2002) or chemodenitrification (Farrenkopf *et al.*, 1997; Luther *et al.*, 1997). Indeed, the measurements of dissolved nitrogen gas in the Arabian Sea (Codispoti *et al.*, 2002; Devol *et al.*, 2006) suggested that the N$_2$ supersaturation is almost twice as great as can be accounted for by amount of nitrate removed (nitrate deficit). Consequently, denitrification in the Arabian Sea ODZ can be conservatively estimated to be at least 50 Tg/y.

Denitrification rates in the other two main ODZs, the ETNP and ETSP; appear to be about 25 Tg a^{-1} each Codispoti *et al.* (2002). In the ETNP denitrification was estimated by the geostrophic flux of nitrate deficit out of the ODZ area, with nitrate deficit determined from nutrient-density relationships (Codispoti, 1973; Codispoti and Richards, 1976). Volumetric estimates of denitrification rate based on ETS activity are in concert with this rate (Codispoti and Richards, 1973; Devol, 1975). The ETSP the denitrification rate is based on measurements of ETS activity (Codispoti and Packard, 1980). As with the Arabian Sea these estimates are again for canonical denitrification. It is likely that processes identified in the Arabian Sea are also occurring in the ETNP and ETSP. Thus, the rate of 25 Tg a^{-1} might be raised to 50 Tg a^{-1}. Given a denitrification rate between 30 and 50 Tg a^{-1} for each of the major ODZ's, global water-column denitrification would appear to between 90 and 150 Tg a^{-1}.

There is also water column denitrification in Black Sea, Cariaco Trench and smaller anoxic basins and fjords, as well as within the more transient hypoxic zones over the continental shelves. The recent work by Kuypers *et al.* (2005) indicated that the denitrification rate off south west Africa is about 1.5 Tg a^{-1}. Codispoti *et al.*, 2002 have estimated the total denitrification in these smaller/more transient sites to be $\sim$10 Tg a^{-1}. Finally, denitrification has been reported to take place in microenvironments within the oxygenated water column such as organic aggregates Aldredge and Cohen, 1987; Wolgast *et al.*, 1998). However no quantitative estimates of the global importance of microsite denitrification are available.

The amount of sedimentary denitrification occurring in the ocean today is one of the most poorly quantified terms in the marine combined nitrogen budget. Most modern measurements of denitrification rate have utilized pore-water NO$_3^-$ profiles (estimated from diffusion calculations–reaction models); whole-sediment incubations, either on deck or in situ, or by the isotope paring technique. It appears that shelf and upper slope sediments are quantitatively the most important sites of sedimentary denitrification (Christensen, *et al.*, 1996; Christensen *et al.*, 1987; Devol, 1991; Devol and Christensen, 1993; Gruber and Sarmiento, 1997; Kristensen, *et al.*, 1999; Middelburg *et al.*, 1996). Typical denitrification rates in these areas

are from 0.1 to 4 mMoles m^{-2} d^{-1} (Dalsgaard *et al.*, 2005; Devol and Christensen, 1993; Devol *et al.*, 1997; Hartnett and Devol, 2003; Middelburg *et al.*, 1996; Seitzinger, 1988; Seitzinger and Giblin, 1996). Given rates of this magnitude, global sedimentary denitrification has been estimated to be somewhere between 100 Tg a^{-1} (Gruber and Sarmeinto, 1997) and 400 Tg a^{-1} (Codispoti, 1997; Codispoti *et al.*, 2001; Middelburg *et al.*, 1997).

Assuming that pelagic water-column and sedimentary denitrification represent the bulk of the combined nitrogen loss from the oceans, adding the two would lead to a total denitrification rate in the range of 190–550 Tg a^{-1}, with the majority of it taking place in the sediments. The total amount of combined nitrogen in the ocean is on order of 550×10^3 Tg, which would put the residence time of combined nitrogen at 1000–3000 years.

Although there is a large range in the estimate of the absolute denitrification, it is possible to constrain the relative amounts of sedimentary and water-column denitrification with stable isotope data (Brandes and Devol, 2002). There is some sedimentary evidence that away from the ODZs the stable isotopic composition of combined nitrogen in the ocean has been relatively constant over the last 10,000 years (Kienast, 2000, also see Deutsch *et al.*, 2004). If this is the case, then the stable isotope composition of combined nitrogen (almost entirely nitrate) is determined by the mass balance of the sources, primarily nitrogen fixation, and the sinks, primarily denitrification. For the $\delta^{15}N$ of combined nitrogen in the ocean to remain constant, the $\delta^{15}N$ of denitrification sink must equal the $\delta^{15}N$ of the nitrogen fixation source, which is ~0‰ (Carpenter *et al.*, 1997). Given an average $\delta^{15}N$ of 5‰ for oceanic nitrate, the net fractionation factor for the sum of water-column denitrification, ~25‰, plus sedimentary denitrification, ~0‰, must be −5‰ to produce a total denitrification sink at 0‰. To achieve this sedimentary denitrification must be about 4 times greater than water column denitrification. Including a loss term for combined nitrogen burial in margin sediments only reduces this ratio to about 3 times water column denitrification (assuming a burial rate one third that of water column denitrification and an isotopic value of the buried material of 6‰).

The current literature would thus suggest a denitrification rate of 200–500 Tg a^{-1}, with 2/3 to 3/4 occurring in the sediments and the remainder in the water column (Codispoti *et al.*, 2001; Gruber and Sarmiento, 1997; Middelburg *et al.*, 1997). Given a combined nitrogen residence time of several thousand years this implies either an equally rapid nitrogen fixation rate (to achieve steady-state) or that the ocean is ''losing nitrate'' (Codispoti, 1995). There are relatively large uncertainties in the estimates of both the nitrogen-fixation rate and the denitrification rate, especially the sedimentary component. Recent work by Vance-Harris and Ingall (2005) suggest that denitrification rates in sandy continental shelf sediments, which comprise 70% of continental shelves, is two orders of magnitude less than in fine grained sediments where the vast majority denitrification work has been done to data. This raises the possibility that sedimentary denitrification has been over estimated. Nevertheless, even if we take a low estimate of the water-column denitrification, the isotopic constraints discussed above still put the total denitrification rate well over 200 Tg a^{-1}, far larger than can be explained by current nitrogen fixation rates, ~100 Tg a^{-1} (Capone *et al.*, 1997; Gruber and

Sarmiento, 1997). However, it is likely that the nitrogen fixation rate has been underestimated. Most nitrogen fixation rates are extrapolated from measurements on a single species, *Trichodesmium*, but it now appears that unicellular diazotrophs in the oligothropic Pacific (and presumably the Atlantic and Indian) Ocean are capable of high nitrogen fixation rates (Montoya *et al.*, 2004, Chapter 4 by Carpenter and Capone, this volume) and that rates of fixation by *Trichodesmium* may also be low (Capone *et al.*, 2005). Also, it may be that nitrogen fixation is more significant at higher latitudes than previously recognized (Sigman *et al.*, 2005) or that it occurs closely associated with denitrification zones, which are areas where N_2 fixation studies are scarce (Deutsch *et al.*, 2007; Capone and Knapp, 2007; see also Chapter 14 by Naqvi, this volume). Nevertheless, based on a global analysis of $N^\star$ in surface waters, Deutsch *et al.* (2007) argue that the total rate of nitrogen fixation can not be pushed beyond about 150 Tg a^{-1}.

This again brings us back to the issue of an unbalanced marine combined–nitrogen budget. Codispoti *et al.* (2001) suggest that perhaps the budget is out of balance because our measurements are being made during a period of rapid change as we enter the "anthropocene" (*sensu* Falkowski *et al.*, 2000). On the other hand, the current estimates of the major terms, denitrification and N_2 fixation, are continuing to evolve so the possibility of a balanced budget can not be ruled out. Possibly we will have the budget resolved by the time the third edition of *Nitrogen in the Marine Environment* is published.

1. Introduction

Since the original volume of *Nitrogen in the Marine Environment* was published in 1983, our views of the marine nitrogen (N) cycle and the utilization of dissolved N by microorganisms have expanded substantially. In the earlier volume, N uptake was reviewed mainly in terms of the kinetics of ammonium (NH_4^+) and nitrate (NO_3^-) uptake and the linkages to internally versus externally controlled cellular growth rate by phytoplankton (Goldman and Glibert, 1983). At that time, these two compounds were thought to be the major nitrogenous nutrients support-ing oceanic primary production and so measuring their uptake, the relative affinity of phytoplankton for NH_4^+ and NO_3^-, and the applicability of the different models of marine phytoplankton growth were of primary concern. These efforts were limited by the inability to accurately determine low concentrations of these compounds in many oligotrophic oceanic environments and the inability to correctly predict growth rates from experiments that measured only instantaneous uptake rates. Since 1983, our ability to measure nanomolar concentrations of nitrogen has greatly

improved (e.g., NO_3^- – Garside, 1985; Raimbault *et al.*, 1990; Steimle *et al.*, 2002; Yao *et al.*, 1998; Zhang, 2000; NH_4^+ – Brzezinski, 1987). However, few researchers have employed these new methods to revisit old questions such as "what are the kinetic constants of open ocean phytoplankton" and "what are *in situ* nutrient uptake rates in the oligotrophic ocean". In general, those studies that have employed these new analytical techniques suggest their use has not significantly altered our perception of kinetic constants in the oligotrophic ocean (*cf.* Goldman and Glibert, 1983 and references therein; versus Garside and Glover, 1991; Harrison *et al.*, 1996; Lipschultz, 2001). In addition to NO_3^- and NH_4^+, we now recognize that organic compounds contribute substantially to primary productivity and methods for measuring dissolved organic nitrogen (DON) and specific components of the DON pool have improved dramatically since 1983 (see Chapter 3 by Aluwihare and Meador, this volume; Chapter 28 by Bronk and McCarthy, this volume).

It has also become increasingly clear that kinetic parameters are themselves physiological "variables." Kinetic parameters vary with physiological state, nutrient prehistory, and phytoplankton species, thus complicating the interpretation of field results, where the physiological state of collected organisms is generally unknown. In coastal areas, we have the additional limitation of being unable to evaluate *in situ* nutrient uptake kinetics because ambient nutrient concentrations are often greater than half-saturation constants, thereby making it impossible to measure non-saturated uptake rates and formulate kinetic parameters. Because of these limitations, measurements in the environment characterize transient responses/capacities in natural assemblages, where there are competitive interactions among multiple nutrient substrates and mixed microalgal populations (species and size). In any case, this may be more informative and relevant than understanding steady state Michaelis–Menten type kinetics in natural or culture systems.

In 1983, studies of N uptake and assimilation in marine systems were scarcer than today and were dominated by investigations of the relative contributions of NO_3^- and NH_4^+ (Table 7.1; and sometimes urea) to total N uptake. On the basis of the models of new and regenerated production at the time (Dugdale and Goering, 1967; Eppley and Peterson, 1979; Ryther and Dunstan, 1971), NO_3^- and NH_4^+ were thought to be the dominant N species influencing total phytoplankton production in the world ocean; NO_3^- was considered the primary source of nitrogen fueling "new" production and NH_4^+ was the dominant regenerated N source. New inputs of N through dinitrogen (N_2) fixation were thought to be trivial and DON was thought to be relatively unavailable to phytoplankton. Since this time, we have many more uptake measurements, not only for NO_3^- and NH_4^+ but also for a variety of other N substrates. In addition, our view of the N cycle has expanded; global estimates of new production from marine N_2 fixation have been revised upward (see Chapter 4 by Carpenter and Capone, this volume), and uptake of DON regenerated through a variety of processes by phytoplankton in the upper water column is now widely recognized (see also Chapter 8 by Bronk and Steinberg, this volume). Unfortunately, never have all things been measured everywhere at one time (see Table 7.1).

Further complications in interpreting uptake data in the context of "new production" arise when one considers that water column regeneration of NO_3^- (i.e.,

Table 7.1 Summary of selected nitrogen (NO_3^-, NO_2^-, NH_4^+, urea, dissolved free amino acids [DFAA], DON) uptake rates from the major ocean basins, and upwelling, coastal and estuarine systems using ^{15}N tracer techniques. Table 7.1 Summary of selected nitrogen (NO$_3^-$, NO$_2^-$, NH$_4^+$, urea, dissolved free amino acids [DFAA], DON) uptake rates from the major ocean basins, and upwelling, coastal and estuarine systems using ^{15}N tracer techniques. Rates were converted to common units (nmol N L^{-1} h^{-1}) using data provided in the original publication or using conversion factors specified in the footnotes (*continued*)

Location	Season	Depth	Fraction	NO$_3^-$ (nmol N L^{-1} h^{-1})	NO$_2^-$ (nmol N L^{-1} h^{-1})	Uptake NH$_4^+$ (nmol N L^{-1} h^{-1})	Urea (nmol N L^{-1} h^{-1})	DFAA (nmol N L^{-1} h^{-1})	DON (nmol N L^{-1} h^{-1})	Reference
Ria de Ferrol, Spain	Annual[o]	Euphotic zone	WW	0.2–5.4		0.2–10.8				Bode *et al.*, 2005
Humber Estuary, England	Spring/Summer	5 m	WW	0–0.22		0–70	0–30			Shaw *et al.*, 1998

[a] Converted from areal rates using the average euphotic depth (120m) and an average photoperiod (8 h) indicated by the authors.

[b] Originally reported as an areal rate so obtained volumetric rate using the depth over which the authors integrated. Volumetric rates are averages for the entire water column integrated.

[c] Originally reported as mmol m^{-2} (12 h)$^{-1}$.

[d] Divided value reported by 24 to get hourly rate.

[e] ρ max values.

[f] Calculated or measured *in situ* specific uptake rates from depth profiles were converted to absolute rates using particulate nitrogen values in tables and figures.

[g] Areal rates reported were averaged over 1–100% light level; this depth varied from 60–100 m so volumetric rates were calculated using an average euphotic depth of 80 m; daily rates reported were based on observed daily variation in uptake, the authors state these were similar to those observed by Dugdale *et al.* (1992) and so hourly rates were calculated using a 12 h uptake period for NO$_3^-$ and NO$_2^-$ and 18 hour uptake period for NO$_4^+$. An 18 h uptake period was used for urea.

[h] Areal rates were integrated over the 1–100% light level; volumetric rates were calculated using 1% light level depth and hourly rates were calculated based on 12 h accounting for the fact that some ammonium was taken up at night (the authors multiplied their 12 h rate by 1.3).

[i] Units are h^{-1}; there was insufficient information to convert units to nmol nitrogen 1^{-1} h^{-1}.

[j] Areal rates were integrated over the 1–100% light level or the euphotic depth so volumetric rates were calculated from mean 1% light depth; daily rates were converted to hourly rates based on the percent daily nitrogen uptake occurring at night reported by the author.

[k] Areal rates were converted based on an average day length of 16 h during the southern transit and an average 70 m euphotic depth.

[k] Mean values.

[l] Areal rates were converted based on an average euphotic depth (to 0.1% light level of 72 m) and converted to hourly rates based on 24 h incubations

[m] Insufficient information to convert areal daily rates (mmol m^{-2} d^{-1}) to volumetric hourly rates.

[n] Rates were obtained using ^{14}C tracer.

[o] Annual = annual range of values.

[p] Absolute rates were obtained by multiplying specific rates by total nitrogen biomass. Total nitrogen biomass was calculated from C biomass using a C:N of 6.6.

[q] Rates are for adenine uptake.

[r] Daily ranges.

[s] Excluded freshwater station.

[+] Only daytime rates are reported here.

Incubations were conducted under simulated *in situ* conditions. WW is whole water. Values in parentheses are standard deviations. If not specified otherwise, daily rates were divided by 24 to obtain hourly rates.

nitrification), can be an important source of regenerated NO_3^- and NO_2^- at least regionally (see Chapter 5 by Ward, this volume), and that bacteria and phytoplankton seem to compete for the same inorganic and organic N sources (see following). While conceptually, the new production paradigm can accommodate these modifications, we must reevaluate the application of traditional ''f-ratios'' (*sensu* Eppley and Peterson, 1979) when estimating new and export production in marine systems.

A major development in the last two decades is the recognition that marine cyanobacteria, such as *Prochlorococcus* and *Synechococcus*, are the numerically dominant primary producers in many open ocean oligotrophic environments. These marine cyanobacteria can account for over half of the observed primary production (e.g., Partensky *et al.*, 1999) and nutrient uptake (e.g., Cavender–Bares *et al.*, 2001) where they occur; however, numerically less abundant picoeukaryote populations are the larger fraction of autotrophic carbon biomass (e.g., DuRand *et al.*, 2001). More recently, it has been hypothesized that picoplanktonic cyanobacteria may be distributed based not only on their ability to adapt to various light environments (Moore *et al.*, 1995) but also on their ability to use different forms of N (e.g., Moore *et al.*, 2002b), including N_2 (Mulholland *et al.*, submitted for publication), and trace metals (e.g., Mann and Chisholm, 2000; Mann *et al.*, 2002; Saito *et al.*, 2002). These observations are only the tip of the iceberg as the growing literature on genomics, proteomics and cellular regulatory mechanisms (see Chapter 30 by Jenkins and Zehr, this volume) highlight further species-specific differences with respect to the marine N cycle.

High nutrient low chlorophyll (HNLC) regions in the eastern equatorial Pacific, open sub-arctic North Pacific, and the Southern Ocean represent about 20% of the world's ocean, and have been the target of intensive studies over the last two decades since the recognition that iron availability may limit productivity in these areas of the ocean (see Chapter 38 by Hutchins and Fu, this volume; Martin and Fitzwater, 1988). In HNLC regions, NO_3^- uptake remains low despite high NO_3^- concentrations (Dugdale and Wilkerson, 1991). These have been sites of large-scale iron fertilization experiments aimed at stimulating primary productivity and CO_2 and nutrient drawdown (DeBaar *et al.*, 2005; Martin *et al.*, 1993).

Our improved, but still incomplete, understanding of water column N regeneration, species and taxa-specific capabilities for N utilization, the discovery of new quantitatively significant taxa, and the exploration of genomes have altered our view of the marine N cycle. We will begin this chapter with a discussion of N limitation in the sea and then discuss the bioavailability of particular forms of N, pathways and regulation of N uptake and assimilation. This chapter will focus on general patterns of N uptake and assimilation, primarily in the open ocean because N cycling in coastal and estuarine systems are considered elsewhere in this volume (see Chapter 11 by Paerl and Piehler, this volume and Chapter 18 by Boynton and Kemp, this volume). While we try to provide a general description of N uptake in the world's oceans, we also refer the reader to the chapters focusing on N cycling in specific marine systems for details. We conclude by outlining some future research directions.

2. Re-Evaluation of Nitrogen Limitation and New Production in the Sea

The idea that marine primary productivity is N limited arose from efforts to understand factors controlling phytoplankton productivity in the sea and the observation that N was often the nutrient factor in shortest supply relative to other macronutrients in marine environments (e.g., McCarthy and Carpenter, 1983; Ryther and Dunstan, 1971). While N is still thought to be limiting in many marine environments, the view of a single most-limiting nutrient has been revised into a more dynamic view of nutrient limitation in marine ecosystems, with multiple and even co-limiting nutrients (e.g., N vs. phosphorus [P], or P vs. iron [Fe]), seasonal shifts between limiting nutrients (Arrigo, 2005; Fisher *et al.*, 1992; Holmboe *et al.*, 1999; Chapter 38 by Huthins and Fu, this volume; Chapter 11 by Paerl and Piehler, this volume), and multi-decadal oscillations between limiting nutrients (e.g., Karl *et al.*, 2001) regulating phytoplankton primary production. For example, NO_3^- uptake can be limited by Si requirements (for diatoms; Dortch and Whitledge, 1992; Dugdale and Wilkerson, 1998; Chapter 37 by Kudela, this volume) or trace metals (Franck *et al.*, 2000; Martin *et al.*, 1993; Milligan and Harrison, 2000), and utilization of N_2 can be limited by cellular Fe or P requirements (Rueter *et al.*, 1992). Organisms that can use N_2 are not N limited by definition but may become P or Fe limited (Chapter 38 by Hutchins and Fu, this volume; Karl *et al.*, 1997; Mills *et al.*, 2004; Sanudo-Wilhelmy *et al.*, 2001).

Nitrogen limitation in the ocean is difficult to assess experimentally because both autotrophic and heterotrophic populations and processes change during nutrient enrichment bioassays and addition of N substrates frequently causes other elements to rapidly become limiting, unless they are also added to incubation bottles. Physiological or biochemical targets such as probes for *ntcA*; (Lindell *et al.*, 1998) and cell surface proteins (Palenik and Koke, 1995) have been used as a means of identifying potential N limitation. However, use of genetic markers as indicators of N limitation, while possible, must be done cautiously because the presence of a gene does not always equate with its expression or activity. Nitrogen limitation in the ocean is also difficult to assess using stoichiometric arguments because many elements are at or near the analytical detection limits in marine environments, organisms have flexible elemental stoichiometry, and many elements have complex cycles in which there are multiple chemical forms that are more or less available. In addition, the relative turnover times of even the major elements are poorly understood with respect to individual organisms and populations. Although the Redfield Ratio, an average of major nutrient ratios in marine particles, might be a useful integrative indicator, and has been used to qualitatively identify shifts from nitrogen to P limitation, experimental evidence suggests that the critical N:P ratio may be substantially greater than 16 (Bertilsson *et al.*, 2003; Leonardos and Geider, 2004; Terry *et al.*, 1985) and highly variable, calling to question the 'numerical value' at which we decide a system is N or P limited.

Dugdale and Goering (1967) distinguished new and regenerated primary productivity based on the ultimate source of N taken up by phytoplankton; new production supported net growth (which could be exported; Eppley and Peterson, 1979) while regenerated production maintained populations. Since it was first articulated, this paradigm has shaped our view and perhaps the way we study N uptake and assimilation in the sea. New production is supported by N sources imported into the euphotic zone from external sources and includes: NO_3^- diffusion and convection from deep water, N_2 fixation, atmospheric deposition, and riverine inputs. At the time this theory was articulated, the primary source of 'new' N to the euphotic zone in the open ocean was thought to be upward diffusion and convection of NO_3^-, while in coastal systems upwelled NO_3^- could be augmented by runoff and riverine inputs. N_2 fixation, another new N source and the ultimate process by which new N is introduced into the ocean, was thought to be of limited importance in most marine systems, although this view has changed in the past several decades (Chapter 4 by Carpenter and Capone, this volume).

Regenerated primary production, on the other hand, described productivity supported by N internally recycled within the system. This component of primary productivity was assumed to be supported mainly by NH_4^+ (nitrification was not detected and assumed to be negligible, and DON was not considered) remineralized through microbial processes (Dugdale and Goering, 1967). In this context, Harrison (1990) reviewed new production and the f-ratio (the ratio of NO_3^- uptake to total NO_3^- plus NH_4^+ uptake) in 152 vertical profiles from temperate coastal and ocean waters. He found that the primary productivity maximum was shallower than the Chlorophyll a (Chl a) maximum and that the f-ratio was lower at the primary productivity maximum than at the Chl a maximum, which was associated with the nitracline. From this, he inferred that the source of N fueling the primary productivity maximum was derived from regenerative processes in the euphotic zone, and productivity associated with the Chl a maximum was fueled by NO_3^- upwelled from below. However, over the last two decades, a number of examples have been put forth to call into question the 'assumptions' of the new and regenerated production paradigms using the simple relationships between NH_4^+ and NO_3^- uptake.

Failing to consider other sources of new or regenerated N can bias estimates of new production and the f-ratio in nature. For example, it has long been recognized that urea uptake can support a significant amount of regenerated production in a wide variety of environments (Bronk, 2002; McCarthy, 1972). Exclusion of urea uptake from estimates of regenerated production has been shown to result in overestimates of the f-ratio, the extent of which depends on the ecosystem type. For example, the f-ratio was overestimated by 6, 17, 24, 42 and 55%, respectively, in upwelling, coastal, polar, oceanic and estuarine waters when urea uptake was not considered (Wafar et al., 1995). Further, we now recognize that the large DON pool may be more labile and available to phytoplankton than was originally thought, which if utilized, would further bias the regenerated production term.

On the other hand annual rates of new production and the f-ratio can be seriously underestimated by failing to consider alternative sources or pathways delivering new N inputs. For example, the upward transport of NO_3^- (Villareal *et al.*, 1999) and cellular release of NH_4^+ and NO_2^- (Singler and Villareal, 2005) by vertically migrating diatom mats has been shown to represent ~20% of the upward diffusive NO_3^- flux in subtropical ocean gyres. In addition, the passage of cold fronts during the period of winter convective mixing can amplify NO_3^- intrusion maintaining high phytoplankton growth rates and leading to enhanced rates of new production (Lomas *et al.*, 2004). In subtropical gyres where conditions are generally downwelling-favorable this is a particular problem as these areas are thought to account for half the ocean export production. Recent studies have focused on new N inputs into the subtropical North Atlantic gyre from N_2 fixation or lateral supply of DON (Mahaffey *et al.*, 2004; Williams and Follows, 1998).

We now recognize that NO_3^- is not always the dominant source of new N in the open ocean (Table 7.1). N_2 fixation is more widespread than previously thought. Filamentous diazotrophs (e.g., *Trichodesmium* sp.; Capone *et al.*, 1997), diazotrophic endosymbionts (Carpenter *et al.*, 1999), and unicellular cyanobacteria all fix N_2 at high rates in nature (Carpenter and Capone, this volume; Montoya *et al.*, 2004; Zehr *et al.*, 2001). In tropical and subtropical waters, it has been calculated that N_2 fixation by *Trichodesmium* sp. alone fuels 50% of the new production (Capone *et al.*, 2005; Karl *et al.*, 1997). Montoya *et al.* (2004) estimated that diazotrophic unicells may contribute up to 10% of total oceanic new production globally.

In most cases, the picture is far more complicated than simply classifying specific N compounds as supporting either new or regenerated production, even within a single aquatic environment. For example, nitrite (NO_2^-) in the water column is not often considered at all but can arise as a result of both assimilatory and dissimilatory metabolisms (e.g., Capone, 2000; Collos, 1998; Collos and Slawyk, 1984; see also Section 3.1.3 following and Chapter 5 by Ward, this volume). Therefore the mechanisms by which NO_2^- is produced blurs the distinction between new and regenerated production derived from its uptake and can lead to either underestimation or overestimation of new production rates from bulk NO_3^- uptake measurements (e.g., Collos and Slawyk, 1983). In the North and South Atlantic, nutrification rates were so intense that the entire NO_3^- pool could be turned over in less than 8 hours (Clark *et al.*, 2008). Lipschultz (2001) and Collos and Slawyk (1984) found high rates of NO_3^- turnover (i.e., nitrification) in the subtropical and tropical Atlantic during periods of summer stratification, while Raimbault *et al.* (1999a) and Ward *et al.* (1989) observed equally high rates of nitrification under similar conditions in the tropical and subtropical Pacific. In the Mediterranean and North Seas, rates of nitrification are so intense throughout the entire euphotic zone that they can account for 90% to >100% of the measured phytoplankton NO_3^- demand (Diaz and Raimbault, 2000; Rees *et al.*, 2002). Moreover, modeling studies for the subtropical Atlantic (Bermuda Atlantic Time-series Study, BATS) suggest that nitrification produces from 55% to 72% of the NO_3^- taken up per day (Martin and Pondaven, 2006; Mongin *et al.*, 2003).

Both reductive and oxidative pathways can produce NO_2^- in the ocean, and until recently it was believed that oxidative pathways dominated. Specifically, it was

thought that the differential inhibition of microbially mediated NH_4^+ and NO_2^- oxidation (Chapter 5 by Ward, this volume) at the base of the euphotic zone resulted in the accumulation of NO_2^- (Olson, 1981). Although it was also speculated that some of the primary NO_2^- maximum might result from the incomplete reduction of NO_3^- by phytoplankton (Kiefer and Kremer, 1981), this conjecture was overlooked for a long time. Increasingly, evidence suggests that both processes are important. Specifically, large shallower NO_2^- peaks have been attributed to incomplete NO_3^- reduction while the broad deeper NO_2^- maximum has been ascribed to uncoupling of the two-step nitrification process (Al-Qutob *et al.*, 2002; Dore and Karl, 1996a,b; Lomas and Lipschultz, 2006; Zafiriou *et al.*, 1992).

Inputs of new N into coastal systems are more diverse than inputs to the open ocean and include compounds considered regenerated N sources in the open ocean. New N can be delivered by rivers, runoff events, and atmospheric deposition and can include a whole spectrum of N compounds including NH_4^+, urea, and DON (e.g., Anderson *et al.*, 2002; Glibert *et al.*, 2001, 2005c; Mulholland *et al.*, 2007). Similarly NH_4^+ derived from natural processes and anthropogenic activities can support 'new' production in estuarine and coastal systems (see Chapter 9 by Seitzinger and Harrison and Chapter 11 by Paerl and Piehler, this volume).

Another complication that arises when estimating new and regenerated production from N uptake is the release of recently assimilated N by cells. We now recognize that a significant fraction of the N taken up during even short-term (hours) incubations can be released as a downstream metabolite (see Chapter 8 by Bronk and Steinberg, this volume). In general, N is taken up by cells, reduced intracellularly to NH_4^+ and then assimilated into amino acids (see following). However, release of $^{15}NH_4^+$ and $DO^{15}N$ has been observed during incubations with $^{15}NO_3^-$ (Bronk and Ward, 1999, 2000; Diaz and Raimbault, 2000; Raimbault *et al.*, 1999b) and $^{15}N_2$ (Glibert and Bronk, 1994; Mulholland and Bernhardt, 2005; Mulholland *et al.*, 2004c). It is unclear why cells would release metabolites either prior to or after their assimilation into organic matter (Bronk, 2002), but N release is highly variable among systems and complicates estimates of f-ratios because NO_3^- and N_2 uptake can be seriously underestimated. For example, natural assemblages in Monterey Bay released up to 80% of the recently assimilated NO_3^- as DON on timescales of hours (Bronk and Ward, 1999, 2000). In contrast, in the equatorial Pacific Ocean <20% of the NO_3^- taken up was released as DON (Raimbault *et al.*, 1999b). Marine N_2 fixers can release 80% or more of recently fixed N_2 as DON and NH_4^+ on similar timescales (Glibert and Bronk, 1994; Mulholland *et al.*, 2004b,c, 2006), but this release is also highly variable both temporally and spatially (Mulholland and Bernhardt, 2005; Mulholland *et al.*, 2004c, 2006).

Another consideration when calculating f-ratios is the diurnal variability of N versus carbon (C) metabolism. When relating new production to C export (*sensu* Eppley and Peterson, 1979), stoichiometric calculations of C export from N uptake can be in error when C and N uptake are not evaluated over appropriate timescales. Diel variability in uptake rates of various N compounds has been demonstrated (e.g., Cochlan and Harrison, 1991b; Cochlan *et al.*, 1991a; Tremblay *et al.*, 2000; Wilkerson and Grunseich, 1990) and failure to integrate daily uptake rates over an entire diel cycle may seriously bias estimates of f-ratios.

Bury *et al.* (2000), on the other hand, found uncoupling between N and C uptake on longer timescales. Similarly, C and N_2 fixation rates appear to be uncoupled or stoichiometrically different from particulate C:N ratios (Mulholland *et al.*, 2007; Mulholland and Capone, 2000; Mulholland *et al.*, 2006) making it difficult or impossible to estimate C export from N_2 fixation.

In addition to complicating our view of the marine N cycle, high rates of inorganic N uptake by bacteria and organic N uptake by phytoplankton may compromise stoichiometric calculation of C assimilation from N uptake (or vice versa) using the Redfield C:N ratio in the euphotic zone (Wheeler and Kirchman, 1986). Further, bacterial uptake of NH_4^+ and NO_3^- can confound computation of the f-ratio leading to over- or underestimates of new production. Consequently, estimating C export from N-based estimates of new production needs to be re-evaluated for a variety of reasons.

In summary, to accurately depict new production in the ocean, even without inputs from rivers, runoff, and atmospheric deposition, one needs to carefully evaluate new N inputs from NO_3^- upwelling and diffusion, and N_2 fixation, and regenerated production from NH_4^+ as well as NO_2^- (and NO_3^- if nitrification is complete), urea, and DON. In addition, one must consider the relative contribution of autotrophic versus heterotrophic processes to N cycling and temporal and spatial scales of variability in N uptake when calculating f-ratios and extrapolating these to C export in the ocean. In short, f-ratios, as currently used, may be misleading or just wrong in depicting new and export production.

3. BIOAVAILABILITY OF NITROGEN COMPOUNDS

The dominant N sources and their relative concentrations are important in determining microbial community structure in aquatic environments. Nitrogen is stable in a variety of oxidative states and so has a complex cycle in the ocean. Different N compounds vary in their abundances, distributions and residence times as a result of environmental constraints and interactions that affect their utilization and their relative availability to a diverse group of microorganisms with different genetic capabilities (Chapter 1 by Gruber, this volume; Sharp, 1983). For example, although N_2 gas is found throughout most oceanic and coastal waters at concentrations near saturation, it is considered to be more biologically inert than other inorganic N forms. On the other hand NO_3^- is abundant and biologically reactive; however, the highest oceanic concentrations are in the reservoirs of deep water where it cannot be accessed by photosynthetic microbes.

Frequently, compounds that are rapidly turning over are highly bioavailable (e.g., NH_4^+, amino acids). NH_4^+ concentrations, at least in the open ocean, are generally at the limits of analytical detection yet NH_4^+ accounts for the bulk of the measured N uptake in many systems (see below). The DON pool, formerly thought to be largely unavailable to primary producers, is the largest dissolved N pool (excluding N_2) in the surface ocean but poorly characterized (Bronk, 2002). Recent studies have demonstrated that portions of this pool are more biologically reactive

and may turn over on shorter timescales than previously thought (see Chapter 3 by Aluwihare and Meador, this volume). Because microorganisms are both consumers and producers of dissolved N, their activity leads to complex temporal and spatial patterns of nutrient distributions and utilization. In this section, we will discuss the various chemical forms of N and their bioavailability to marine microbes, including interactions between bacteria and phytoplankton, followed by a discussion of nutrient interactions and examples of taxon–specific N uptake. We have also compiled a table of representative uptake rates for various N compounds across environments (Table 7.1) demonstrating the wide temporal and spatial variability in uptake rates and the relative contribution of different forms of N across environments. The latter is more difficult to assess across environments because the oceanic database is skewed towards measurements of NO_3^- and NH_4^+ uptake.

3.1. Uptake of dissolved inorganic nitrogen

Two decades ago, our view of N cycling was simpler; relative uptake of NH_4^+ and NO_3^- provided an index of new production (Table 7.1), consequently, rate measurements of NH_4^+ and NO_3^- dominate our database of N uptake across systems; and phytoplankton were primary consumers of dissolved inorganic N (DIN) (NH_4^+, NO_3^-, NO_2^-) and urea in the euphotic zone while bacterial heterotrophs and grazers were primary consumers of organic compounds and regenerators of reduced inorganic compounds (Fig. 7.1A). We now recognize that bacteria and phytoplankton can be both consumers and producers of most forms of N and that their role as producers or consumers can change on a variety of temporal and spatial scales as well as with taxonomic diversity (Fig. 7.1B). Because their size spectra overlap, it is often difficult to distinguish which group or which cells are taking up which compounds in bulk nutrient uptake bioassays. Further, in the age of genomics, genetic capacity determines whether cells can produce transportors and enzymes necessary to take up, reduce, and assimilate various N compounds. Even if genes are present, it doesn't mean that they are expressed, and even if genes are expressed, it doesn't mean enzymes are active (see Chapter 32 by Berges and Mulholland, this volume).

3.1.1. NH_4^+

NH_4^+ is often the dominant form of dissolved N taken up in a variety of marine and estuarine systems (Table 7.1). Some notable exceptions are upwelling regimes (see Chapter 17 by Wilkerson and Dugdale, this volume) and eutrophic coastal systems (see Chapter 11 by Paerl and Piehler, this volume). This form of N is energetically efficient for cells to use because it is already reduced and is a common cellular transient in N metabolism, requiring little additional energy for assimilation (Fig. 7.2). Despite the low NH_4^+ concentrations in oceanic systems, uptake and regeneration of NH_4^+ are tightly coupled (Glibert, 1993) resulting in rapid turnover times of the relatively small standing stock. Consequently, low ambient NH_4^+ concentrations still support high rates of NH_4^+ uptake (and therefore growth rates, e.g., Furnas and Crosbie, 1999). Because many NH_4^+ uptake measurements
Figure 7.1 Classical and current views of the N cycle in the surface waters of oligotrophic oceans. The composition of the dissolved N pool is shown with approximate relative concentrations of inorganic and organic constituents indicated by the sizes of the boxes. Dashed lines indicate transformations and processes included in the newer view of N cycling. (A) Some phytoplankton use simple and more complex organic compounds as a source of N and phytoplankton can be sources of inorganic and organic N as well. (B) There are multiple species of phytoplankton (cyanobacteria) in the open ocean that fix N_2. (C) Bacteria compete for NO_3^- and NH_4^+. (D) Bacteria can take up and excrete urea and also be a source of DON. (E) Some oceanic bacterioplankton appear to fix N_2 (modified from Zehr and Ward, 2002).
Figure 7.2 Intracellular pathways and enzymes involved with N transport, reduction and assimilation (modified from Capone, 2000).

made using stable isotopes do not account for NH_4^+ isotope dilution caused by regeneration of NH_4^+ in incubation bottles (Glibert *et al.*, 1982) it is likely that the importance of NH_4^+ uptake to total N nutrition of cells is underestimated, at least in some systems and during long incubations (see Chapter 31 by Lipschultz, this volume for a further discussion of isotope dilution).

In most studies examining the relative uptake of different N sources, NH_4^+ is commonly found to be preferred over urea, NO_3^- or NO_2^- for all taxa and this is attributed largely to the low energetic demand for its uptake and assimilation (Syrett, 1981). However, the relative preference for uptake of N compounds is difficult to assess in natural communities where nutrient pre-history is largely unkown and communities include a mixture of algae and bacteria. McCarthy *et al.* (1977) developed a Relative Preference Index (RPI) to evaluate nutrient preferences for phytoplankton N uptake, but it has since been argued that the RPI does not reflect real physiological preference under all conditions (Stolte and Riegman, 1996). Moreover, the use of the RPI is often biased by the dominant nutrient present as well as by substrates present at low concentrations for which uptake and regeneration are tightly coupled (e.g., NH_4^+ or urea). Nanomolar N uptake kinetic studies in the North Atlantic have shown that picoplankton have an enhanced capacity for NH_4^+ uptake and this has been argued as evidence of physiological preference (Harrison *et al.*, 1996). However, it is important to keep in mind that low rates of NH_4^+ uptake by autotrophs, or uptake of any N substrate for that matter, need not reflect low NH_4^+ bioavailability. Genetic capability and the availability of trace metals and other micronutrients (e.g., N, P, Si) can potentially reduce uptake rates of particular N compounds thereby complicating assessments of physiological preference (see Chapter 38 by Hutchins and Fu, this volume). In addition, estuarine and coastal populations appear to use a variety of N compounds simultaneously and the relative

uptake of various N compounds changes on short time scales (e.g., days) (Morse *et al.*, in preparation; Mulholland *et al.*, in preparation).

Without question, NH_4^+ is efficiently used by aquatic autotrophs; however, bacteria also consume significant amounts of NH_4^+ in natural systems. Uptake of NH_4^+ by bacteria is relatively high in oligotrophic gyres and in the coastal ocean. In Atlantic coastal waters, about 78% of total NH_4^+ uptake was by prokaryotes and a significant portion of that by heterotrophic bacteria (Wheeler and Kirchman, 1986), comparable to findings in the Pacific Ocean near the Hawaiian Islands (Laws *et al.*, 1985). A smaller fraction of the bacterial N demand was met by NH_4^+ in some eutrophic systems, where concentrations of free and combined amino acids were high (Fuhrman *et al.*, 1988; Hoch and Kirchman, 1993). However, in an extreme case, the very turbid and eutrophic Thames River, heterotrophic uptake of NH_4^+ exceeded 80% of the total NH_4^+ uptake (Middelburg and Nieuwenhuize, 2000). High rates of heterotrophic uptake of NH_4^+ in turbid environments could be due light limitation of autotrophic C fixation (e.g., Vincent, 1992). Uptake of NH_4^+ by bacteria also appears to vary seasonally, with higher uptake rates in summer (Fuhrman *et al.*, 1988; Hoch and Kirchman, 1995) when thermal stratification increases in most ocean systems and NH_4^+ concentrations reach annual minima (e.g., Lipschultz, 2001), and NH_4^+ turnover is rapid.

Because they are primarily heterotrophic, bacterial uptake of NH_4^+ may also depend on the availability of a labile C source (e.g., Gardner *et al.*, 1996). Goldman and Dennett (2001) found that NH_4^+ uptake by bacteria was dependent upon the availability of labile organic C sources to stoichiometrically balance N uptake. NH_4^+ uptake by bacteria was previously thought to be inhibited by amino acids; however, this does not appear to be the case (Jorgensen *et al.*, 1999b; Kirchman, 1994; Kirchman *et al.*, 1989). In fact, bacteria can simultaneously metabolize amino acids and NH_4^+ (Goldman and Dennett, 1991, 2000, 2001; Tupas and Koike, 1990, 1991). In N and C-limited bacterial cultures, dissolved combined amino acids (DCAA) were more important during stationary phase growth while dissolved free amino acids (DFAA) and NH_4^+ were more important N sources during exponential growth (Middelboe *et al.*, 1995b). These observations suggest that bacteria have flexible metabolisms and can satisfy their N demand using a variety of compounds depending both upon their relative availability and the physiological state of cells in the environment.

3.1.2. NO_3^-

Nitrate was thought to be the predominant source of ''new N'' to the euphotic zone and so its uptake has been more widely measured that any other N compound (Table 7.1). That said, NO_3^- upwelled from the deep ocean is not ''new N'' in the context of oceanic N inventories in general (see discussion of N_2 fixation below and Chapter 4 by Carpenter and Capone, this volume).

Assimilation of NO_3^- is more energetically demanding than NH_4^+, because assimilation of NO_3^- requires the synthesis of NO_3^- and NO_2^- reductases, associ–ciated active transport systems, and the turnover of cellular ATP and NADPH (Chapter 32 by Berges and Mulholland, this volume; McCarthy, 1981; Syrett, 1981). Further, supply of NO_3^- is limited by rates of nitrification and vertical

mixing. Diatoms have traditionally been thought to be the primary consumers of NO_3^- in the environment because they are often the dominant taxa in upwelling systems where NO_3^- concentrations are often high (Kokkinakis and Wheeler, 1987, see Chapter 17 by Wilkerson and Dugdale, this volume). However, because diatoms also require silicate, this element can limit their growth in high NO_3^- environments (Dugdale and Wilkerson, 1998). Alternatively, Fe can limit NO_3^- and silicate uptake in vast expanses of the ocean that are characterized by high nutrient and low chlorophyll concentrations (Martin and Fitzwater, 1988; Martin *et al.*, 1989; Timmermans *et al.*, 1998, 2004). NH_4^+ recycling and high concentrations of NH_4^+ are also thought to limit NO_3^- uptake in some oceanic regions (Wheeler and Kokkinakis, 1990, also see section on nutrient interactions below).

In order to assimilate NO_3^- for growth, phytoplankton must first possess the genetic capacity to synthesize the necessary enzymes and transport systems; not all phytoplankton do. For example, most of the strains of *Prochlorococcus* that have been studied in culture to date have been found to be unable to grow on either NO_3^- or NO_2^- as a sole N source (El Alaoui *et al.*, 2001; Moore *et al.*, 2002b). Notable exceptions are some recent strains isolated from the Red Sea (Fuller *et al.*, 2003). In contrast, most of the *Synechococcus* strains studied so far can use both NO_3^- and NO_2^- as sole N sources (e.g., Bird and Wyman, 2003; Moore *et al.*, 2002b). These observations have particular ecological significance because these two genera of marine cyanobacteria are numerically dominant in the Atlantic and Pacific oligotrophic ocean gyres (e.g., Campbell *et al.*, 1994; DuRand *et al.*, 2001) and contribute significantly to ocean primary productivity, overall autotrophic biomass, and export production (Goericke *et al.*, 2000).

Prochlorococcus and *Synechococcus* often display seasonal and geographic patterns that are consistent with their genetic capabilities (e.g., Johnson *et al.*, 2006). In the Sargasso Sea, *Synechococcus* has an annual biomass maximum in the late spring/early summer immediately following the period of winter convection and entrainment of deep NO_3^- concentrations in surface waters, whereas *Prochlorococcus* has an annual maximum late in the summer during the period of maximum thermal stratification when NO_3^- concentrations and upward mixing are low (e.g., Lipschultz, 2001; Steinberg *et al.*, 2001). Geographically, both *Synechococcus* and *Prochlorococcu,* can be found in shallow coastal environments where a variety of N substrates are available (see references in Partensky *et al.*, 1999; Scanlan, 2003). Based on the observation that *Synechococcus* but not *Prochlorococcus* can utilize NO_3^-, Bird and Wyman (2003) proposed that *Synechococcus* is more important in oceanic new production. However, although growth of a *Synechococcus* bloom in the Sargasso Sea was supported by NO_3^-, this 'new production' was not linked to export production (Glover *et al.*, 1988; *sensu* Eppley and Peterson, 1979). Current dogma holds that *Prochlorococcus* does *not* assimilate NO_3^- (nor fix N_2), and therefore, by definition, *Prochlorococcus* does *not* contribute to oceanic new production (*sensu* Dugdale and Goering, 1967). Indeed, it is paradoxical that although cultured *Prochlorococcus* strains cannot utilize NO_3^-, *Prochlorococcus* is the most abundant picoplankton population near the nitracline at the base of the euphotic zone, while *Synechococcus* is dominant in the surface ocean during periods of convective mixing; DuRand *et al.*, 2001).

Recent flow cytometry-stable isotope data suggests that natural populations of *Prochlorococcus* inhabiting the Sargasso Sea deep chlorophyll maximum contribute to new production (Casey *et al.*, 2007). Furthermore Sedwick *et al.* (2005) observed minima in dissolved Fe and in total dissolvable Fe in the Sargasso Sea deep chlorophyll maximum and suggested that these minima arise because of significant export production from this depth horizon. Mass sedimentation of picoplankton embedded in aggregates has been observed (Waite *et al.*, 2000) and cyanobacteria have been found in salp fecal pellets or aggregates (Goericke *et al.*, 2000; Pfannkuche and Lochte, 1993; Turley and Mackie, 1995) and fecal pellets of the copepod *Calanus finmarchicus* and the tunicate *Oikopleura* (Urban *et al.*, 1993a,b). These observations differ significantly from the view that diatoms and other species more prone to gravitational settling and less tightly controlled by grazers dominate new and export production from the euphotic zone (e.g., Barber and Hiscock, 2006; Buesseler, 2001; Gaines and Elbrachter, 1987; Goldman, 1993; Goldman and Mcgillicuddy, 2003; Goldman *et al.*, 1992). Indeed, mounting evidence suggests that the relative contribution of picoplankton and nanoplankton to oceanic export production needs to be reevaluated (Richardson *et al.*, 2004, 2006).

Heterotrophic bacteria can also take up NO_3^- and their capacity to do so varies according to their genetic make-up, physiological status, and nutrient environment. As for some clones of *Prochlorococcus*, the genome of *Silicibacter pomeroyi*, a bacterium whose relatives comprise 10–20% of coastal and oceanic mixed layer bacteria, contained genes for NH_4^+ and urea transport and assimilation, yet genes for NO_3^- and NO_2^- assimilation were not found (Moran *et al.*, 2004). In contrast, other bacterial groups appear to have the genetic capacity to take up and assimilate NO_3^- and NO_2^- (Allen *et al.*, 2001), and this has been confirmed in field incubations (Kirchman, 2000; Middelburg and Nieuwenhuize, 2000).

3.1.3. NO_2^-

Because nitrite reductase (NiR) is required for NO_3^- assimilation, organisms that assimilate NO_3^- can readily assimilate NO_2^-. However, some organisms that cannot use NO_3^- can use NO_2^- (e.g., some clones of *Prochlorococcus*; Moore *et al.*, 2002b). It has been suggested that this rather unique N physiology has arisen from the evolutionary loss of genes necessary for assimilation of NO_3^- (Garcia-Fernandez and Diez, 2004; Garcia-Fernandez *et al.*, 2004) and the resultant evolution of many ecotypes specifically adapted for unique environments where NO_2^- production can be high (see Chapter 5 by Ward, this volume). This could offer another explanation for the deep maximum in *Prochlorococcus* abundance; this maximum co-occurs with both the nitracline (Olson *et al.*, 1990; Partensky *et al.*, 1999) and the deep NO_2^- maximum.

Generally speaking, when NO_2^- is abundant in the euphotic zone, NO_2^- uptake can be significant (e.g., Glibert *et al.*, 1991), however, NO_2^- uptake is measured far less routinely than NO_3^- and NH_4^+ uptake. NO_2^- concentrations are generally low, but can at times accumulate throughout the entire euphotic zone (Al-Qutob *et al.*, 2002; Lomas and Lipschultz, 2006) as well as at the base of the euphotic zone in what has been termed the primary NO_2^- maximum (e.g., Rakestraw, 1936). Further, high NO_2^- concentrations have been found in estuaries and coastal systems at least seasonally (Filippino *et al.*, in revision; Morse *et al.*, in preparation; Bronk, personal

communication). There remains an active debate as to the proximate source of this NO_2^-, phytoplankton release or nitrification (Lomas and Lipschultz, 2006), and could likely be different between oceanic and coastal regions. The determination of the "source" of the observed NO_2^- in the ocean is not merely a pragmatic issue; it has large implications for the definition of new production (*sensu* Dugdale and Goering, 1967). One of the major assumptions of the new production paradigm is that euphotic zone nitrification is negligible (i.e., NO_3^- is entrained with deep water, not regenerated within the euphotic zone). We now know this assumption is untrue in stratified surface waters (Lipschultz, 2001; Raimbault *et al.*, 1999b; Ward, 1985), and probably in shallow estuaries, coastal plumes and shallow shelf waters (Filippino *et al.*, in revision; Morse *et al.*, in preparation). Consequently, we must revisit this assumption if we hope to correctly parameterize models of new production (e.g., Martin and Pondaven, 2006; Mongin *et al.*, 2003). Clearly, our understanding of NO_2^- cycling in the ocean is far from complete.

3.1.4. N_2

The special case of N_2 fixation is addressed by Carpenter and Capone (Chapter 4, this volume) and will not be discussed in detail here, other than to say that, like NO_3^- uptake, this is the ultimate source of new N to the ocean and it is an energetically costly way for cells to acquire N, requiring a large amount of ATP (Postgate, 1998). N_2 fixation is limited to cells that have the genetic capability to synthesize nitrogenase, the enzyme complex mediating the reduction of N_2. This limits the number of taxa that can fix N_2. Most of the identified organisms capable of N_2 fixation in the ocean are cyanobacteria, either free-living or in symbioses with some marine diatoms and dinoflagellates. There are also α- and γ-proteobacteria and archael N_2 fixers in estuarine, coastal, and open ocean systems (Mehta and Baross, 2006; Mulholland *et al.*, submitted for publication; Short *et al.*, 2004).

Because nitrogenase is inhibited by oxygen, many cyanobacteria synthesize heterocysts, armored cells, that retard oxygen diffusion in and that exclude oxygen evolving processes, in which they perform N_2 fixation (see Chapter 35 by Berman-Frank *et al.*, this volume). The marine non-heterocystous cyanobacteria *Trichodesmium* spp., are unusual in that they lack the ability to form heterocysts, but they do form diazocytes, groups of nitrogenase-containing cells that play similar roles but lack many of the protective mechanisms of heterocysts (Bergman and Carpenter, 1991; El-Shehawy *et al.*, 2003; Fredriksson and Bergman, 1997). These specialized cells are also under genetic control and are regulated by feedback from extracellular nutrients (Cai and Wolk, 1997; El-Shehawy *et al.*, 2003; Wolk, 2000). In the marine environment, N_2 fixation is thought to be limited by phosphorus (Karl *et al.*, 2001; Mills *et al.*, 2004; Sañudo-Wilhelmy *et al.*, 2001; Wu *et al.*, 2000; Zehr *et al.*, 2007). Until fairly recently, N_2 uptake was considered quantitatively insignificant and so generally excluded from N budgets and calculations of f-ratios in oceanic environments. To date, it is not included routinely in studies of N uptake (Mulholland *et al.*, submitted for publication), although rates of N_2 uptake can be significant (Table 7.2). Mapping the distribution of *nif* genes (genes encoding nitrogenase) in the environment and estimating rates of N_2 fixation have been the topics of intense research over the last two decades (see Chapter 4 by Carpenter

Table 7.2 Ranges of water column N$_2$ fixation rates

Date	Location	Depth	N$_2$ fixation (nmol N L^{-1}h^{-1})	Method	Reference
2001–2003	Gulf of Mexico	Surface	0.011–0.23	^{15}N$_2$	Mulholland et al. (2006)

[a] Converted from daily rate assuming N$_2$ fixation persisted for 24 h per day.
[b] Report rates from outside the phosphate enriched area.
[c] Used averages from control incubations.
Rates are presented as hourly rates because it is unclear whether N$_2$ fixation by unicellular diazotrophs exhibits diel periodicity (updated from Mulholland et al., 2006). AR is acetylene reduction.

and Capone, this volume). It has now become apparent that organisms containing *nif* genes are widely distributed in the marine environment and that N_2 fixation can be regionally and globally significant; N_2 fixation by diazotrophic endosymbionts can contribute significantly to new production in some environments (Carpenter et al., 1999), N_2 fixation by *Trichodesmium* sp. can contribute up to 50% of the new production where they occur (Capone et al., 2005; Karl et al., 1997; Mahaffey et al., 2004), and unicellular diazotrophs may contribute up to 10% of global oceanic new production (Montoya et al., 2004).

The oceanic N inventory largely depends on the balance between N inputs from terrestrial systems and N_2 fixation versus N losses from denitrification. Based on current estimates, the oceanic N budget is far from balanced (e.g., oceanic denitrification far exceeds N_2 fixation; Codispoti, 2007; Codispoti et al., 2001; Chapter 1 by Gruber, this volume). A better understanding of the geographical distribution and limitations on marine N_2 fixation is required to understand N cycling and oceanic N budgets under present, past, and future oceanic scenarios.

3.2. Bulk organic nitrogen dissolved

DON can often be the largest pool of dissolved combined N but it is largely uncharacterized (see Chapter 3 by Aluwihare and Meador, this volume; Bronk, 2002). The marine DON pool consists of highly reactive and relatively recalcitrant fractions and, while largely uncharacterized, includes a variety of compounds such as urea, dissolved free and combined amino acids and a variety of cellular intermediates, and excretion and degradation products that can be readily taken up (Table 7.1) and metabolized by phytoplankton and bacteria in the environment. Unfortunately, rates of DON uptake (excluding urea) are rarely measured.

DON can be rendered more or less available through extracellular enzymatic reactions that degrade DON into usable components (e.g., Chapter 32 by Berges and Mulholland, this volume; Chrost, 1991; Hoppe, 1983; Hoppe et al., 2002; Mulholland et al., 1998; 2002a; Palenik and Morel, 1990a,b; Pantoja and Lee, 1999; Pantoja et al., 1997) and photochemical reactions (Bushaw-Newton and Moran, 1999). The components and characteristics of the DON pool are described by Aluwihare and Meador (Chapter 3, this volume) and will not be discussed further here.

As for inorganic N, bacteria and phytoplankton are both sources and sinks of DON in the environment. Over the last two decades there has been a growing realization that organic N sources can be important components of the total N uptake in most marine systems where labile DON compounds, including urea, are often more abundant than DIN (Berman and Bronk, 2003; Bronk et al., 2007). Two decades ago, Paul (1983) stated that it was difficult to draw conclusions about organic N uptake based on the limited available data. A later review (Antia et al., 1991), summarized organic N uptake by phytoplankton by compound and by species but, much of this review focused on the physiological capability of cultured organisms rather than the ability of natural populations to use organic N compounds. There has been a resurgence of interest in the role of DON, and dissolved organic matter (DOM) in general, in the nutrition of phytoplankton as it has become clear

that DOM-enrichment has contributed to the degradation of coastal waterways (Glibert et al., 2001; Paerl, 1988; Chapter 11 by Paerl and Piehler, this volume) and that DON can be a quantitatively important source of N to organisms in the environment.

The quality and quantity of DON relative to DIN can influence community structure either directly or indirectly (e.g., Berman and Chava, 1999; Lewitus et al., 2000; Zubkov et al., 2003, 2004). While direct uptake of DOM by mixed communities of microalgae has been demonstrated (see Lewitus, 2006; Nilsson and Sundback, 1996; Paerl, 1991; Paerl et al., 1993; Wheeler et al., 1977), the number of studies examining this phenomenon has decreased since culture studies in the 1960s and 1970s. The recent resurgence in studies examining uptake of DON (Antia et al., 1991; Berman and Bronk, 2003; Bronk, 2002; Flynn and Butler, 1986) has been largely focused on potentially harmful algal bloom species (primarily dinoflagellates; Table 7.3; Berg et al., 1997, 2003a; Doblin et al., 1999; Fan et al., 2003b; Mulholland et al., 2002a; Smayda, 1997). Because amino acid uptake studies were previously biased towards diatoms and are currently biased towards potentially harmful taxa, little is known about DOM uptake by many flagellates (including non–toxic dinoflagellates) and picoplanktonic cyanobacteria. In addition, these taxonomic groups are difficult to culture axenically, culture collections have fewer representatives of these taxa (Graneli et al., 1997; John and Flynn, 1999; Zubkov et al., 2003), and monospecific populations of these organisms are rarely encountered in nature.

Despite these limitations, field studies suggest that many taxa use components of the DON pool for their nutrition. Chrysophytes, cryptophytes and dinoflagellates have notoriously versatile metabolisms (Antia, 1980; Gaines and Elbrachter, 1987) and Kristiansen (1990) thought it doubtful that there were any strictly photautotrophic crysophytes. Paerl (1991) demonstrated amino acid uptake by axenic Synechococcus and linked this to their high productivity in DIN-limited waters. High rates of DON uptake have been observed in populations dominated by Prochlorococcus, who take up methionine and leucine competitively with bacteria (Zubkov et al., 2003, 2004). Moreover, this ability may give Prochlorococcus a competitive advantage over other phytoplankton in the oligotrophic ocean gyres.

3.2.1. Urea

Measurements of urea concentrations and uptake rates in marine systems are now almost as common as measurements of the more 'traditional' N sources NO_3^- and NH_4^+ (Table 7.1). Urea is one of the simplest organic compounds, and its importance in supporting marine primary productivity has been recognized for several decades (e.g., McCarthy, 1972; McCarthy et al., 1977; Remsen et al., 1972a,b), despite the fact that it constitutes a small fraction (5.2% ± 3.4%) of the bulk DON pool in most marine systems (Bronk, 2002). Indeed, urea contributes on average 18.8% ± 15.4% of the total measured N uptake across a wide range of marine systems (Bronk, 2002). Moreover, urea uptake can contribute over 50% of the total measured N uptake in some coastal systems (Glibert et al., 1991; Harrison et al., 1985; Kokkinakis and Wheeler, 1988; Kudela and Cochlan, 2000; Mulholland et al., 2004d, unpublished data; Rees et al., 2002) and urea turnover times can be as short as

Measurements reflect data collected when the autotropic community was clearly dominated by a single functional group (e.g., diatoms) or a specifc bloom-forming organism (e.g., *Prorocentrum minimum*) as indicated by ''natural bloom'' in the Methods column. More recently, flow cytometry has been used as a means to separate sub-populations from istopic incubations ('FCM' in Methods column).

several hours (Lomas *et al.*, 2002; Tamminen and Irmisch, 1996). As for NH_4^+, rapid recycling and subsequent isotope dilution can result in underestimates of urea uptake (Bronk *et al.*, 1998; Hansell and Goering, 1989; see also Chapter 31 by Lipschultz, this volume), making even more striking the dichotomy between the low concentrations of urea (and low contribution to total DON pools) and the high uptake rates (Lomas *et al.*, 2002). However, urea isotope dilution measurements are rare and it is not entirely clear when or where isotope dilution would be most important.

Many field studies have presented data suggesting that phytoplankton are the dominant urea consumers in marine systems (e.g., Cho and Azam, 1995; Cho *et al.*, 1996a; Kokkinakis and Wheeler, 1988; Remsen *et al.*, 1972a; Savidge and Hutley, 1977; Savidge and Johnston, 1987; Tamminen and Irmisch, 1996) and that bacteria are the predominant urea producers (Cho *et al.*, 1996a; Jørgensen *et al.*, 1999a). However, we now know that bacteria are both sources and sinks of urea (Cho *et al.*, 1996a; Middelburg and Nieuwenhuize, 2000; Tungaraza *et al.,* 2003a,b). Urea uptake was higher in the bacteria than phytoplankton size fraction in the Thames Estuary (Middelberg and Nieuwenhuize, 2000) and in the North Sea (Tungaraza *et al.*, 2003a; Gilbert *et al.*, 2005). This could be due to the turbid nature of these systems, as urea uptake by phytoplankton has been shown to be light dependent (Lomas, 2004a; Mitamura, 1986; Mitamura and Saijo, 1975, 1980). However, light limitation of urea uptake does not appear to be universal because urea uptake rates in the phytoplankton size fractions were comparable during the day and night during blooms of *Aureococcus anophagefferens* (Boneillo and Mulholland, unpublished data), *Prorocentrum minimum*, and *Akashiwo sanguinea* (Mulholland *et al.*, unpublished data), and natural populations from the Sargasso Sea (Price and Harrison, 1988b). In *P. minimum* cultures, nighttime urea uptake was negligible in nutrient replete cultures but increased when cultures were grown on media with only 10 μM nitrogen (Mulholland *et al.*, unpublished data). Due to the nickel dependence of urease, the enzyme necessary for urea degradation in cells, this element is also thought to limit urea uptake and assimilation in the environment (Milligan and Harrison, 2000; Oliveira and Antia, 1986; Price and Morel, 1991; Rees and Bekheet, 1982; Syrett and Peplinska, 1988).

Although a variety of algal taxa can take up urea, recent work has focused on urea uptake during harmful algal blooms (HABs). The primary motivation behind this has been the long-term changes in organic to inorganic nutrient loading (e.g., Anderson *et al.*, 2002; Gilbert *et al.*, 2005) and a desire to test the hypothesis that this change has favored the selective growth of HABs. However, results have been conflicting. For example, in axenic cultures of *A. anophagefferens*, urea uptake rates were only ~50% of those found in natural bacterial associated with this organism (Berg *et al.*, 2002), consistent with the high bacterial urea uptake rates observed by Middelburg and Nieuwenhuize (2000). In contrast, in natural communities dominated by *A. anophagefferens*, urea uptake in the phyto–plankton size fraction was greater than that measured in the bacterial size fraction (Lomas, unpublished data; Mulholland *et al.*, 2002b, 2004a). During a red tide bloom of *Lingulodinium polyedra* on the California coast urea uptake rates were

twice those of NH_4^+ or NO_3^- uptake (Kudela and Cochlan, 2000). Urea and NH_4^+ uptake rates were comparable during mixed dinoflagellate blooms in the Neuse and Choptank River estuaries (Fan *et al.*, 2003b), while urea uptake rates far exceeded those of other N sources in populations dominated by *Karenia brevis* in the Gulf of Mexico (Mulholland *et al.*, 2006). These findings support the hypothesis that the ability to take up urea and other organic N at enhanced rates may favor the selective growth of some harmful algal species (Anderson *et al.*, 2002).

3.2.2. Amino acids

Uptake of DFAA was formerly thought to be the purview of heterotrophic bacteria, despite early observations that phytoplankton could take up DFAA (North and Stephens, 1967; Wheeler *et al.*, 1974, 1977). Although uptake of DFAA by bacteria can contribute substantially to this group's N demand, uptake of amino acids by phytoplankton was thought to be low because low affinities or uptake capacities for these compounds was demonstrated in culture systems (e.g, high K_s values compared with environmental concentrations; Antia *et al.*, 1991) and theoretically, bacteria have more favorable surface area to volume ratios. The latter, however, has not been evaluated extensively (see Kirchman, 2000) and we now know that uptake is not due to simple diffusion processes. Most studies demonstrating a low affinity for amino acid uptake in phytoplankton were done in cultures where nutrient interactions, preconditioning, and unrealistically high concentrations may have confounded the ability to estimate kinetic parameters in a way that would be representative of natural systems. An increase in the affinity for amino acids has indeed been observed when cells are N-deprived (Antia *et al.,* 1991; Flynn and Syrett, 1985, 1986a; Flynn *et al.*, 1987; North and Stephens, 1972) but, it is difficult to maintain cultures under N deprivation. Few studies have investigated amino acid uptake at concentrations representative of natural waters. In one such study, larger diatoms were able to take up amino acids at lower concentrations than smaller species (Flynn, 1990).

Because of the general perception that amino acids are taken up primarily by bacteria, in nature, uptake of amino acids is generally attributed to bacteria without adequate evaluation of just "who" is actually taking up these compounds. Uptake of organic compounds by bacteria is generally assessed using radio-labeled (^{14}C and ^3H) compounds. In general, phytoplankton ecologists have employed ^{15}N tracer techniques while microbial ecologists employ radio-tracer techniques. Consequently, the bias for organic compounds has been to attribute their uptake to bacteria, regardless of the experimental design and community composition. In contrast to prevailing views, microalgae accounted for more than 50% of glycine uptake in natural populations from coastal waters in the Pacific dominated by nanoplankton (Wheeler *et al.*, 1977). In estuarine environments along the Atlantic coast dominated by pelagophytes and dinoflagellates, the phytoplankton size fraction was responsible for a significant portion of the amino acid N (and C) uptake (Table 7.3; Mulholland, unpublished data; Mulholland *et al.*, 2002b, 2003). Amino acid uptake rates are high in communities dominated by phytoplankton mixotrophs (Mulholland *et al.*, 2002b, 2003, 2004d). In fact, the majority of leucine N and C was taken up by

the >20 μm size fraction during a bloom of the dinoflagellate *Prorocentrum minimum* (Rocha *et al.*, 2004) and this has important implications for evaluating bacterial productivity in natural systems by leucine incorporation (Mulholland *et al.*, in review). Similar results have been observed in the open ocean. Using a combination of radiotracers and flow cytometry, the marine cyanobacteria *Prochlorococcus* (the same size as heterotrophic bacteria and therefore negates the surface area to volume ratio argument) has been shown to account for 25–33% of the total microbial uptake of methionine and leucine (Zubkov *et al.*, 2003, 2004).

Although DFAA concentrations are fairly low in marine and estuarine systems, as for NH_4^+ and urea, their turnover can be quite rapid (Keil and Kirchman, 1991; Middelboe *et al.*, 1995a), and their production has been correlated with *in situ* primary productivity (Bronk *et al.*, 1998; Sellner and Nealley, 1997). As for NH_4^+, uptake and release of DFAA appear to be tightly coupled (Fuhrman, 1987), but not all amino acids are used to the same degree as indicated by the relative differences in the compositions of the intracellular free and combined amino acids and extracellular amino acid pools. Also, microalgal uptake of amino acids may not occur simultaneously with photosynthesis (e.g., Flynn and Butler, 1986). Because the turnover of DFAA can at times exceed estimated bacterial N demand (Fuhrman, 1990; Gardner *et al.*, 1993; Keil and Kirchman, 1991; Kirchman *et al.*, 1989) it is likely that there is either extracellular degradation of DFAA, regeneration of DFAA nitrogen as NH_4^+ (Cotner and Gardner, 1993), or the uptake of DFAA by organisms other than bacteria.

A variety of phytoplankton are known to possess cell surface oxidases (Palenik and Morel, 1990a,b) and extracellular oxidation of amino acids has been shown to occur in nature (Pantoja and Lee, 1994; Mulholland *et al.*, 1998, 2002a). Direct uptake of amino acid-derived N from this process represented up to 4% of the observed NH_4^+ uptake in a mid-Atlantic estuary (Mulholland *et al.*, 2003). Recently, a cell surface protein expressed under N-limitation was identified as a deaminase suggesting that these enzymes are regulated by cellular N status as for other pathways of N uptake and metabolism (Palenik and Koke, 1995). Failure to account for alternative pathways for mobilization of DON might result in underestimates of its utilization in nature.

3.2.3. Peptides/proteins

Together DFAA and DCAA are thought to account for about 50% of the bacterial N demand (Coffin, 1989; Keil and Kirchman, 1991; Kirchman, 2000; Middelboe *et al.*, 1995a) and about 25% of the bacterial C demand in estuarine and coastal systems (Middelboe *et al.*, 1995a). DCAA concentrations are higher than those of DFAA, and estuarine DCAA can account for up to 13% of total DON (Keil and Kirchman, 1991). DCAA lability can vary greatly since they are comprised of a mixture of peptides, proteins and other amino acids that require acid hydrolysis to release them from their chemical or physical matrix. Moreover, many amino acids may be trapped in refractory matrices preventing their mobilization in natural environments.

In living phytoplankton and zooplankton cells, proteins account for a major fraction of the cellular C and most of the N (Dortch *et al.*, 1984; Kirchman, 2000;

Nguyen and Harvey, 1994). We therefore expect organic matter released from living organisms to contain protein; the predominance of amide N in the high molecular weight (HMW) DOM pool seems to confirm this, and in fact, proteins have now been identified in seawater (Suzuki *et al.*, 1997; Tanoue, 1995; Tanoue *et al.*, 1996; Yamada and Tanoue, 2003). The relatively low contributions of combined amino acids to the total N pool suggest that: (1) protein N is not the dominant form of HMW-DON, (2) protein and peptide N is rapidly degraded and consumed in the environment, and/or (3) that analytical methods currently being employed, other than NMR, underestimate the contribution of proteins to this fraction of the DOM pool (see Chapter 3 by Aluwihare and Meador, this volume). In seawater, most microbes and phytoplankton can take up only inorganic or small organic compounds (Antia *et al.*, 1991; Nikaido and Vaara, 1985). The use of larger organic compounds, such as peptides and proteins, by microorganisms is often limited by the size of the compound. However, a variety of microorganisms including phytoplankton (Berg *et al.*, 2002; Mulholland *et al.*, 2002a, 2003; Stoecker and Gustafson, 2003) and bacteria (Chrost, 1991; Hoppe, 1983; Hoppe *et al.*, 2002) have extracellular proteases and hydrolases (Chapter 32 by Berges and Mulholland, this volume). For example, axenic *Aureococcus anophagefferens* (pelagophyceae) cultures hydrolyzed aminopeptides and chitobiose at rates that are significant relevant to bacterial extracellular hydrolysis (Berg *et al.*, 2002). There do not appear to be any studies of the direct uptake (by diffusion) of polypeptides by phytoplankton or microalgae (Antia *et al.*, 1991), although a dipeptide, glycylglycine was reported to be a good N source for the growth of three marine prymnesiophytes (Turner, 1979). Recent work also suggests that uptake of dialanine can be significant in populations dominated by a variety of bloom-forming mixotrophic phytoplankton (Mulholland and Lee, in revision).

3.2.4. Other organic compounds

Only 5% to 18% of bulk DON has been identified as urea, DFAA or DCAA, proteins/peptides, however, it is estimated that anywhere from 12% to 72% of DON is bioavailable in marine and estuarine systems (Bronk, 2002 and references therein). Consequently, compounds other than those discussed above (e.g., amino sugars, purines, pyrimidines, and nucleic acids) are likely available to bacteria and/or phytoplankton, either directly or indirectly through bacterial regeneration of these substrates to NH_4^+, urea or amino acids, however, little is known about their uptake characteristics (Antia *et al.*, 1991). Recent discoveries of the genes encoding all enzymes for a complete urea cycle in a diatom (Armbrust *et al.*, 2004), genes encoding proteins capable of cyanate metabolism in cyanobacteria (Garcia–Fernandez *et al.*, 2004), and the ability of *Synechococcus* to grow on cyanate as a sole source of N (Palenik *et al.*, 2003) suggests that we are only beginning to understand the capacity of marine microbes to utilize DOM in nature.

Bulk DON uptake by microorganisms has been examined using a bioassay approach (Stepanauskas *et al.*, 1999a,b; Berg *et al.*, 2003b) as well as by synthesizing ^{15}N-labeled DON (Bronk and Glibert, 1993). Berg *et al.* (2003b) observed that 25–36% of the available N in HMW-DON, isolated from shallow eutrophic sediments, was depleted during growth of axenic cultures of *Aureococcus anophagefferens*. Bulk

DON uptake by natural populations of Chesepeake Bay phytoplankton often exceeded rates of combined NH_4^+ and NO_3^- uptake during spring and summer with uncharacterized DON uptake (i.e., not urea) equivalent to about 12% of the NH_4^+ uptake rates (Bronk and Glibert, 1993). In addition, high molecular weight humic material is thought to represent a significant source of N in some systems (Carlsson et al., 1998; Legrand and Carlsson, 1998; Stolte et al., 2002). To date, culture and field studies have primarily investigated DOM uptake by microplankton and so there are very few studies examining DOM uptake by nanoflagellates or picoplankton (Lewitus, 2006).

Besides supplying N, other advantages of DOM uptake might also include access to organically-bound trace metals, augmentation of autotrophic C acquisition, and access to P. Heterotrophic capabilities appear to be widespread in pennate but not centric diatoms (Lewitus, in press), dinoflagellates, chrysophytes, cryptophytes, and other algal taxa. Osmotrophy, the uptake of DOM, has not been widely assessed in marine phytoplankton (but see Stoecker, 1999), however, among dinoflagellates, phagotrophy is common (Anderson et al., 2002; Burkholder et al., 1997; Carlsson et al., 1998; Graneli and Moreira, 1990; Lewitus, in press; Mahoney and Mclaughlin, 1977). Indeed, direct uptake of HMW-DOM (>1 kD) has been hypothesized as a "niche" for photo- and heterotrophic flagellates in direct competition with bacteria (Legrand and Carlsson, 1998; Marchant and Scott, 1993; Schuster et al., 1998; Sherr, 1988; Tranvik et al., 1993). Although there is still only a limited amount of information regarding the use of "uncharacterized" DOM by natural communities, this may be a significant source of N to phytoplankton and bacteria in nature.

3.3. Nutrient interactions

3.3.1. Nutrient/nutrient interactions

The interaction between NH_4^+ and NO_3^- was reviewed by Dortch (1990). Several conclusions were drawn that continue to be valid more than a decade later: (1) ambient concentrations of NH_4^+ can reduce, but do not completely inhibit, NO_3^- uptake and, (2) the concentration of NH_4^+ at which NO_3^- uptake is depressed varies greatly between phytoplankton species (for example, compare Collos et al., 2004; Dortch et al., 1991a) and with nutrient prehistory (Dortch et al., 1991a). Furthermore, the bulk of the evidence suggests that the repression in NO_3^- uptake rates by NH_4^+ is not direct, but rather mediated by organic metabolites, likely glutamine or the glutamine:glutamate or glutamine:α-ketoglutarate ratio, which are ultimately related to the overall N status of the cell (e.g., Flynn, 1990; Flynn et al., 1989; Page et al., 1999; Stephens et al., 2003).

Field studies continue to support the conclusion of Dortch (1990), that the effect of NH_4^+ on NO_3^- uptake is highly variable. For example, NO_3^- uptake rates in natural assemblages dominated by the coccolithophorid Emiliania huxleyi from the subarctic NE Pacific Ocean were reduced by 50% at NH_4^+ concentrations of 0.24 μM with nearly complete inhibition at 2.2 μM (Varela and Harrison, 1999a). Based on the average ambient NH_4^+ concentrations during these blooms, this translates into a 38–70% reduction in NO_3^- uptake rates, the majority of which occurred

during the daylight period. Similar reductions in NO_3^- uptake were negatively correlated with NH_4^+ concentration in the subarctic Pacific (Wheeler and Kokkinakis, 1990). Likewise, for the picoplankter, *Micromonas pusilla*, NH_4^+ concentrations of 1–10 μM inhibited NO_3^- uptake (Cochlan and Harrison, 1991a). A more extreme example comes from the Tagas estuary (Portugal) where NH_4^+ concentrations in excess of 10 μM only reduced NO_3^- uptake rates by 24%, with lower NH_4^+ concentrations exhibiting no significant impact on NO_3^- uptake (Cabrita *et al.*, 1999). These results attest to the variability in the response of populations to the dominant source of combined N.

Other environmental variables such as temperature, light, and availability of trace metals and other macro- and micronutrients (see Chapter 37 by Kudela, this volume and Chapter 38 by Hutchins and Fu, this volume) also affect nutrient interactions and the effects vary depending on the dominant species. As growth temperature decreased, so to did the extent to which NH_4^+ inhibited NO_3^- uptake for the diatoms, *Chaetoceros* sp. and *Thalassiosira weissflogii*, and the dinoflagellates, *Prorocentrum minimum* and *Gyrodinium uncatenum* (Lomas and Glibert, 1999a,b). This may explain the higher than expected rates of NO_3^- uptake during the winter/spring period when NH_4^+ concentrations are high in estuarine and coastal systems (e.g., Chesapeake Bay). The may not hold true for summer assemblages in Chesapeake Bay. During a bloom of the dinoflagellate, *Prorocentrum minimum*, there was a positive relationship between temperature and the affinity for NH_4^+ and amino acids and a negative relationship between temperature and affinity for NO_3^- (Fan *et al.*, 2003b). In addition to temperature, Yin *et al.* (1998) showed that NH_4^+ inhibition of NO_3^- uptake was light dependent. In light–limited cultures, there was no short-term NH_4^+ inhibition of NO_3^- uptake by the diatom, *T. pseudonana*, while under saturating and moderate light NO_3^- uptake was reduced by 70% and 62%, respectively, by NH_4^+. Confounding effects from multiple environmental variables and stressors complicate our understanding of nutrient interactions in the natural environment.

Like NO_3^- uptake, N_2 fixation (and the development of heterocysts) is thought to be inhibited by NH_4^+. This conjecture is based on a variety of field and laboratory studies. However, most laboratory studies employ unrealistically high NH_4^+ concentrations (>100 μM) (e.g., El-Shehawy *et al.*, 2003; Ohki *et al.*, 1991). In recent studies conducted under oligotrophic conditions (in terms of N), N_2 fixation by *Trichodesmium* spp., proceeded simultaneously with the uptake of NH_4^+ (Mulholland and Capone, 1999, 2000, 2001; Mulholland *et al.*, 2001, 2004b) suggesting that this view needs to be revisited in open ocean environments where inorganic N concentrations are rarely above 1 μM, and most often at or near the analytical detection limit, and there is tight coupling between NH_4^+ production and uptake (Mulholland *et al.*, 2001, Sunda personal communication).

Several studies have also been conducted to explore interactions between urea and uptake of other N substrates. In N sufficient cultures of the diatom *Thalassiosira pseudonana* and *T. weissflogii* (growing in NO_3^- replete media) the addition of urea partially inhibited NO_3^- uptake (Lomas, 2004b; Price and Harrison, 1988a) and urea additions of 5 μM resulted in 28% reduction of NO_3^- uptake by *Micromonas pusilla* (Cochlan and Harrison, 1991a). However, for *T. weissflogii*, the reduction in

NO_3^- uptake by urea was different than that observed upon the addition of NH_4^+ (Lomas, 2004b). Addition of NH_4^+ to urea-grown cultures of the diatoms *T. weissflogii, T. pseudonana* and *Skeletonema costatum* decreased urea uptake rates by more than 30% (Horrigan and McCarthy, 1982; Lomas, 2004b). Short-term additions of either NH_4^+ or NO_3^- did not alter urea uptake rates in natural phytoplankton populations from the Baltic Sea, although inhibition of urea uptake by NH_4^+ was observed after one day (Tamminen and Irmisch, 1996). In the Oslofjord, measured urea uptake rates were inversely related to ambient NH_4^+ concentrations (Kristiansen, 1983), while in the northeast Pacific Ocean, high NO_3^- concentrations ($>20\ \mu M$) led to higher urea uptake rates than under low NO_3^- conditions in the 'diatom' fraction but not in the nanoplankton fraction (Kokkinakis and Wheeler, 1988). Lund (1987) observed that for *S. costatum* the following combinations of N sources showed mutual interference on uptake rates: NH_4^+ on NO_3^-, NH_4^+ + urea on NO_3^-, urea on NH_4^+, NO_3^- + urea on NH_4^+, NO_3^- on urea, NH_4^+ on urea, and NH_4^+ + NO_3^- on urea, whereas there was no mutual interference of NO_3^- on NH_4^+ and of urea on NO_3^-. Moreover, summed uptake rates for oxidized (NO_3^-) and reduced N sources (urea, NH_4^+) greatly exceeded the rate necessary to maintain growth rates suggesting N uptake in excess of that necessary for growth. In studies of the marine N_2 fixer, *Trichodesmium*, uptake of N_2 could account for net growth although NH_4^+ uptake accounted for up to 80% of the N turnover in culture vessels (Mulholland and Capone, 1999, 2001). This finding is consistent with a number of field studies where summed N uptake greatly exceeds the *in situ* growth rate and suggests that gross N productivity exceeds net community growth.

As for other forms of N, NH_4^+ was thought to inhibit uptake of DFAA but this does not appear to be universally true (see Antia *et al.*, 1991 and references therein). Amino acid uptake by phytoplankton was not inhibited by the presence of NH_4^+, NO_3^-, NO_2^-, urea or other amino acids in several studies (Flynn and Syrett, 1986b; Flynn and Wright, 1986; Flynn *et al.*, 1987). Similarly, Goldman and Dennett (2000) found that the presence of NH_4^+ did not inhibit amino acid uptake by bacteria. In fact, the relative assimilation of DFAA, DCAA and NH_4^+ varied between C and N limited cultures and during exponential versus stationary phase growth suggesting that physiological status plays a role in determining nutrient uptake capacity (Middelboe *et al.*, 1995a).

In nature, a diverse suite of N compounds are often available and can be taken up. Clearly nutrient interactions are complex and vary between environments and the organisms inhabiting them. Nitrogen uptake varies as a result of physiological adaptations of particular organisms to the environment, their physiological state, and the degree to which they are acclimated to their changing environment. One could argue that organisms are adapted to the nutrient environment in which they live and the timescales of natural variations characteristic of that environment.

3.3.2. Environmental interactions
Light is a key environmental factor having an impact on nearly all phytoplankton physiological processes; N uptake is no different. Nutrient uptake versus irradiance curves often show a hyperbolic relationship that have been mathematically fit by

both a Michaelis-Menten type model and Jassby-Platt type photosynthesis model (e.g., Cochlan et al., 1991b; Hu and Smith, 1998; Kudela and Cochlan, 2000; Kudela et al., 1997; Lim et al., 2006; Muggli and Smith, 1993; Paasche et al., 1984; Priscu et al., 1991). Photoinhibition of N uptake has been observed (e.g., Hu and Smith, 1998; Planas et al., 1999), but it is far from universal. What is universal, however, is the need to include a term for dark N uptake. Unlike, dark photosynthetic C fixation, dark N uptake can be anywhere from 10–100% of the uptake rate measured in the light, and this varies with physiological condition of the resident population, N source, and phytoplankton species. Indeed, the ratio of dark uptake to light uptake ($V_D:V_L$) is often used as a proxy for nutrient status. Values close to unity suggest that the studied population is N stressed, and therefore assimilating all N that is encountered. For example, Gyrodinium aureolum did not take up NO_3^- in the dark under replete growth conditions, but when NO_3^- starved, $V_D:V_L$ values approached 0.5, with no significant increase in light uptake rates (Paasche et al., 1984). Consistent with laboratory studies on Prorocentrum minimum (Paasche et al., 1984), natural bloom populations of Prorocentrum minimum displayed a $V_D:V_L$ ratio of ~0.5 (Fan and Glibert, 2005). This is not always the case however, as MacIsaac (1978) observed strong light dependence of NO_3^- and NH_4^+ uptake in Gonyaulax polyedra ($V_D:V_L$ range 0–0.3), whereas Kudela and Cochlan (2000) found $V_D:V_L$ values >0.5 for NO_3^-, NH_4^+ and urea.

In addition to diel variability in N uptake rates, there are also differences between N substrates in the irradiance level where uptake saturates. Interestingly, Kudela and Cochlan (2000) observed that NO_3^- uptake by Gonyaulax polyedra saturated at the lowest irradiance (~3% of incident irradiance), whereas NH_4^+ (7%) and urea (12%) uptake saturated as much higher irradiances. Natural phytoplankton populations along an upwelling gradient displayed similar values for NO_3^- (5%) and NH_4^+ (2%) uptake (Kudela et al., 1997). The light dependence of measured N uptake response is also related to the pre-conditioning of the population being studied. For example, populations collected from the base of the euphotic zone, and therefore likely acclimated to low light, display much less light dependence of NO_3^- and urea uptake, presumably due to reduced capacity for uptake at higher irradiances (e.g, Cochlan et al., 1991b).

One characteristic of all of these previous studies is that samples were collected during the light period and then incubated in the dark to determine the dark N uptake rates. Fundamentally, dark N uptake relies on previously stored photosynthate and therefore it is possible that the dark uptake rates measured in the above studies are higher than if N uptake were measured during night time. Some of the earliest studies on nighttime NO_3^- uptake measured very low rates (e.g., MacIsaac, 1978; MacIsaac and Dugdale, 1969, 1972). Recent work in more oligotrophic environments has shown that nighttime NO_3^-, NH_4^+ and urea uptake rates, like daytime populations incubated in the dark, show $V_D:V_L$ ratios of 0.3–1.0 (e.g., Lipschultz, 2001; Price and Harrison, 1988b; Tremblay et al., 2000). As expected, some of this variability is related to N limitation. Natural picoplankton populations in the Sargasso Sea have $V_D:V_L$ values for NO_3^- uptake >0.5 when ambient NO_3^- concentrations are below 30 nM, but <0.1 when ambient NO_3^- concentrations exceed 500 nM (Lomas et al., in review). It is apparent that the

interaction between light and N uptake is very complicated and unifying rules for all phytoplankton at all growth states are not yet developed.

3.4. Phytoplankton diversity and nitrogen uptake

There is a diverse and growing body of results from culture studies indicating that phytoplankton diversity is an important variable when it comes to understanding N cycling in the marine environment. There is also quite a bit of information on N uptake from natural systems during monospecific blooms or from flow cytometrically sorted populations (Table 7.3). Studies have indicated that there is preferential utilization of NO_3^- by diatoms in coastal and estuarine environments (Lomas and Glibert, 1999a,b, and references therein), that *Prochlorococcus* strains are unable to grow on NO_3^- (Moore *et al.*, 2002b), and that low DIN and high DON selectively favors the growth of harmful algal species (Anderson *et al.*, 2002). The latter observation has received the most attention and is discussed further.

Harmful algal blooms (HABs) appear to be increasing in their frequency and duration in coastal systems around the world as a result of cultural eutrophication (GEOHAB, 2001; Glibert *et al.*, 2005a,b; Chapter 11 by Paerl and Piehler, this volume). The special case of HABs has been the subject of much recent research on N cycling in coastal systems (see review by Anderson *et al.*, 2002 for further details). In particular, DON has been implicated as a nutrient source that may preferentially stimulate harmful algal blooms (HABs) (e.g., Anderson *et al.*, 2002; Graneli *et al.*, 1999). Many HABs are known mixotrophs and can acquire C both autotrophically and heterotrophically through the assimilation of organic molecules. Because DON also contains C, using DON as an N source can offer a metabolic supplement to strictly autotrophic C assimilation.

Many harmful algal taxa are not strong competitors for inorganic N sources in nature and their uptake kinetics for inorganic N sources are 'average'. For example, *Alexandrium catenella* was not a strong competitor for NO_3^-, NO_2^-, NH_4^+, or urea at low concentrations ($<10\ \mu M$ N) compared with other phytoplankton, but labile organic N compounds could be important in triggering blooms (Collos *et al.*, 2004). The brown tide organism, *Aureococcus anophagefferens*, has been shown to grow on organic substrates, in cultures, and to take up and grow on organic compounds, including urea, in nature (Berg *et al.*, 1997; Gobler and Sanudo-Wilhelmy, 2001; Gobler *et al.*, 2002; Lomas *et al.*, 2004; Mulholland *et al.*, 2002b, 2004a). In contrast to *A. catenella*, *A. anophagefferens* has demonstrated equally high affinity for NH_4^+ and urea in culture and natural systems (Lomas *et al.*, 1996; Mulholland *et al.*, 2002b).

Growth of the red tide dinoflagellate, *Karenia brevis*, has been linked to N compounds, including DON, released from the marine N_2 fixer, *Trichodesmium* (Bronk *et al.*, 2004; Mulholland *et al.*, 2004c). Further, *Prorocentrum minimum* and *Pfiesteria* sp. are thought to consume DON and have been linked to systems with high DOC:DON ratios (Glibert *et al.*, 2001). However, both of these species can use a range of N sources in cultured and natural systems (Fan *et al.*, 2003b; Lewitus *et al.*, 1999). In a seasonal study of N utilization by bloom-forming

species in a lower Chesapeake Bay subtributary, the dominant N source varied seasonally as the bloom species changed, over the course of individual blooms, and over diel cycles suggesting substantial metabolic flexibility in N acquisition (Mulholland *et al.*, in preparation). So, although organisms appear to be adapted to where they live, the overall metabolic flexibility of organisms may be important when a diverse array of nutrients are delivered at a variety of temporal and spatial scales.

4. Pathways of Nitrogen Uptake and Assimilation

Up to this point, we have discussed primarily uptake of N with respect to the extracellular environment. However, N uptake and assimilation are stepwise processes that can result in uncoupling between uptake and growth (e.g., Wheeler, 1983) and, as alluded to above, feedback from intracellular metabolites may be important regulators of N uptake from the environment. In addition to feedback regulation, most of the enzymes involved in the uptake and assimilation of N are tied to energy sources and so are affected by light, the presence of oxygen, and the supply of enzyme co-factors and metabolic substrates. For example, uptake and reduction of NO_3^-, NO_2^-, and urea have been linked to the light supply in phytoplankton due to the necessity for ATP and NADPH from photophosphorylation. While uptake and reduction of these compounds is thought to proceed at maximum rates only in the light under nutrient replete conditions, when N is depleted, active uptake of these compounds may occur even in the dark (Antia *et al.*, 1991).

4.1. Nitrogen transport and assimilation

Nitrogen can enter cells via passive diffusion, but under low nutrient, oligotrophic conditions concentration gradients across the cell membrane might actually result in a net efflux of nutrients from the cell. Because most N sources are present at low concentrations in marine environments, they are generally taken up via active membrane transport systems and permeases. A variety of transporters, transporter complexes, and permeases have been identified that facilitate the uptake of inorganic and organic N and its concentration in cells (see Chapter 32 by Berges and Mulholland, this volume).

Generally, there are several transporters and uptake systems for common N compounds. For example, permeases or other transporters seem to be necessary for uptake of NH_4^+ at low concentrations (<1 μM; most oligotrophic environments) (Herrero *et al.*, 2001). Genes encoding permeases have been found and one (*amt1*) seems responsible for most transport when there are micromolar concentrations (Herrero *et al.*, 2001; Montesinos *et al.*, 1998). More recent evidence in the marine diatom *Cylindrotheca fusiformis* suggest that there are two subgroups of NH_4^+ transporters, *amt1* and *amt2*, with multiple copies of each (Hildebrand, 2005).

Expression of both transporters are increased during growth on NO_3^-, although differentially, and it is suggested that *amt2*, might actually function as an N sensor rather than an efficient transporter. Research into NO_3^- transporters (NAT) in marine phytoplankton have shown that they are induced under both N starvation and growth on NO_3^- enriched medium (Hildebrand and Dahlin, 2000b). In cyanobacteria an inducible ABC-type permease, encoded by the gene cluster *urtABCDE*, is required for the uptake of urea at low concentrations (<1 μM) even though the internal enzyme to metabolize urea is constitutively expressed (Valladares *et al.*, 2002). More detailed information on the genes encoding for N transporters in marine phytoplankton can be found in Chapter 30 by Jenkins and Zehr in this volume.

Although active transport is energetically costly, uptake is more rapid than passive diffusion (Neame and Richards, 1972), the result being that many metabolites are stored internally. The diatoms are perhaps the best known for this due to their large internal vacuole space. Estimated intracellular concentrations of many N substrates (e.g., NH_4^+, NO_3^-, NO_2^-, urea, amino acids) can be in excess of millimolar concentrations (e.g., Dortch *et al.*, 1984; Lomas and Glibert, 2000; Lourenco *et al.*, 1998). It has been hypothesized that unicellular cyanobacteria, *Synechococcus*, may use its N-rich phycobilipigments as a storage pool during times of 'plenty' (Barlow and Alberte, 1985; Wyman *et al.*, 1985), although the existence of a photosynthetic and a non-photosynthetic phycoerythrin pool has been debated (Kana and Glibert, 1987a,b) along with the ability of *Synechococcus* to mobilize photosynthetically coupled phycoerythrin upon N starvation (Glibert *et al.*, 1986).

Because common intermediates can accumulate intracellularly, uptake of N is sensitive to both intracellular nitrogen pools and the composition and concentrations of extracellular N sources. As discussed above, the presence of NH_4^+ in the growth medium can differentially inhibit the uptake of different N compounds, and although this is likely a result of the different energetic demands for their reduction, the inhibitory effect of NH_4^+ is more often thought to be exerted through feedback from intracellular pools resulting from its assimilation (e.g., Flores and Herrero, 2005). NH_4^+ is a common intermediate to inorganic N reduction and glutamine (gln) and glutamate (glu) are the primary products of N assimilation. These common intermediates may be important in regulating N uptake and assimilation through feedback from product pools and the glutamine:glutamate ratio (Flynn, 1991; Chapter 30 by Jenkins and Zehr, this volume).

Inorganic N is taken up by marine microorganisms, primarily via active membrane transport, reduced to NH_4^+, and then assimilated by microorganisms into amino acids through the glutamine synthetase (GS)/glutamate synthase (GOGAT) pathway (Bressler and Ahmed, 1984; Miflin and Lea, 1980; Fig. 7.2). Glutamate dehydrogenase (GDH) does not represent a significant pathway for NH_4^+ assimilation in most plants (e.g., Suzuki and Knaff, 2005), but is an important enzyme involved in regeneration of N from zooplankton (see Chapter 8 by Bronk and Steinberg, this volume). Because of the added energy and reductant necessary to reduce NO_3^-, NO_2^-, and N_2 to NH_4^+, NH_4^+ was thought to be the N source

preferentially assimilated by phytoplankton (e.g., Eppley and Thomas, 1969, but see Thompson *et al.*, 1989). Stepwise reduction of NO_3^- to NH_4^+ requires nitrate (NR) and nitrite (NiR) reductases and reduction of N_2 to NH_4^+ requires the enzyme complex dinitrogenase reductase (NA). The reduction of NO_3^- to NO_2^- is mediated by NR while the reduction of NO_2^- to NH_4^+ is mediated by NiR, the former is thought to be the rate-limiting step of the enzyme pair and therefore, intracellular accumulation of NO_2^- during NO_3^- assimilation is thought to be minimal. NR appears to be both constitutive and inducible in marine microbes. In addition, there appears to be NH_4^+ promoted repression of NR both at the level of gene expression and enzyme activity (Berges, 1997; Flores and Herrero, 2005).

   Intracellular hydrolysis of urea and its ultimate assimilation occurs through one of two enzymatic pathways: urease or ATP:urea amidolyase. The later has been demonstrated to exist exclusively in the chlorophyte algae (Leftley and Syrett, 1973) and involve the ATP-dependent catalysis of urea to allophanate and urea carboxylase (Bekheet and Syrett, 1977). Urease is widespread in chromophytic algae (Oliveira and Antia, 1986) and involves the nickel-dependent hydrolysis of urea into two ammonia molecules and carbon dioxide. Urease activity appears to be constitutive in a number of marine diatoms such as *Cyclotella cryptica* (Oliveira and Antia, 1986), *Thalassiosira pseudonana* (Peers *et al.*, 2000), and *T. weissflogii* (Lomas, 2004b; Milligan and Harrison, 2000; Peers *et al.*, 2000) but appears to be N-regulated in other cases. There does appear to be species differences in the degree of constitutive expression versus upregulation of urease activity depend-ing upon the form of N in the growth medium. For example, in *T. pseudonana* but not *T. weissflogii* urease activity was upregulated 4- and 8-fold in cultures grown on NO_3^- and urea relative to those grown on NH_4^+ (Peers *et al.*, 2000). In contrast, cell-specific urease activities were higher in *Synechococcus* WH7805 growing on NO_3^- relative to cells grown on either NH_4^+ or urea (Collier *et al.*, 1999), while *Aureococcus anophagefferens* and *Prorocentrum minimum* exhibited high urease activities regardless of the N source (Fan *et al.*, 2003a). The dinoflagellate *Alexandrium fundyense* displayed inducible urease activity, although no urease activity was observed in NO_3^--replete cultures, and only very low activity was observed when grown on NH_4^+; once cultures became N limited, urease activity increased (Dyhrman and Anderson, 2003).

   Microalgae that use DFAA require active transport mechanisms because passive diffusion at environmentally relevant concentrations is theoretically unlikely (Antia *et al.*, 1991; Raven, 1980). Most algae that take up amino acids use them as N sources after catabolizing them or incorporate them directly into proteins (Antia *et al.*, 1991). There appear to be at least three different transport systems for amino acid uptake corresponding to the net charge of the amino acids well as "general" amino acid transport systems (see review by Antia *et al.*, 1991). The ability to take up multiple amino acids through common pathways and the range of apparent turnover times for individual amino acids complicates our interpretation of uptake studies that employ amino acids either singly or in combination. Amino acid uptake by microalgae can be induced by both N deprivation (Flynn and Syrett, 1985; North and Stephens, 1971, 1972; Wheeler *et al.*, 1974) and C deprivation

(e.g., during the dark period; Flynn and Butler, 1986), and the induction time appears to be influenced by the size of the intracellular amino acid pool. Despite the resurgence of interest in amino acid uptake by phytoplankton, little is known about its regulation.

Once taken up, amino acids appear to be stored in two separate intracellular pools: a storage pool and a metabolic pool. Intracellular and extracellular amino acid pools differ in their composition suggesting that amino acids are not taken up directly into the storage pool; rather they are first metabolized by cells. In fact, the composition of the intracellular amino acid pool varies with physiological status and the relative sizes of the glutamine and glutamate pools have been used to evaluate the physiological status of microalgae (Flynn, 1990; Flynn and Al-Amoudi, 1988; Mulholland and Capone, 1999; Mulholland et al., 1999), with higher intracellular gln:glu ratios characteristic of N replete cells.

4.2. Nitrogen uptake kinetics

The kinetics of N uptake by marine phytoplankton have been thoroughly reviewed (McCarthy, 1981), and differences between internally (Droop model) and externally controlled nutrient uptake models articulated (Goldman and Glibert, 1983). However, until recently, methodological constraints have limited the ability to accurately determine half-saturation concentrations in the open ocean where concentrations of most N compounds are nearly an order of magnitude lower than analytical capabilities (e.g., Goldman and Glibert, 1983). Analytical techniques have improved over the past 20 years (e.g., Garside, 1985; Zhang, 2000), but relatively few new studies have used these techniques to reevaluate half-saturation concentrations in the open ocean. Harrison et al. (1996) determined half-saturation constants (K_s) for natural phytoplankton assemblages for NO_3^- and NH_4^+ uptake on several cruises throughout the North Atlantic, and confirmed that K_s values in the open ocean were commonly <40–60 nM for both substrates. A similar conclusion was reached for natural populations in the Sargasso Sea (Lipschultz, 2001), and in several culture studies (Garside, 1991; Raimbault et al., 1990; Sunda, unpublished data) corroborating field studies.

Perhaps the most significant advance in the study of phytoplankton uptake kinetics is not that there are more data available, but rather a change in 'philosophy' with respect to NO_3^- uptake at environmentally relevant concentrations (Collos et al., 2005). Nearly all aquatic biogeochemical models use a 'classical' kinetics formulation to describe N uptake (e.g., Fasham et al., 1990; Moore et al., 2002a), but recent data for coastal systems suggests that this may not be entirely appropriate, and indeed may result in significant underestimates of NO_3^- - assimilation. Estuarine and coastal NO_3^- concentrations far exceed those in the open ocean, and not surprisingly, it appears that the characteristics of NO_3^- uptake kinetics differ between these two regions. When NO_3^- uptake kinetic experiments are conducted over the range of ambient NO_3^- concentrations, linear and biphasic uptake kinetics, in addition to classical uptake kinetics, have been observed. Half-saturation concentrations are difficult to estimate when linear and biphasic uptake kinetics are observed, but have generally fallen in the range of 1–10 μM (Cochlan and Bronk,

2001; Lomas and Glibert, 2000). During an annual study of NO_3^- uptake kinetics in a coastal Mediterranean lagoon Collos et al. (Collos et al., 1997) observed a shift from classical uptake kinetics to linear kinetics as the population shifted from being dominated by the smaller diatom *Chaetoceros* spp. to dominace by the larger diatom *Thalassiosira*. It has been hypothesized that linear uptake rates are driven by an active uptake mechanism to fill storage vacuoles (Collos et al., 1997; Lomas and Glibert, 2000). Winter/spring diatom populations in Chesapeake and Delaware Bays, dominated by *Rhizoselenia* and *Skeletonema* displayed biphasic kinetic patterns (Lomas and Glibert, 1999) and this may be an adaptation to a patchy or sporadic nutrient supply (e.g., Serra et al., 1978). Cultures (Collos et al., 1982; Lomas and Glibert, 2000) and natural estuarine populations of flagellates and dinoflagellates (Fan et al., 2003b) have also been shown to display biphasic and linear uptake kinetics. Collos et al. (2005) have summarized all of the existing data on multiphasic NO_3^- uptake and present a very convincing argument that there is indeed some degree of half-saturation concentration acclimation to elevated ambient NO_3^- concentrations.

Because kinetic parameters are not simply due to the inherent capabilities of cells, but also reflect the physiological status and nutrient prehistory it is often difficult to relate kinetic measurements to growth rates in the field where these things are unknown at the time of sampling. Consequently, determination of intra- versus extracellular controls on uptake and the taxa-specific differences in uptake capabilities have come largely from culture studies, which lack the complexities of natural systems. For example, because cultured dinoflagellates have generally higher K_s values for DIN than diatoms, it is assumed that they are poor competitors under DIN-rich conditions (e.g., Smayda, 1997). But, this is not always observed in nature. Many organisms can modulate their internal nutrient quotas and their short-term nutrient uptake rates in response to external nutrient concentrations (Droop, 1973; Morel, 1987). Large differences in half-saturation concentrations for growth versus short-term uptake may allow organisms to be more competitive under a wider range of nutrient conditions. So, even though kinetic data provide useful snapshots of cellular capabilities in the field and meaningful ''yardsticks'' of taxa-specific capabilities in culture systems, it is important to keep in mind the limitations of these data for making broad inferences in natural systems.

There is little information on uptake kinetics for organic N compounds and what is available is largely from culture systems where growth conditions may be unrepresentative of natural systems (Antia et al., 1991). The kinetics of urea uptake have been examined in natural systems but K_s values vary widely. Low K_s values (<2 μM) were observed in a range of environments from the Ross Sea (Cochlan and Bronk, 2001), to the mid-Atlantic Neuse estuary experiencing a mixed dinoflagellate bloom (Fan et al., 2003a,b), to a northeastern US coastal bay experiencing a bloom of *Aureococcus anophagefferens* (Lomas et al., 1996), and a mixed autotrophic community from the Baltic Sea (Tamminen and Irmisch, 1996). Much higher K_s values (5 to >30 μM) were observed in natural populations dominated by *P. minimum* in the Choptank River estuary (Fan et al., 2003b) and in *Trichodesmium* spp. collected from the tropical North Atlantic Ocean (Mulholland and Capone, 1999). Cultures of *P. minimum* and *Trichodesmium* species had much lower K_s values for urea uptake.

Although the number of representative species is limited, the available data suggests that autotrophic phytoplankton have consistently lower K_m values for urease than do bacteria (cf. Fan *et al.*, 2003a; Jahns, 1992; Mobley and Hausinger, 1989; Syrett and Al-Houty, 1984). Interestingly, studies on urea biogeochemistry commonly observe that bacteria are predominantly urea regenerators and phytoplankton are predominantly urea consumers (e.g., Cho *et al.*, 1996a; McCarthy, 1972; Radach *et al.*, 1990; Remsen *et al.*, 1972a). One could pose the hypothesis that functional differences in the ureases of bacteria versus phytoplankton contribute to view that urea uptake is more common in phytoplankton than in bacteria. Similarly, the early kinetic observations of amino acid and DON uptake by phytoplankton may have contributed to the view that amino acid uptake is more common in bacteria than in phytoplankton. In some initial studies bacteria exhibited biphasic uptake kinetics with both a high affinity active uptake system and a low affinity diffusion transport mechanism. However, in early studies with microalgae only low affinity DOM uptake systems were observed (see Lewitus, 2006).

Uptake kinetics for dissolved free amino acids have been measured in culture systems for a variety of organisms and the observed kinetic parameters have been used to argue against significant amino acid uptake by phytoplankton in nature (Antia *et al.*, 1991). Efforts to describe amino acid uptake kinetics in nature have yielded confusing results. Populations dominated by *A. anophagefferens* and *Karenia brevis* did not exhibit Michaelis-Menten type kinetics for amino acids; rather high uptake rates were measured at low amino acid concentrations and uptake rates decreased with increasing amino acid concentrations (Bronk *et al.*, 2004; Mulholland *et al.*, 2002b). As for amino acids, K_s concentrations for bulk DOM uptake were higher for microalgae than bacteria and microalgae K_s concentrations of particular DOM components were higher than concentrations in nature suggesting that DOM uptake in nature was not significiant (see Lewitus, 2006). However, complex DOM uptake kinetics, including an active uptake system at low concentrations, have been described for *Chlaymdomonas* (Bennett and Hobbie, 1972 and for other microalgae (Flynn and Butler, 1986, Hellebust, 1978; Lewitus, 2006). Clearly, there is need to examine uptake kinetics for dissolved organic N compounds (particularly amino acids) more rigorously in nature.

4.3. Transient or surge uptake

Many cultured marine phytoplankton possess the capacity to take up N substrates at rates that far exceed instantaneous growth rates in nature and those predicted using simple Michaelis–Menten kinetics (McCarthy and Goldman, 1979; Glibert and Goldman, 1981; Collos, 1982). These short-lived 'transient' uptake phenomena are uncoupled from cellular growth and have been termed surge uptake to distinguish this from internally and externally controlled N uptake (Conway *et al.*, 1976; Goldman and Glibert, 1983). Enhanced N uptake capabilities appear to be induced by N limitation. Nitrogen perturbation experiments demonstrate that N-limited or starved cultures display surge uptake and that the pattern varies depending on the algal taxa, the N source, the duration of the starvation period, and the nutrient history prior to starvation (Cochlan and Harrison, 1991b; Collos, 1983, 1984; Dortch *et al.*,

1982, 1991b; Horrigan and McCarthy, 1982; Raimbault and Gentilhomme, 1990; Raimbault *et al.*, 1990). Further, N-starved cells appear to adjust their metabolism to retain the capacity to exploit nutrients when they are resupplied. N-starved phytoplankton had similar NH_4^+ uptake capacities as exponentially growing cells; however incorporation of this NH_4^+ into macromolecules was reduced under N-starvation (Kanda and Hattori, 1988). In exponentially growing cells, uptake is tightly coupled with growth and synthesis of cellular macromolecules. Uncoupling between nutrient uptake and growth is characteristic of nutrient stress and allows cells to prioritize nutrient acquisition so that they can recover and later translate this into growth. During an acclimation experiment, *Isochrysis galbana* cultures increased their uptake efficiency in response to a pulsed NH_4^+ delivery system (e.g., increasingly high and rapid uptake during pulses and decreased excretion of N between pulses; Gentilhomme and Rich, 2001).

Nutrient interactions also affect the capacity for surge uptake. For example, NH_4^+ can reduce the capacity for surge uptake of NO_3^- or urea (Horrigan and McCarthy, 1982). In addition, surge uptake can result in the release of primary metabolites (e.g., NH_4^+ release following surge uptake of urea; Price and Harrison, 1988a). It is intriguing to think of the physiological controls where excess N might be taken up only to be released again once the cell 'realizes' that it has indeed taken up more than it can metabolize.

5. Regulation of Nitrogen Uptake and Assimilation

What we know about the regulation of N uptake and assimilation has increased tremendously over the last two decades. A variety of factors regulating uptake and assimilation of N have long been recognized, however, recent advances in genomic and proteomic research have put these into a new context and have expanded our understanding of cellular regulation in general. For example, enzyme activity has been studied for decades but only recently have we begun to isolate genes and develop gene probes from marine phytoplankton and bacteria (see Zehr and Ward, 2002). Various mechanisms are involved in the regulation of enzyme proteins and gene expression and these include enzyme induction or repression, feedback regulation, post-translational modification and regulatory circuit control. For inducible enzymes, there is potential for using gene expression (presence or absence) or enzyme activity as markers for enzymatically mediated uptake and assimilation. However, interpreting results can be complicated because many genes are constitutively expressed or their expression and abundance are entrained in the cell cycle or other cellular rhythms (Chapter 32 by Berges and Mulholland, this volume; Herrero *et al.*, 2001; Hildebrand and Dahlin, 2000; Song and Ward, 2004). Many older studies can be reinterpreted given our current understanding of genes and gene expression. Induction of enzyme synthesis can be in response to depletion of an intracellular product pool or the availability of an inducer compound in the extracellular environment, such as an enzyme substrate. For example, *Dunaliella tertiolecta* NR transcription is induced

by NO_3^- and repressed by NH_4^+ but is not induced under N depletion (Song and Ward, 2004). The accumulation of intracellular product pools can result in the feedback inhibition of downstream processes such as uptake and assimilation. Post-translational modification of enzymes can regulate uptake and assimilation by modulating the number of active sites available for catalyzing specific reactions. Studies examining the transcriptional activation of enzymes involved in uptake and assimilation of N have begun to demonstrate clear functional relationships between genomes and ecological capabilities. For example, the presence of NH_4^+ (or a metabolic product of NH_4^+ assimilation) represses protein expression (i.e., enzymes) involved in the assimilation of alternative N sources (e.g., NO_3^- and N_2) in some organisms (e.g., Eppley, 1978; Eppley et al., 1969). However, this inhibition is not caused by the NH_4^+ itself, rather, through the feedback of some product of its incorporation through GS/GOGAT (e.g., a nitrogenous metabolite; Flores and Herrero, 1994) or possibly the intracellular balance of C and N (e.g., Flynn, 1991).

Nutrient preferences and interactions can also be described in the context of cellular N control systems. While enzyme systems are often shown to be regulated independently, regulatory systems wherein groups of enzymes are regulated in concert have been described for N control in microbes. Nitrogen control through the nitrogen regulatory system (Ntr) is well-characterized in enteric and some other proteobacteria. In the marine realm, N control is probably best described for cyanobacteria. In cyanobacteria N control consists of repression of selected N pathways when other, more easily assimilated or preferred N sources are available (Herrero et al., 2001). Nitrogen control in cyanobacteria is mediated by *ntcA*, a transcriptional regulator and so differs from the Ntr system, although there are some similarities (e.g., in the signal transduction protein) (Flores and Herrero, 2005; Herrero et al., 2001). The *ntcA* genes are thought to regulate genes associated with NO_3^- uptake (Lindell et al., 1998; Suzuki et al., 1995), N_2 fixation (Herrero et al., 2001), and urea uptake (Collier et al., 1999; Flores and Herrero, 2005; Rocap et al., 2003). The N control gene, *ntcA*, is widely distributed in many cyanobacteria (Frias et al., 1993) but not in all cyanobacteria (Garcia-Fernandez and Diez, 2004). There may be important species or strain-specific differences in the genes that are controlled as part of a regulatory system. For example, transcripts of the high affinity NH_4^+ transporter (*amt1*) and the transcriptional activator of genes involved in N metabolism (*ntcA*) were not correlated in axenic *Prochlorococcus* strain PCC 9511 suggesting that *amt1* is not N-regulated in this strain (Lindell et al., 2002) even though it appeared to be regulated by N in other strains of *Prochlorococcus* (Rocap et al., 2003). In addition, glutamate synthase and some urease enzymes do not appear to be under N control in some organisms (Herrero et al., 2001; Lomas, 2004b; Peers et al., 2000; Valladares et al., 2002).

Genes for a variety of other N transporters have now been identified (Dufresne et al., 2003; Hildebrand and Dahlin, 2000) and appear to be subject to different types of control (Hildebrand and Dahlin, 2000; Lindell et al., 2002; Sakamoto et al., 1999; Suzuki et al., 1995; Wang et al., 2000). In addition, groups of genes (forming operons) appear to be regulated in concert. For example, transporter-encoding genes for NO_3^- uptake in *Synechococcus* (Suzuki et al., 1995) are

clustered with the structural genes for NR and NiR. The entire operon is expressed only when NH_4^+ is not present in the growth medium with the presence of NO_3^- or NO_2^- apparently having an inducer effect (Herrero *et al.*, 2001). This is similar to the dual control of assimilatory NR in bacterial *ntr* systems (Lin and Stewart, 1998; Moreno-Vivián *et al.*, 1999). Nitrogenase genes have also been identified (*nif*) and are clustered together (Herrero *et al.*, 2001). Many enzyme sytems are subject to multiple levels of control. So, in addition to nitrogen regulation at the level of gene expression, there are also pathways responsible for post-translational regulation of enzyme systems that include modification, reversible inactivation, and short-term inhibition (Herrero *et al.*, 2001, see also Chapter 30 by Jenkins and Zehr, this volume).

5.1. Whole genome analyses

Most species of picoplanktonic marine cyanobacteria currently identified belong to two genera, *Synechococcus* and *Prochlorococcus*. Together, these groups are thought to comprise 20–40% of chlorophyll biomass and carbon fixation in the oceans (Partensky *et al.*, 1999). Genomic analyses of *Prochlorococcus* (Dufresne *et al.*, 2003, Rocap *et al.*, 2003) and *Synechococcus* (Palenik *et al.*, 2003) have revealed an extensive array of information on N utilization by these important genera and provide an excellent example of how genomic analysis can yield insights into ecological capabilities. Examining their genetic capabilities, *Synechococcus* strain WH8102 can use NH_4^+, NO_2^-, NO_3^-, urea, cyanate, amino acids and peptides; *Prochlorococccus* MIT9313 can use all except NO_3^- and cyanate; *Prochlorococccus* MED4 only NH_4^+, urea, cyanate and peptides; and *Prochlorococccus* SS120 only NH_4^+ and amino acids (Dufresne *et al.*, 2003; Fuhrman, 2003; Palenik *et al.*, 2003; Rocap *et al.*, 2003). Virtually all isolated marine *Synechococcus* strains except *Synechococcus* sp. MIT9220, isolated from the equatorial Pacific, are capable of using NO_3^- as an N source for growth (Scanlan and West, 2002). Even the strain that can't use NO_3^- as an N source can use NO_2^-, NH_4^+ and urea as N sources. It appears that during the evolution of *Prochlorococcus*, genes for NO_3^- / NO_2^- transport and reduction (NR and NiR) were lost while the genes for nitrite reductase were retained or reacquired in some cases and lost in others (Dufresne *et al.*, 2003; Garcia-Fernandez *et al.*, 2004; Rocap *et al.*, 2003).

It has been hypothesized that each *Prochlorococcus* ecotype uses the N species that is most prevalent at the light levels to which they are adapted; NH_4^+ in the surface waters and NO_2^- at depth (Rocap *et al.*, 2003). *Synechococcus* on the other hand has retained NR and so is able to bloom during NO_3^- upwelling events (Dufresne *et al.*, 2003; Glover *et al.*, 1988; Rocap *et al.*, 2003) and this may contribute to its relative abundance in coastal systems. For example, *Synechococcus* is usually less abundant than *Prochlorococcus* in extremely oligotrophic environments, where NO_3^- concentrations are generally below the limits of analytical detection, but has a broader global distribution (Palenik *et al.*, 2003; Scanlon and West, 2002). *Prochlorococcus* strains also appear less versatile in their ability to use DON than *Synechococcus* (Palenik *et al.*, 2003; Rocap *et al.*, 2003). The *Synechococcus* genome also contains amino acid and oligopeptide transporters as well as

cyanate transporters and cyanase (degradation enzyme) suggesting that these can also be used as N sources. In fact, *Synechococcus* strain WH8102 can grow in culture on cyanate as a sole N source although cyanate use in nature has not been characterized (Palenik *et al.*, 2003).

Thalassiosira pseudonana, a diatom, has a genome that encodes multiple transporters for NO_3^-, NH_4^+ and as well as putative genes for uptake and catabolism of organic N including amino acids, purines and urea (Armbrust *et al.*, 2004). Two major intermediates of the urea cycle, ornithine and arginine are integrated into cell metabolism (Armbrust *et al.*, 2004). Other N-regulated proteins have been identified on the cell surfaces of *Emiliania huxleyi* and these are present under N-limitation or during growth on urea (Palenik and Koke, 1995). As more genomes are analyzed, we will learn more and more about the genetic capabilities of phytoplankton taxa and groups. Yet while genetic information can be invaluable for determining ultimate capacity, experimental evidence is often lacking to demonstrate that particular genes are actually expressed and active.

6. What Does the Future Hold?

While our knowledge of the marine N cycle has certainly increased over the last two decades, much remains to be learned. The number of N uptake measurements has increased significantly as has the diversity of N compounds used in these studies, but our understanding of the spatial, temporal and biological variability of N uptake in nature remains limited. Perhaps our understanding of the controls on N uptake in natural systems is still hindered by a lack of adequate methods. We know that a variety of compounds are used simultaneously from uptake studies done on bulk communities and that these confound our ability to calculate f-ratios. Maybe the f-ratio is no longer a useful metric for estimating new production. We also know that there are inherent differences in the capabilities of organisms and their flexibility in acquiring N from forms available in the environment, but know little about cell-specific and taxa-specific uptake of particular N substrates.

We've just begun to scratch the surface of answering questions regarding the 'preferences' of particular microbes for different N substrates in their natural environment by applying single-cell technologies (e.g., micro-FISH, CARD-FISH and flow cytometry) to N cycling studies (see also Chapter 31 by Lipschultz, this volume). For example, flow cytometric sorting has been shown to be effective for directly assessing assimilation of a variety of nutrients by marine phytoplankton versus bacteria in natural water samples (e.g., Boneillo *et al.*, unpublished data; Casey *et al.*, 2007; Zubkov and Tarran, 2005; Zubkov *et al.*, 2001, 2003, 2004; see Table 7.3). Flow cytometric sorting protocols have traditionally used inherent pigment signatures and DNA stains to separate populations and enable inferences between broad phylogenetic groups. However, these are general markers and do not allow one to investigate diversity and functions within broad phylogenetic categories such as bacteria and picoeukaryotes (e.g., Worden, 2006; Worden *et al.*, 2004).

With the advance of new molecular methods that combine the genetic specificity of FISH techniques with tyramide signal amplication (CARD-FISH), we can use flow cytometry to assess N uptake by phylogenetically distinct populations of bacteria (e.g., Pernthaler et al., 2002a,b; Sekar et al., 2004) and picoautotrophs (e.g,. Biegala et al., 2003; Pernthaler et al., 2003). Now the primary limitation to these studies has shifted to the choice of isotopic tracer. Obviously ^{15}N is the tracer of choice for N uptake studies, but this is a stable isotope and therefore requires substantial masses for sample analysis. For example, to study N uptake by a bacterial clade that comprises 10% of the total oceanic bacterial community, one would need to sort ~10 L of seawater to get ~4 µg N sample to analyze. Even with a high-speed cell sorter, without some form of concentration protocol (e.g., Casey et al., 2007), this is not practical. Radioisotope tracers improve sensitivity but then one must assume some stoichiometric conversion to units of N. Although still in their infancy these new methods have promise for the study of bacteria and phytoplankton physiology in mixed assemblages and are a vast improvement over crude size-fractionation techniques.

These new methods are particularly useful for the study of microbial groups that are not amenable to culturing. For example, many taxa, particularly many known mixotrophs, are difficult to culture or do not grow well in unialgal cultures, suggesting that some sort of mutualism exists between certain phytoplankton and associated bacterial assemblages (e.g., Doucette, 1995; Rooney-Varga et al., 2005). Application of new techniques will be necessary to provide direct evidence for nutritional linkages and flows of N between microbial consortia and groups. Moreover, the degree to which mixotrophy occurs in the environment is relevant for ocean biogeochemical models, which commonly parameterize heterotrophic and autotrophic organisms separately and into several ecologically functional groups (e.g., N_2 fixers, cyanobacteria, picoeukaryotes) based on what is known about their physiology. Much of what is known about algal physiology arises from culture studies that fail to represent the complexities characterizing biologically-mediated elemental cycling in natural systems.

The natural environment is undergoing significant and important changes. We have seen the anthropogenic increase in atmospheric carbon dioxide (CO_2) translate into increases in the CO_2 concentrations in the surface ocean (Bates, 2001) with an associated decrease in ocean pH. It has been hypothesized that elevated pCO_2 may impair the competitive ability of coccolithorids (Tortell et al., 2002); a very important species with respect to N cycling globally, or differentially impact phytoplankton growth rates, even within the same taxonomic group (e.g., diatoms; Kim et al., 2006). It has also been hypothesized that the shift to a high CO_2/low pH ocean, may significantly affect N cycling in anticipated and unanticipated ways such as the balance between nitrification/denitrification (Huesemann et al., 2002) and N inputs due to N_2 fixation (Hutchins et al., 2007). Another change, closer to home for those of us living in coastal communities, is a shift in forms of N being released into coastal systems. The past few decades have seen a significant change from inorganic nutrient loading to organic nutrient loading (Chapter 11 by Paerl and Piehler, this volume), and it has been suggested that this change in the primary N agents leading to eutrophication may be selecting for harmful and nuisance algal species (e.g.,

Anderson *et al.*, 2002). However, much work remains to verify this observation across a range of environments. For example, harmful algal blooms also occur in upwelling systems (Kudela *et al.*, 2005) where there is abundant NO_3^-.

The marine N cycle is exciting and over the past two decades, since the first edition of Nitrogen in the Marine Environment, there has been an explosion in our knowledge of temporal and spatial variability of N assimilation as well as a broader appreciation for the N substrates that are assimilated. With new methods in hand and an environment changing at unprecedented rates in response to anthropogenic forcing, the next two decades will also be exciting as we further explore the physiological plasticity of microbial populations and directly test ecological hypotheses in the environment.

1. INTRODUCTION

Primary producers in oceanic surface waters have the chemical characteristics of healthy robust cells in regions where the concentrations of dissolved inorganic nitrogen (DIN) is often below the limit of detection (i.e., 0.03 μM). This apparent paradox is possible because of the process of nitrogen (N) regeneration and its tight coupling to N uptake. The objectives of this chapter are to review the forms and sources of regenerated N, both inorganic and organic, to describe the various processes that result in N regeneration and to survey N regeneration rates in

estuarine, coastal, and open ocean systems. The focus of the chapter is on water column N regeneration. Sediments are discussed from the perspective that they serve as a source of N to the water column. The chapter concludes with a brief survey of methods and recommendations for future research.

2. Types of Regenerated Nitrogen

Nitrogen is regenerated in both inorganic and organic forms. The inorganic forms include ammonium (NH_4^+), nitrate (NO_3^-), and nitrite (NO_2^-). Organic forms include urea, dissolved free amino acids (DFAA), nucleic acids, and a broad suite of dissolved combined amino acids (DCAA) and proteins, as well as other largely unidentified components of the dissolved organic nitrogen (DON) pool including enzymes (Chapter 3 by Aluwihare and Meador, this volume).

2.1. Inorganic

Ammonium is released during bacterial remineralization of dissolved organic matter (DOM) in the water column (e.g., Goldman *et al.*, 1987) and in sediments (Chapter 19 by Joye and Anderson, this volume), is an excretory product of zooplankton (Chapter 26 by Steinberg and Saba, this volume), and can be produced during the photochemical breakdown of DOM (Chapter 10 by Gryzbowski and Tranvik, this volume). The most prevalent oxidized form of inorganic N, NO_3^-, is the end product of nitrification ($NH_4^+ \rightarrow NO_2^- \rightarrow NO_3^-$; Chapter 5 by Ward, this volume). The other oxidized form, NO_2^- is produced as an intermediate during the process of nitrification and denitrification ($NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$; Chapter 6 by Devol, this volume). Nitrite is also released photochemically from the reduction of NO_3^- (Zafiriou and True, 1979).

Vertical profiles of NH_4^+ are generally highly variable due to the large number of processes that can produce and consume NH_4^+. In contrast, the classic water column nutrient profile, low concentrations in surface water and higher concentrations at depth, is epitomized by NO_3^-. The NO_3^- is incorporated into particulate organic matter (POM) in surface waters, driving the concentration to near zero. As POM sinks through the water column, the N is remineralized to NH_4^+, which is ultimately nitrified to NO_3^-. As a result, concentrations of NO_3^- in the deep ocean are many times higher (i.e., >30 µM) than those commonly observed in surface waters. Profiles of NO_2^- concentrations often have subsurface maxima generally the result of phytoplankton excretion or an imbalance between NH_4^+ oxidation and NO_2^- oxidation (Lomas and Lipschultz, 2006; Chapter 5 by Ward, this volume). This review will focus on regeneration of reduced N (NH_4^+ and DON) and readers are directed to the other chapters noted above for information on the cycling of NO_3^- and NO_2^-.

2.2. Organic

Of the organic forms, urea and DFAA have received the most attention. Urea is an excretory product of zooplankton and fish. Bacteria also release it during the degradation of some N compounds, such as purines (Jørgensen, 2006).

Concentrations of urea in marine systems tend to be less than 1 μM in most systems though in some circumstances much higher concentrations have been observed (e.g., 10 μM in the Resolute Passage, Conover *et al.*, 1999). DFAAs are produced intracellularly by phytoplankton and bacteria and are released during such processes as bactivory and grazing. Concentrations of DFAA tend to be lower than urea at less than 0.5 μM (Bronk, 2002).

The nucleic acid pool is composed of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Viruses, which are basically little packets of DNA, are so small that they are not removed by standard filtration. As a result, a significant fraction of the measured nucleic acid pool is composed of DNA contained within viruses. Accordingly, the DNA pool can be divided into three fractions—free or enzymatically hydrolysable dissolved DNA (ehD-DNA), dissolved DNA (D-DNA) within viruses, and uncharacterized bound DNA (Brum, 2005; Jiang and Paul, 1995). In the North Pacific Subtropical gyre 49–63% of the measured total D-DNA is contained within viruses with the remainder found within the ehD-DNA fraction (Brum, 2005). In the Gulf of Mexico, however, only 8–15% of D-DNA is found within viruses, 50% is in the ehD-DNA fraction, and 35–42% is in the unidentified bound fraction (Jiang and Paul, 1995). Turnover times of the ehD-DNA pool are likely shorter than those of the D-DNA bound in viruses, which is protected to some extent from hydrolytic enzyme activity (Siuda and Chrost, 2000; Weinbauer *et al.*, 1993). Proteins and DCAA are also produced by phytoplankton and bacteria and are likely released during processes that destroy cells such as grazing and viral infection and lysis. Another organic N fraction is composed of the extracellular enzymes that are released primarily by bacteria and function to break down DOM into smaller moieties that can then be taken up (Chapter 32 by Berges and Mulholland, this volume). In one bacterial culture study, the bacteria *Psuedoalteromonas atlantica* produced a wide array of extracellular enzymes, some of which retained activity for as long as 15 days after secretion (Hoffman and Decho, 2000).

3. Sources of Regenerated Nitrogen

Biological sources of N include: direct release, either active or passive, from phytoplankton, N_2 fixers, bacteria, and macroalgae (Branch and Griffiths, 1988; Mann, 1982); viral infection and subsequent lysis of both autotrophs and heterotrophs; fecal pellet dissolution, excretion, and grazing (i.e., feeding on phytoplankton) or bactivory (i.e., feeding on bacteria) by micro- and macrozooplankton and other macroorganisms (Tupas and Koike, 1990); and release from corals, detritus, and sediments. At any given time, many processes likely contribute to release. As a result, the magnitude of the different release processes is difficult to quantify and teasing them apart is an active area of ongoing research.

3.1. Phytoplankton

Nitrogen release from phytoplankton can occur two ways. First is direct release, which includes active release, often termed exudation, or passive diffusion from the cell (Fogg, 1983). The second is mediated release, where the release occurs when phytoplankton

cells are grazed, commonly called "sloppy feeding" (e.g., Lampert, 1978; Møller, 2007), or infected with a virus, the final stage of which results in cell rupture (e.g., Bratbak et al., 1993; Fuhrman, 1999; Gobler et al., 1997; Murray, 1995; Suttle, 1994).

3.1.1. Active and passive models of direct release

Two models have been proposed to account for direct release of N from cells—the active release outflow model (Fogg, 1966) and the passive diffusion model (Bjørnsen, 1988; Bratbak and Thingstad, 1985; Fogg, 1966). The outflow model is a viable explanation for DOC release but is unsatisfying as an explanation for release of DON. In the outflow model, release results when excess photosynthates accumulate within the cell when carbon (C) fixation exceeds assimilation as a result of nutrient limitation (Fogg, 1983; reviewed in Carlson, 2002). The cell dumps the C because it does not have the N available to make cellular constituents such as proteins or enzymes. This apparent excess of DOC, relative to DON production, has been observed in a number of environments (e.g., Alvarez-Salgado et al., 1999; Doval et al., 1997; Søndergaard et al., 2000; Williams, 1995). It is highly unlikely that cells would have an excess of N over C, however, so there is no similar rationale for dumping N. Murray (1995) used a modeling approach to suggest that direct DOM release can be a cost-effective, indirect means of reducing viral infection in phytoplankton. By releasing DOM the phytoplankton are supporting bacterial populations that can kill viruses, which the bacteria contact with much greater frequency than phytoplankton because of their small size. If DOM release can facilitate a decrease in the number of viruses able to infect phytoplankton, than the cost of the release may be energy well spent.

In the passive diffusion model, low molecular weight (LMW) compounds diffuse through the cell membrane as a result of the large concentration gradient between internal (i.e., mM) and external (i.e., nM to μM) N pools. Passive release likely varies based on physiological stress, exposure to UV radiation, and changes in temperature or light levels. One theory suggests that bacteria are ectoparasites on phytoplankton by taking up DOM, which keeps the concentration of extracellular DOM low resulting in a larger concentration gradient between organic pools inside and outside of the cell (Bjørnsen, 1988). If this theory is correct, smaller cells should have higher release rates per unit biomass, relative to larger cells, because they have a larger surface to volume ratio. In one ^{15}N study, Hasegawa et al. (2000a) found that smaller plankton did indeed release more DON compared to larger cells.

3.1.2. Magnitude of direct release

The magnitude of direct release has been a topic of much debate (Bronk and Ward, 2000; Bronk et al., 1994; Slawyk et al., 1998; Slawyk et al., 2000). A similar debate took place around DOC release in the 1960s and 1970s (Sharp, 1977). Cultures are the tool of choice for the study of direct release because they remove the effect of other trophic levels, such as grazing or, under axenic conditions, bacteria (reviewed in Antia et al., 1991; Bronk and Flynn, 2006). Nitrogen release has been studied extensively in culture and there is abundant literature on uptake and release, particularly of DON, from work done in the 1950s–1970s (reviewed in Antia

et al., 1991). On average, 19.3 ± 16.2% of gross N uptake of a number of different substrates is released as DON in the culture work reviewed in Table 8.1. This percent release is generally lower than the mean percent release observed in the field and discussed later in the chapter, which suggest the other trophic levels (i.e., grazers) are important in release of DON. From cultures we know that direct release is generally highest immediately after cells are transferred to new media (Collos *et al.*, 1992; Jones and Stewart, 1969; Slawyk and Raimbault, 1995). If the increased direct release is a response to a change in environmental conditions, and not a result of stress during transfer, then the amount of extracellular release in the ever-changing natural environment may be much higher than indicated by long-term culture studies (e.g., Bronk, 1999).

Direct release also likely changes at different phases of the cell cycle—exponential, stationary, and senescent. One common observation in cultures is an increase in direct release during senescence. For example, the highest rates of DCAA release occur during stationary phase while release during active growth is low (Flynn and Berry, 1999). The decline of phytoplankton blooms is another time period characterized by significant DOM release from phytoplankton due to such processes as cell stress or death, high rates of viral infection, or high grazing pressure (e.g., Carlson *et al.*, 1994; Jenkinson and Biddanda, 1995). There seems to be a pattern of low rates of release in actively growing cells, such as those found at the beginning of a bloom, and high rates of release when cells are stressed by nutrient limitation, light inhibition, etc., such as at the end of a bloom (Larsson and Hagström, 1979).

Nutrient status would also likely affect measured release rates and here the reverse trend is seen. *Scenedesmus quadricauda* cultures grown under N–replete conditions had higher DON release rates than cultures that had been grown under N–limited conditions suggesting that cells may suppress release to meet their cellular N demand (Nagao and Miyazaki, 2002). They also found evidence that *Scenedesmus quadricauda* released more of the DON that was stored intracellularly prior to the substrate addition than the other culture tested, *Microcystis novacekii*. In a suite of different batch cultures most DOM production occurred during nutrient replete growth (Biddanda and Benner, 1997). In another study with batch cultures of the cyano–bacterium *Synechococcus,* DOC release increased when cells went from N sufficient to N deficient conditions (Bronk, 1999). In contrast, DON release measured using ^{15}N tracers and short-term incubations of subsamples of the culture, was highest when cells were N sufficient as was the percentage of NH_4^+ uptake released as DON (Bronk, 1999). When NH_4^+ concentrations fell below the level of detection, release rates decreased by a factor of four to seven (Bronk, 1999), consistent with Biddanda and Benner (1997).

When considering release under N-limited conditions it is important to remember that the commonly measured DON release rates are net rates such that reincorporation of recently released DON would result in an underestimate of the true DON release rate. Many phytoplankters can use organic N to fulfill their nutritional requirements such that reincorporation is likely, particularly under N-limiting conditions (reviewed in Bronk *et al.*, 2007). An example of this was seen in a culture study with *Alexandrium catenella* where DON release was observed early in the

Table 8.1 The percentage of gross nitrogen (N) uptake released as dissolved organic nitrogen (DON) or dissolved free or combined amino acids (DFAA, DCAA) measured using changes in concentrations (CC) or ^{15}N techniques (^{15}N) where the DON was isolated with ion retardation columns (IRC) or wet chemical (WC) methods

Culture	Substrate	N Form Released	N Release: Gross N uptake (%)	Method	Reference

[a] Percent release equals release divided by uptake + DCAA release + DFAA release; the uptake rate was calculated as the increase in algal N over the first day.
[b] Cells preserved with formalin prior to filtering.
[c] Mean in light 3 h incubations.
[d] Calculated by converting the change in DON concentrations over 14 days into a per hour rate.
[e] Estimated using ^{15}N mass balance not actual uptake and release rates.
[f] When both DFAA and DCAA release was measured the two rates were combined in calculating the mean % release.
Data are presented as the mean $\pm$ standard deviation. When ranges are presented, the mean % release was calculated using the median value in the range; the standard deviation was calculated by propogating the available error terms.

culture but DON reincorporation was measured later in the experiment (Collos et al., 2004).

3.1.3. Programmed cell death

Death and subsequent lysis of phytoplankton cells can result from attack by viruses (e.g., Brussaard, 2004; Proctor and Fuhrman, 1990) or attack by fungi or other parasites (e.g., Holfeld, 1998). These processes result in the cells bursting open and releasing their cellular contents; viral release will be covered in more detail in a later section of this chapter. Another more direct form of release that is gaining attention in oceanography is programmed cell death (PCD), also known as autocatalytic cell death. Bidle and Falkowski (2004) define PCD as a form of autocatalytic cell suicide in which an endogenous biochemical pathway leads to morphological changes and ultimately, cellular dissolution. Proteases exist within cells or at the cells' surface and perform a number of functions including metabolic regulation through enzyme degradation and protein breakdown. Actual cell lysis is believed to involve a caspace-like compound. Programmed cell death can occur due to advanced age or in response to environmental stress such as nutrient deprivation, exposure to intense light (e.g., Llabrés and Agusti, 2006) or excessive salt concentrations or oxidation stress (Bidle and Falkowski, 2004).

There have been a number of studies that provide evidence that PCD occurs in cultures including cultures of the diatom *Ditylum brightwellii* in response to N and phosphorus (P) limitation (Brussaard et al., 1997), in N-depleted *Thalassiosira weissflogii* (Berges and Falkowski, 1996), in *Peridinium gatunese* in response to CO_2 limitation (Vardi et al., 1999), in *Dunaliella tertiolecta* in response to light deprivation (Segovia et al., 2003), in *Trichodesmium* IMS101 in response to P and iron starvation and excess light (Berman-Frank et al., 2004), and in freshwater *Anabaena* spp. in response to osmotic stress (Ning et al., 2002).

Though PCD no doubt occurs, it is a challenge methodologically to quantify it independent of other processes like viral infection. It is important to quantify the contribution of PCD to DOM release, however, because different routes of cell lysis likely generate DOM of different lability. If a cell lyses from viral infection, DOM within the host cell is shunted towards the production of more viruses until the cell eventually bursts. In PCD, however, the cell is lysed via the action of proteolytic enzymes resulting in DOM and enzymes entering the environment. From a bacteria's perspective, the DOM around cells that had lysed via PCD would likely be more labile and of better quality than around cells that had burst due to viral infection. One approach to quantifying PCD is to measure the concentration of cytoplasmic esterases (Brussaard et al., 1995; van Boekel et al., 1992) and then to make the following assumptions: (1) esterases enter the water during lysis, (2) only phytoplankton release substantial levels of esterases (Agusti et al., 1998), and (3) grazing processes, such as sloppy feeding, do not result in esterase release. The last of these assumptions seems unlikely and there has been considerable debate as to how to quantify the many assumptions (Agusti and Duarte, 2002; Riegman et al., 2002). Although there may be reason to question the exact magnitude of the rates measured, the general patterns in lysis rates discussed below appear robust.

In the northwestern Mediterranean Sea, rates of phytoplankton lysis were highest at the surface and declined sharply with depth. Lysis rates ranged from 0.026 day^{-1} to 1.0 day^{-1} such that lysis rates were $\sim$50% of the gross phytoplankton growth rate at the surface but only 7% at the deep chlorophyll maximum (Agusti *et al.*, 1998). Another study in the northwestern Mediterranean found that phytoplankton cell lysis was highest in the summer (0.41 $\pm$ 0.049 day^{-1}) and lowest in the winter (0.061 $\pm$ 0.005 day^{-1}) with rates strongly correlated with temperature ($r^2 = 0.71$, $p < 0.00001$, Agusti and Duarte, 2000). There was also a one to two month lag between maximum average monthly gross primary production and the maximum average lysis rate (Agusti and Duarte, 2000). Brussaard *et al.* (1995) estimated that 75% of phytoplankton death during the crash of the spring bloom in the North Sea was due to lysis although it was relatively low at other times of the year. The current understanding is that lysis rates can be high, particularly when sinking rates and grazing rates are low. If cells do not rapidly sink or are grazed their extended time in the water column provides greater opportunity for viral attack or to be confronted by some other negative environmental variable.

3.1.4. Mediated release

Sloppy feeding, by zooplankton, and viral infection, with eventual cell rupture, are two important processes that can result in N regeneration (discussed in more detail in Sections 3.4 and 3.5). Though the classic example of sloppy feeding is a diatom being fed on by a copepod, the importance of sloppy feeding by smaller heterotrophic flagellates has also been suggested in a number of studies (e.g., Glibert, 1998; Legendre and Rassoulzadegan, 1995; Varela *et al.*, 2003a). DON release mediated by copepods increased when cells were N-limited, suggesting a possible additive effect of direct release by N stress and mediated release via grazing (Miller and Glibert, 1998). In a culture study with *Scenedesmus quadricauda* and *Microcystis novacekii*, however, only minimal DON release was observed when cells were N-limited (Nagao and Miyazaki, 2002). A similar observation was made during a culture study with two clones of marine *Synechococcus* (Bronk, 1999); rates of DON release, as well as the percentage of NH_4^+ uptake released as DON decreased when the cells entered N-limitation. In the case of viral infection, the phage can increase to such numbers within the cell that they burst the cell. In the process, they release any dissolved intracellular components into the environment.

3.1.5. Other release mechanisms

Direct release can also include release due to osmotic changes. Organisms are generally adapted to a fairly narrow salinity range. When cells are outside of that range some can protect themselves through the synthesis and accumulation of osmoprotective compounds, some of which contain N such as glycine betaine (e.g., Keller *et al.*, 1999). Phytoplankton can also release reduced organic (dissolved primary amines, DPA) and inorganic N (NH_4^+ or NO_2^-) as a protective mechanism against high light levels (Lomas and Glibert, 1999, see Section 5.2.3 below). Another understudied form of release is the lysis of protoplasm during spermatogenesis brought on by N starvation (Sakshaug and Holm-Hansen, 1977).

Ammonification is another process that can result in N release. The simplest definition of the process is the release of NH_4^+ from organic matter (e.g., Herbert, 1999). It can occur by a number of different processes including remineralization by bacteria in the water column and sediments. Photochemical ammonification occurs abiotically when NH_4^+ is released from organic matter as a result of exposure to UV radiation (reviewed in Bronk, 2002 and Chapter 10 by Gryzbowski and Tranvik, this volume). Ammonium efflux from cells has also been observed following urea uptake in a number of culture experiments (e.g., Price and Harrison, 1988; Rees and Bekheet, 1982; Uchida, 1976). The release may be due to passive diffusion through the cell membrane and is likely unavoidable because NH_3 is lipid soluble.

3.1.6. Release by different phytoplankton groups

In the field, cells that possess large intracellular vacuoles might be expected to be particularly important in dissolved N release but the reverse is often observed. As noted above, in a ^{15}N study, smaller phytoplankton cells released more $DO^{15}N$ than larger cells (Hasegawa et al., 2000a). In upwelling regions of the central Atlantic dominated by large phytoplankton (>2 μm) the percent of total N uptake released as DON was $<30\%$ (Varela et al., 2005). In oligotrophic regions dominated by smaller phytoplankton, however, the percent of total N released as DON was often $>50\%$, although it was highly variable (Varela et al., 2005). In another study, low rates of DON release occurred where small cells (<2 μm) dominated total biomass and primary production (Varela et al., 2003a). However, the highest DON release rates were measured when smaller cells contributed more to total biomass than to primary production. The smaller cells were largely flagellates that, due to the small contribution this size class made to primary production, were likely heterotrophs. As such, they would have likely contributed to DON release via direct release, enhanced by their small surface to volume ratio, as well as via sloppy feeding.

One group of algae that has received considerable attention is the colonial, mat-forming diatom *Rhizosolenia* (Villareal et al., 1993). *Rhizosolenia* persist in oligotrophic regions generally dominated by small picoplankton. They persist in these regions because of their ability to migrate vertically into the nitracline where they fill large internal vacuoles with NO_3^- (Villareal et al., 1999). Higher C:N and carbohydrate to protein ratios have been observed in negatively buoyant mats suggesting that cellular N levels play a role in buoyancy (Villareal et al., 1996). Once at the surface, the cells can release NO_3^-, NO_2^-, NH_4^+ and presumably DON directly or when grazed during sloppy feeding. Rates of inorganic N release were measured in vertically migrating mats collected in the oligotrophic North Pacific gyre. Average rates of release were 27.1 ± 8.3 and 3.6 ± 1.9 nmol N (μg Chl a)$^{-1}$ h^{-1} for NO_3^- and NH_4^+ respectively (Singler and Villareal, 2005); the magnitude of DON release in the ocean via this mechanism has yet to be quantified. It has been estimated that the equivalent of 3–35% of the new NO_3^- consumed in the surface mixed layer in the central Pacific gyre could be transported via this vertical migration (Villareal et al., 1996). A number of other large phytoplankton may employ similar vertical migrations as part of their N acquisition strategies

including the dinoflagellate *Pyrocystis* and the diatom *Ethmodiscus* (Villareal and Lipschultz, 1995; Villareal *et al.*, 1996).

3.2. N₂ fixers

Estimates of N_2 fixation rates in the global ocean continue to rise as results emerge from studies with the main N_2 fixer in the ocean *Trichodesmium*, the heterocystous endosymbiont *Richelia*, as well as more recently discovered N_2 fixers including unicellular diazotrophic cyanobacteria and bacterioplankton (Capone *et al.*, 1997; Hansell and Feely 2000; Karl *et al.*, 1997; Lipschultz and Owens, 1996; Montoya *et al.*, 2004; Zehr *et al.*, 1998 and 2001). *Trichodesmium* is involved in N release directly, through release of amino acids, DON, and NH_4^+ (reviewed in Table 8.2). *Trichodesmium* is also a source of NH_4^+ and DON as a result of remineralization by associated bacteria, sloppy feeding and excretion by grazers (Sellner, 1992; Sheridan *et al.*, 2002).

In natural populations of *Trichodesmium* up to 50% of the recently fixed N_2 is released directly as DON during growth (Glibert and Bronk, 1994), primarily as DFAA (Capone *et al.*, 1994). Other evidence for N release by *Trichodesmium* in the field includes high concentrations of NH_4^+, NO_3^-, and DON seen within *Trichodesmium* blooms at the subtropical North Pacific station ALOHA (Karl *et al.*, 1992; Letelier and Karl, 1996). In natural populations from the Caribbean Sea and cultured populations of *Trichodesmium* NIBB1067, lysogenic phages have been identified that can infect cells resulting in lysis and the release of cellular contents (Ohki, 1999). An estimated 0.3–6.5% of *Trichodesmium* trichomes were lysed by viruses per day in the Tropical North Pacific Ocean (Hewson *et al.*, 2004). This viral lysis estimate translates to an estimated N release rate between 3 and 65% of *Trichodesmium* production. An estimated 0.32–15 nmol colony^{-1} h^{-1} was released due to peptidase and b–glucosamidase activity associated with bacteria residing among *Trichodesmium* colonies in the subtropical Atlantic Ocean (Nausch, 1996). *Trichodesmium* appears to have few grazers. One exception is the copepod *Macrosetella gracilis*, which regularly associates with and consumes *Trichodesmium* colonies, releasing NH_4^+ (and likely DON) through excretion and sloppy feeding to surface waters where *Trichodesmium* occur (O'Neil and Roman, 1992; O'Neil *et al.*, 1996). *Trichodesmium* is also known to migrate vertically (up to 70 m) in the water column, using carbohydrate ballasting, as a means of acquiring P deeper in the water column (Villareal and Carpenter, 2003). The recent discovery of many unicellular N_2 fixers raises interesting questions about the fate of the recently fixed N_2 by the group. If the smaller unicellular forms can be grazed, then the fate of the N from unicellular N_2 fixers may be very different from that of the large colonial forms (Montoya *et al.*, 2004).

Two other N_2 fixers that have been studied are *Aphanizomenon* and *Nodularia*. In a study in the Baltic, $7.7 \pm 2.1\%$ and $6.7 \pm 2.1\%$ of the $^{15}N_2$ gas recently fixed by *Aphanizomenon* and *Nodularia* respectively appeared in the picoplankton fraction, which indicates N_2 fixation and subsequent N release and reincorporation.

Table 8.2 Summary of published rates of ammonium (NH_4^+) regeneration and dissolved organic nitrogen (DON) release from N_2 fixers in the field in the light. The standard deviations were calculated using propogation of error.

Organism	Location	Date/ Culture	Rate Measured	N release rate pmol N colony^{-1}h^{-1}	N release: N_2 fixation (%)	Reference
Trichodesmium thiebautii	Caribbean	Sept 1991	$N_2 \rightarrow$ glutamate (light)[a]	88 ± 112	34 ± 38	Capone *et al.* (1994)
Trichodesmium thiebautii	Caribbean	Sept 1991	$N_2 \rightarrow$ glutamate (dark)[a]	30 ± 21	3 ± 1	Capone *et al.* (1994)
Trichodesmium thiebautii	Caribbean	Sept 1991	$N_2 \rightarrow$ glutamine (light)[a]	18 ± 29	10 ± 17	Capone *et al.* (1994)
Trichodesmium thiebautii	Caribbean	Jan 1992	$N_2 \rightarrow$ glutamate (light)[a]	73 ± 49	44 ± 40	Capone *et al.* (1994)
Trichodesmium thiebautii	Caribbean	Jan 1992	$N_2 \rightarrow$ glutamine (light)[a]	32 ± 67	12 ± 10	Capone *et al.* (1994)
Trichodesmium thiebautii	Caribbean	Jan 1992	$^{15}N_2 \rightarrow$ DON	114 ± 148	44 ± 32	Glibert and Bronk (1994)
Trichodesmium thiebautii	Caribbean	Jan 1992	$^{15}N_2 \rightarrow$ LMW DON[b]	63 ± 81	25 ± 16	Glibert and Bronk (1994)
Trichodesmium sp.	Gulf of Mexico	July 2001 and 2002	$^{15}N_2 \rightarrow$ Total N[c]	515 ± 348	52 ± 22	Mulholland *et al.* (2006)
Trichodesmium sp.	Gulf of Mexico	June 2003	$^{15}N_2 \rightarrow$ Total N[c]	364 ± 201	40 ± 18	Mulholland *et al.* (2006)
Trichodesmium sp.	Gulf of Mexico	Nov 2003	$^{15}N_2 \rightarrow$ Total N[c]	680 ± 450	51 ± 30	Mulholland *et al.* (2006)
Trichodesmium sp.	Gulf of Mexico	June 2003	$^{15}N_2 \rightarrow NH_4^+$[d]	154 ± 143	37 ± 57	Mulholland *et al.* (2006)
Trichodesmium sp.	Gulf of Mexico	Nov 2003	$^{15}N_2 \rightarrow NH_4^+$[d]	155 ± 87	75 ± 34	Mulholland *et al.* (2006)

[a] Rates were determined by net changes in dissolved free amino acid concentrations as determined with HPLC.
[b] The sample was passed through a Centriprep ultrafilter with a 10,000 MW cutoff.
[c] Total release, including DON and NH_4^+ release, was estimated as the difference between gross acetylene reduction and net $^{15}N_2$ uptake.
[d] Release of NH_4^+ was measured with ^{15}N isotope dilution.

3.3. Bacteria

Bacteria contribute to NH_4^+ regeneration and DON release during remineraliza-tion of POM (e.g., Smith *et al.*, 1992), by bactivory or as a result of viral lysis (e.g., Alonso *et al.*, 2000). It has also been suggested that bacteria can release ammonia (NH_3) via simple diffusion because intracellular concentrations are so much higher than extracellular concentrations (Hoch *et al.*, 1992). Considering the controversy over the percentage of bacteria that are actively growing (e.g., Smith and del Giorgio, 2003), the role of bacteria in NH_4^+ regeneration is still largely unknown.

With respect to NH_4^+ regeneration, bacteria differ from phytoplankton in that bacteria can serve as both sources and sinks. Whether bacteria are a source or a sink for NH_4^+ depends on their nutritional state, the availability and quality of N substrates (e.g., C:N ratio), and their gross growth efficiency (Goldman and Dennett, 1991; Goldman *et al.*, 1987; Jørgensen *et al.*, 1993). When the C:N ratio of bacteria is greater than the C:N ratio of the substrate, bacteria will regenerate NH_4^+ (Billen, 1984; Goldman *et al.*, 1987). With a bacterial C:N ratio of 4–5 (Goldman and Dennett, 1991) this means that bacteria would only regenerate NH_4^+ when they were consuming very low C:N substrates such as amino acids or peptides (e.g., Kirchman *et al.*, 1989, 1990). Kirchman *et al.* suggest that NH_4^+ utilization may be repressed by amino acid uptake. In this way bacteria also differ from other heterotrophs, such as protozoa, which rely on particulates and so are only a source of dissolved N, not a sink (Kirchman, 2000). The role of bacteria in N regeneration can be described by a simple model (Parnas, 1975).

According to this model, the rate of N excretion (E_N) is:

$$E_N = C_T \frac{1}{C{:}N_S} - \frac{GGE}{C{:}N_B \times 1000} \qquad (8.1)$$

with C_T ($= C_B + C_R$) where C_B is the C that goes into biomass and C_R is the C that is respired. $C{:}N_S$ and $C{:}N_B$ are the C:N ratios of the organic substrate and a bacteria cell respectively and GGE is gross growth efficiency (= $C_B C_T^{-1} \times 100$, Goldman *et al.*, 1987). When E_N is positive, N is excreted. When E_N is negative, net N is consumed. The relationship between bacterial growth efficiency and the C:N ratio of a substrate is given in Fig. 8.1 and described in detail in Kirchman (2000). In the range of growth efficiencies and $C{:}N_S$ ratios likely found in nature, the model predicts that bacteria should excrete NH_4^+. Based on a suite of culture experiments, however, Goldman *et al.* (1987) speculate that bacterial substrates in marine systems will have a $C{:}N_S$ ratio greater than 10 such that actively growing bacteria are unlikely to be efficient NH_4^+ remineralizers. Bacteria are also efficient competitors with phytoplankton for NH_4^+ (Kirchman, 2000). When bacteria are utilizing NH_4^+, any release of NH_4^+ would likely be an indirect effect of a process such as bactivory. In a series of incubations done with surface water collected in Sugami Bay, Japan, variable amounts of either glucose (C only) or glutamate (C and N) were added as the C source. Rates of NH_4^+ regeneration, measured with isotope dilution, were up to 4.5 times higher in the whole water glutamate treatments with 67% of the NH_4^+ regeneration occurring in the <1 μm size fraction (Hasegawa *et al.*, 2005).
Figure 8.1 The relationship between bacterial growth efficiency and the C:N ratio of the dissolved organic matter (DOM) substrate ($C:N_s$). The curved indicate zero flux for a given bacterial C:N ($C:N_b$). Taken from Kirchman (2000).

A weakness of the model discussed above is its reliance on detailed information about C:N ratios of bacterial substrates that is currently unavailable. A later study modeled bacterial growth by optimizing electron flow, substrate uptake kinetics, and bacterial C:N ratio (Vallino *et al.*, 1996). This study found that the $C:N_S$ ratio is not always an accurate predictor of whether bacteria will remineralize NH_4^+.

With respect to DON, urea appears to be the most important form released. In two cultures of commercially available marine bacteria, urea production was highest when cell growth declined and at the start of stationary phase (Therkildsen *et al.*, 1997), which suggests that intracellular purines and pyrimidines were likely sources of the urea. Some portion of the intracellular RNA pool is likely degraded to urea and NH_4^+, particularly during exponential growth (Mason and Engli, 1993; Therkildsen *et al.*, 1997). In another study, production of NH_4^+ and urea by natural bacterial populations was observed in Lake Kinneret, Israel, the Charente Estuary, France, and the French coast of the Atlantic (Berman *et al.*, 1999). In these studies, guanine, hypoxanthine, and arginine additions resulted in increases in urea concentrations over time. The significance of the finding to natural waters is unknown, however, because the DON compounds tested were added at concentrations much higher than those found in the environment (40 mM, Berman *et al.*, 1999). Urea release has also been documented during bioassays in the Gulf of Riga (Jørgensen *et al.*, 1999). In a series of bacterial culture experiments, the concentration of D-DNA increased in the medium as a result of viral infection and bactivory (Alonso *et al.*, 2000). Finally, in another study the depletion of a number of nucleotide bases (guanine, hypoxanthine, adenine, xanthine, and pyrimidines) was followed by the production of urea in dark bioassays with bacteria collected off the coast of Denmark (Berg and Jørgensen, 2006).

In addition to urea, bacteria produce a suite of extracellular enzymes. These enzymes become components of the DON pool itself, as well as important agents that alter the characteristics of the DON itself (e.g., Martinez *et al.*, 1996). Bacteria also release amino acids. There is an abundant literature of bacterial amino acid secretion related to the biotechnology field (e.g., Krämer, 1994) but much less is known in marine systems.

3.4. Viruses and other parasites

A potentially large but unquantified mechanism for N regeneration is viruses. The role of viruses in N regeneration is three-fold. First, after a virus infects an autotrophic (including phytoplankton and macroalgae) or heterotrophic host, the phage increase to such numbers that the cells burst releasing the dissolved materials inside. As a result viral lysis is a highly efficient mechanism for moving cellular contents to the DOM pool. Second, viruses are the most abundant fraction of the plankton with concentrations ranging from 10^9 to 10^{11} viral particles L^{-1} (Suttle, 2005; Wommack and Colwell, 2000). Due to their small size (20–200 nm, Brussaard, 2004), viruses are themselves components of the DOM pool, which can make up a significant fraction of "dissolved" DNA. Third, viruses are important determinants of autotrophic and heterotrophic community structure (see reviews by Fuhrman, 1999; 2000; Suttle, 2005; Wommack and Colwell, 2000). As a result, viruses can, for example, act to select for a phytoplankton community that is more or less susceptible to a process such as sloppy feeding. Viruses that infect marine bacteria and cyanobacteria appear to be very common while viruses infecting eukaryotic marine phytoplankton are much less so. Relative to viruses that infect bacteria, the number of viruses isolated that infect eukaryotic phytoplankton are few (reviewed in Bidle and Falkowski, 2004 and Brussaard, 2004).

Viral abundance tends to be positively correlated with both chlorophyll concentrations and bacterial abundance (Maranger and Bird, 1995). Data on viral-mediated mortality are highly variable. A number of different approaches have been used to quantify phage-induced mortality of bacteria and phytoplankton but the task has proved challenging. Best estimates are that viruses kill an estimated ~20–40% of bacteria daily (Suttle, 2005). There are even fewer estimates of phytoplankton mortality but these too cluster in the ~10–40% range with extreme examples where 100% of the mortality of a phytoplankton bloom was attributed to viruses (reviewed in Brussaard, 2004).

A conceptual model of the incorporation of viruses and viral lysis into the aquatic food web was offered by Wommack and Colwell (2000). Each time a cell lyses the contents of the host cell are released including macromolecules, cell organelles, and viral particles. Theoretically, the end result of viral lysis is to divert C and N, fixed by phytoplankton and transformed into bacterial biomass, away from zooplankton consumers into the DOM pool (Bratbak *et al.*, 1994; Fuhrman, 1992; Fuhrman and Noble, 1995; Murray and Eldridge, 1994). More recently it has been demonstrated that viral infection can increase the sinking rate of a phytoplankton cell (*Heterosigma akashiwo*) likely resulting in more particulate material leaving surface waters (Lawrence and Suttle, 2004). This is an important variable to consider with respect to N release. In waters with a deep mixed layer, viral lysis would likely occur

in the mixed layer and the N released would be retained in the surface. In waters with a shallow mixed layer, however, the acceleration in sinking rates due to viral infection could result in transport of the cells out of the mixed layer, such that the N released when cells lyse would not be available to support surface production (Lawrence and Suttle, 2004).

A number of studies have examined the effects of viral lysis on the flux and composition of the DOM pool. Changing the abundance of viruses within experiments results in a change of bacterial abundance (Proctor and Fuhrman, 1991) and a change in the composition and concentration of DOM (Peduzzi and Weinbauer, 1993; Weinbauer and Peduzzi, 1995). The magnitude of the increase in regeneration caused by viruses is likely a function of the abundance of viruses and hosts, the burst size, and viral production rates (e.g., Miki and Yamamura, 2005). In a model of the flux of C through a microbial food web with and without viruses, the presence of viruses resulted in a 27% increase in bacterial respiration and production and a 37% decrease in C transfer to protozoan grazers (Fuhrman, 1992). Experimental evidence has since supported the model results with respect to increased bacterial respiration (Middelboe et al., 1996) and the presence of viruses enhancing the transfer of bacterial production to the DOM pool (Middelboe and Lyck, 2002). In a number of experiments and field studies phage lysis products stimulated bacterial growth and metabolic activity, indicating that viral lysis can contribute to a loop in which a portion of available nutrients cycle between the DOM pool and bacterial biomass without contributing to higher trophic levels (e.g., Middelboe and Lyck, 2002; Middelboe et al., 1996). An estimated 6–26% of organic C production goes into the DOC pool as a result of viral lysis in a process termed the viral shunt (Wilhelm and Suttle, 1999). Finally, changes in DOM composition with viral lysis have been demonstrated in mesocosm experiments (Weinbauer and Peduzzi, 1995). In experiments conducted during a number of phytoplankton blooms bacterial abundance was found to increase significantly after viral infection increased and the bloom crashed (e.g., Bratbak et al., 1998; Castberg et al., 2001; Gobler et al., 1997). In similar experiments viral lysis was suggested to be responsible for the near complete conversion of lost Phaeocystis pouchetii biomass to bacterial biomass through production of excess DOC (Bratbak et al., 1998).

Though viruses have received the most attention, fungi are also a source of parasitic infection although most work on phytoplankton fungal infection has been done with freshwater species (e.g., Holfeld, 1998). Similar to viral infection, fungal infection can also result in N release. As with viruses, fungal infections have been linked with mass mortalities and have been implicated in controlling bloom formation and affecting phytoplankton community composition (Park et al., 2004). The apparent relationship between phytoplankton size and parasite infection differs between viral and fungal infection, however. There are a number of studies showing viral infection of smaller phytoplankton species, such as chrysophytes and cyanobacteria, but viral infection does not appear to be as common for the larger dinoflagellates and diatoms (Brussaard, 2004). In contrast, eukaryotic parasites, such as fungi, appear more common in these larger cells (Park et al., 2004).

Epibiotic association with zooplankton can also take a number of forms (reviewed in Carman and Dobbs, 1997). Parasitic infection can have a number of

negative effects including the development of lesions through which DOM can be lost (Park *et al.*, 2004). Similarly, if the parasitic infection is extreme, mass mortality can occur resulting in substantial DOM release (Gomez-Gutierrez *et al.*, 2003).

3.5. Zooplankton

Zooplankton play a key role in regeneration of N in marine systems through their grazing and metabolism. Microzooplankton (<200 μm, the majority of which are heterotrophic protozoans) contribute to regeneration mainly through excretion. The larger mesozooplankton (200 μm – ~2 cm, including the abundant crustaceans, such as copepods) and macrozooplankton (>2 cm, such as the larger gelatinous zooplankton) contribute to N regeneration via excretion, sloppy feeding, and dissolution of egested fecal pellets. The relative importance and rates of these metabolic processes to N regeneration are discussed in detail in Chapter 26 by Steinberg and Saba (this volume, summarized in Table 8.3). In the following section we focus on the ecological and environmental significance of N regeneration by marine zooplankton.

Table 8.3 Example ammonia excretion rates for a variety of zooplankton taxa summarized from Chapter 26 by Steinberg and Saba (this volume; see their Table 26.4 for details and references)

Taxa	Range of Excretion rates ($\mu mol \, N \, indiv^{-1} h^{-1}$)
Microzooplankton	
Ciliates	3.6×10^{-8} to 3.8×10^{-5}
Flagellates	2.3×10^{-9} to 7.1×10^{-8}
Crustacea	
Copepods	1.7×10^{-4} to 1.7×10^{-2}
Amphipods	4.2×10^{-3} to 2.2×10^{-1}
Euphausiids	8.3×10^{-3} to 8.6×10^{-1}
Ostracods	1.7×10^{-3}
Shrimp	6.3×10^{-2} to 1.3
Mysids	3.2×10^{-1} to 4.8
Gelatinous zooplankton	
Chaetognaths	1.7×10^{-3} to 6.7×10^{-3}
Ctenophores	2.5×10^{-3} to 4.6×10^{-1}
Heteropods	1.6×10^{-1}
Pteropods	3.2×10^{-2} to 2.0×10^{-1}
Salps	5.8×10^{-3} to 1.2
Scyphomedusae	2.3×10^{-2} to 45.5
Siphonophores	4.2×10^{-3} to 8.3×10^{-3}
Hydromedusae	1.7×10^{-3} to 4.6×10^{-2}
Polychaetes	2.9×10^{-2} to 3.5×10^{-1}

3.5.1. Release by different zooplankton groups

The principal regenerators of NH_4^+ in marine pelagic ecosystems are typically thought to be the protozoan microzooplankton, with mesozooplankton playing a more minor role (Bode et al., 2004a; Dam et al., 1993; Glibert et al., 1992; Miller and Glibert, 1998). For example, Verity (1985) estimated that N regeneration by tintinnid ciliates exceeded that by meso/macrozooplankton in Naragansett Bay by a factor of 2–3. In a more extreme case, microzooplankton remineralization in Kanehoe Bay, Hawaii exceeded that by meso/macrozooplankton by a factor of 30–40 (Caperon et al., 1979). Ammonium regeneration by copepods was only 3–19% of that by the <94 μm plankton fraction off the coast of Japan (Hasegawa et al., 2000a), and 0.9–10% of the total N regeneration by microplankton (note: the term microplankton includes bacteria as well as microzooplankton) from Chesapeake Bay (Miller and Glibert, 1998). Within the microplankton size range (<200 μm), the most important NH_4^+ regenerators are in the smaller size classes— with the 1–15 μm nanoflagellate and small ciliate fraction generally being the most important (Glibert, 1982; Le Corre et al., 1996; Maguer et al., 1999; Probyn, 1987), and the <1 μm bacteria fraction more important in some instances (e.g., Harrison et al., 1983; Probyn, 1987). This can vary by environment and season, however. For example, larger flagellates and ciliates in the 15–200 μm fraction accounted for 50% of the microplankton N regeneration in spring and summer in the western English Channel (Maguer et al., 1999), and copepods, rotifers, tintinnids, and heterotrophic dinoflagellates in the 45–200 μm fraction produced most of the regenerated NH_4^+ in summer in Oslofjord (Paasche and Kristiansen, 1982).

One difficulty encountered when trying to quantify the role of different size fractions to regeneration is the assumption that the different fractions measured will equal the sum of the parts. Studies have shown, however, that the sum of the rates measured in the different size fractions often exceeds that of the total rate in the unfractionated sample (Glibert et al., 1992).

Although bacteria and protozoan microzooplankton often account for the majority of N regeneration within a given system, mesozooplankton, through processes such as selective grazing and sloppy feeding, have a number of important modifying and indirect effects on N regeneration (Glibert et al., 1992; Miller et al., 1997). For example, in microcosm experiments with natural microplankton (<200 μm) amended with nutrients and copepod grazers, NH_4^+ concentration changes in treatments containing microplankton + copepods + nutrients compared to treatments containing microplankton + nutrients exceeded that expected from copepod release rates alone, suggesting that copepods increased nutrient regeneration by microzooplankton (Miller et al., 1997). A similar result was found in earlier mesocosm studies where the presence of copepods resulted in higher nutrient regeneration, primary production, and growth rates of bacteria and heterotrophic nanoflagellates (Roman et al., 1988). Miller et al. (1997) suggest that release of DON from zooplankton, via sloppy feeding or excretion, may stimulate NH_4^+ regeneration by bacteria by providing a relatively low C:N ratio substrate for bacterial growth.

Trophic cascade effects (top-down control of food webs by predators leading to alternating high/low abundance of each subsequent lower trophic level) can alter the amount and type of N released and regenerated. Copepods can control the

abundance of ciliates, thus releasing grazing pressure and indirectly stimulating NH_4^+ regeneration by flagellates (Glibert et al., 1992; Miller et al., 1995). In a study of an upwelling system off Spain, N regeneration by microplankton (bacteria, heterotrophic flagellates, and ciliates) was always higher than that of mesozooplankton, however, the relative contribution of each changed depending on the stage of the upwelling cycle (high production vs. low production) (Bode et al., 2004b), presumably due to trophic structure changes and resultant changes in N regeneration during and in between upwelling pulses.

Mesozooplankton alone can also contribute significantly to regeneration. For example, krill swarms in the Antarctic can be important regional sources of NH_4^+ (Atkinson and Whitehouse, 2000; Huntley and Nordhausen, 1995). As noted above, Hasegawa et al. (2000a) found that microplankton (<94 μm) were relatively more important in the release of DON than copepods in coastal waters off Japan, however, release of DFAAs by copepods was sometimes as large as release by microplankton (<202 μm) in Long Island Sound (Fuhrman, 1987). Many gelatinous zooplankton form blooms, which could also contribute substantially to NH_4^+ regeneration. In Kiel Bight during the summer, standing stock of the medusae *Aurelia aurita* outweighs that of micro- and the rest of the meso-macrozooplankton community by 1.5–4 times (Schneider, 1989). In years of high biomass, NH_4^+ regeneration by *Aurelia aurita* exceeds that of all other zooplankton. This medusae is the second most important supplier of regenerated nutrients in Kiel Bight (supplying 11% of phytoplankton N requirements), with bottom sediments being the largest regenerated N source (Schneider, 1989). In other systems, however, gelatinous zooplankton do not appear to be important N regenerators. In Chesapeake Bay the contribution of NH_4^+ regeneration from medusae and ctenophores to phytoplankton primary production was minor (supplying 0.6% of phytoplankton N requirements, Nemazie et al., 1993). Furthermore, the dominant copepod in Chesapeake Bay, *Acartia tonsa*, only could supply 0.4–1% of the NH_4^+ required by phytoplankton, and thus Nemazie et al. (1993) concluded microzooplankton must be the dominant regenerators of NH_4^+ in this estuary. Pitt et al. (2005) suggests gelatinous zooplankton such as scyphozoan medusae promote growth of phytoplankton both from the bottom up, by supplying NH_4^+ through metabolism, and via top-down control, by consuming other zooplankton that feed on phytoplankton.

Finally, a variety of zooplankton have recently been shown to produce colored (chromophoric) DOM (CDOM), a fraction of which is fluorescent (FDOM) (Steinberg et al., 2004; Urban-Rich et al., 2004, 2006). Although the nitrogenous composition of CDOM/FDOM is little known, fluorescent humic-like material (likely fulvic and humic acids) is produced during grazing, influencing the optical characteristics of coastal waters (Urban-Rich et al., 2006). A recent culture study shows that humic-N can be a source of N for coastal phytoplankton (See et al., 2006).

3.5.2. Contribution of zooplankton regeneration to primary production

The role of zooplankton in the regeneration of NH_4^+ (and in only a handful of studies, DON) to fuel phytoplankton productivity has been determined in a number of studies, examples of which are shown in Table 8.4. The amount of primary production that can be supported by zooplankton NH_4^+ excretion depends on environment, taxa studied,

Table 8.4 Percent contribution of zooplankton ammonia excretion (or ammonia + urea[a]) to nitrogen requirements of phytoplankton primary production in a variety of environments (after Bidigare, 1983; LeBorgne, 1986; Hernández-León *et al.*, 2008)

Deborah A. Bronk and Deborah K. Steinberg

and season, and ranges widely from <1–285%, but is normally in the range of 3–50% (Table 8.4). Even individual species (e.g., tintinnids *Tintinnopsis* spp., ctenophores *Mnemiopsis leidyi*, and euphausiids *Euphausiia superba*, Table 8.4) that are abundant and key components of the planktonic food web at certain times of the year can have a large impact on supplying regenerated N to meet phytoplankton requirements. The contribution of zooplankton NH_4^+ excretion to phytoplankton N requirements might be expected to be lower in environments where phytoplankton rely primarily on new N (NO_3^-), such as upwelling or high latitude regions, and higher in areas that rely more heavily on recycled N (NH_4^+), such as oligotrophic, open–ocean regions. On a global scale in the open ocean, this appears to be true. Hernández-León *et al.* (2008) calculated the potential contribution of open-ocean mesozooplankton community excretion to fuel primary production by assigning to latitudinal range literature values of mesozooplankton specific NH_4^+ excretion (fraction of body N excreted d^{-1}) and rates of primary production by biogeochemical province. The largest contribution of NH_4^+ excretion to primary production was indeed in the tropics (mean of 47% of the primary production), decreasing in the subtropics and temorate regions (27–28%) to the polar areas (4–8%), with a global average of 23% (Hernández-León *et al.*, 2008). However, comparing individual studies of excretion by mixed mesozooplankton (i.e., excluding studies of individual species) in different environments shows there are no obvious distinctions between the importance of N regeneration by zooplankton to phytoplankton N demand in oligotrophic vs. upwelling regions (Table 8.4). For example, within upwelling regions, some studies indicate a minor contribution to phytoplankton N demand of around 4% (e.g., Isla *et al.*, 2004b) while others show a more major contribution of 44% (Smith and Whitledge, 1977). For comparison, in the oligotrophic Sargasso Sea, western N. Atlantic, and Mediterranean Sea, N regeneration by mixed mesozooplankton often accounts for as low as <6% of the phytoplankton demand, but can be as high as 160% (e.g., offshore station in Mediterranean Sea) (Table 8.4).

Similarly, it might be predicted that zooplankton N regeneration of NH_4^+ in coastal and inshore temperate environments would contribute least to phytoplankton primary production during the spring bloom, and become relatively more important in summer or other times of the year when phytoplankton typically rely more on recycled nutrients. This does appear to be true for a study in Narragansett Bay, where regeneration of NH_4^+ by tintinnids is more important during the summer than the rest of the year (Verity, 1985, Table 8.4). The opposite trend, however, is apparent in a study where NH_4^+ excretion by ctenophores and mixed mesozooplankton in Great South Bay, NY is more important to phytoplankton primary production in spring (contributing to 39% of phytoplankton N demand) than in summer (contributing to 1–3% of phytoplankton N demand) (Park and Carpenter, 1987, Table 8.4). In inshore waters, nutrient regeneration by the benthic community can be a more important source to phytoplankton than zooplankton regeneration (e.g., Schneider, 1989).

3.5.3. Vertical transport
While zooplankton fuel primary production in the surface waters, they can also contribute to N regeneration at depth. A process that has received attention in the last two decades is the transport of regenerated N below the euphotic zone by diel

vertically migrating mesozooplankton. Diel migrators consume organic particles in the surface waters at night and metabolize the ingested food below the mixed layer during the day resulting in excretion at depth (e.g., Longhurst and Harrison, 1988). This "active" vertical N and C flux can be significant compared to passive sedimentation of organic particles measured by sediment traps (Al-Mutairi and Landry, 2001; Dam et al., 1995; Le Borgne and Rodier, 1997; Longhurst et al., 1990; Steinberg et al., 2000; Steinberg et al., 2002; Zhang and Dam, 1997). The total active N flux is both excreted dissolved NH_4^+ and DON, as well as particulate organic N (PON) in fecal pellets produced at depth, which can subsequently leach DON (e.g., Jumars et al., 1989). On average, migratory dissolved N flux for a number of open ocean environments varies from 0.6 to 3.6 mg N m^{-2} day^{-1} and is equal to 9–45% of the sinking PON flux; maximum dissolved N fluxes can exceed the sinking PON flux (see Table 4 in Steinberg et al., 2002). Migratory active dissolved N flux on average could support a small proportion (2–10%) of phytoplankton N demand for primary production (Al-Mutairi and Landry, 2001; Dam et al., 1995; Longhurst et al., 1989; Rodier and Le Borgne, 1997—calculated from their Table 8; Steinberg et al., 2002). Zooplankton migratory N flux has implications for bacterial regeneration of zooplankton-derived DON in the mesopelagic zone, as a significant proportion of the total dissolved N (TDN) excreted by migrators at depth can be excreted as DON. In the equatorial Pacific, 46% (HNLC area) and 60% (oligotrophic site) of TDN excreted by vertical migrators was as DON (Le Borgne and Rodier, 1997) and 32% of the TDN excreted by migrators was as DON in the Sargasso Sea (Steinberg et al., 2002).

3.6. Nekton

The contribution of marine nekton (the stronger swimming pelagic macroorganisms) such as fish and decapod crustaceans (e.g., shrimp) to regeneration of N in marine systems has received considerably less attention than has zooplankton (Haertel-Borer et al., 2004). In addition, the quantification and significance of large consumer-driven nutrient recycling is much better known in freshwater systems (e.g., see review by Vanni, 2002). These larger motile organisms contribute to N regeneration via excretion or dissolution of egested feces (although the role of sloppy feeding has not been studied for these larger organisms and may also contribute to the dissolved N pool), transport of nutrients via migration, and release of sediment bound nutrients back into the water column by bioturbation. One discipline where regeneration of N by nekton has been studied intensely is aquaculture. High densities of farmed fish can lead to elevated NH_4^+ concentrations, which can be toxic to the fish, as well as lead to high sediment loading by fish feces, resulting in anoxic bottom sediments, a decrease in benthic diversity, and other problems (Ip et al., 2001; Wu, 1995). In this section we focus on the ecological and environmental significance of N regeneration by marine nekton. For a comprehensive review of the physiology of N metabolism and excretion by fish, see the volume of *Fish Physiology* dedicated to N excretion edited by Wright and Anderson (2001).

Like the zooplankton (see Chapter 26 by Steinberg and Saba, this volume), marine teleost fish are primarily ammonotelic (Wood, 2001), but also can excrete a significant proportion of their TDN as urea or other DON compounds (in both early

developmental stages and as adults) (Anderson, 2001; Torres *et al.*, 1996; Walsh *et al.*, 2001; Wood, 2001; Wright and Fyhn, 2001; Wright and Land, 1998). For example, in a survey of 16 marine fish species, Walsh *et al.* (2001) found urea excretion by teleosts constituted 1–24% of the combined NH_4^+ plus urea excreted. For one species for which TDN excretion was measured, DON (urea plus unknown compounds) constituted 4–31% of the TDN excreted. For the sardine *Sardinop sagax*, DON constituted 31% of the TDN excreted by unfed fish and 25% for fish fed mysids (van der Lingen, 1998). Marine elasmobranchs (sharks, skates, and rays) are primarily ureotelic but excretion rates have been measured on very few species (Wood, 2001), thus their contribution to N regeneration will not be considered here.

Diet can play an important role in N recycling by nekton, and may lead to trophic effects on N regeneration in a given ecosystem. For example, N assimilation efficiencies for omnivorous anchovies (*Engraulis capensis*) and sardines (*Sardinops sagax*) from upwelling regions fed phytoplankton are lower (83% and 79%, respectively) than those fed zooplankton (87% and 93%, respectively) (James *et al.*, 1989; van der Lingen, 1998). N assimilation efficiency for Atlantic menhaden (*Brevoortia tyrannus*), however, was similar (∼92%) for feeding on phytoplankton or zooplankton (Durbin and Durbin, 1981). The stoichiometry of consumer-driven nutrient recycling also has an important trophic impact, as the N:P ratio of excretion can have significant effects on phytoplankton physiology and community structure (e.g., Elser and Urabe, 1999).

The contribution of nekton NH_4^+ regeneration to phytoplankton N requirements for primary production has been determined in several studies. Based on their measured N excretion rates of anchovy (*Engraulis mordax*) and jack mackerel (*Trachurus symmetricus*), and fisheries data from the California Cooperative Oceanic Fisheries Investigations (CalCOFI) survey, McCarthy and Whitledge (1972) estimated regeneration of NH_4^+ and urea by pelagic fish off the coast of southern California accounts for 10% of the NH_4^+ and 2% of the urea required by phytoplankton for primary production. Omnivorous fish in a surf zone ecosystem supply <1% of the total phytoplankton N requirements (Cockcroft and Du Preez, 1990), with penaeid prawns supplying 12% (Cockcroft and McLachlan, 1987), and mysids 10% (Cockcroft *et al.*, 1988), of the phytoplankton N requirements in this same system.

Nekton represent an important local source of regenerated N in a number of habitats. The release of NH_4^+ and P by nekton (fish and shrimp) in intertidal creeks of a salt marsh estuary in South Carolina was quantified by Haertel-Borer *et al.* (2004). They found NH_4^+ excretion by nekton in early spring and summer (mean of 199 μmol NH_4^+ m^{-2} h^{-1}, in a water column depth of 0.4–0.7 m) was considerably higher than by meso- and macrozooplankton (approximately 2 μmol NH_4^+ m^{-2} h^{-1}, calculated from their Table 6) and higher than all other sources of NH_4^+ (e.g., atmospheric deposition, benthic remineralization, bacteria) with the exception of oyster reefs (oysters plus sediment and epifauna) (mean of 229 μmol NH_4^+ m^{-2} h^{-1}, in summer). Although nekton excretion was relatively more important in NH_4^+ release than bioturbation in their experiments, nekton excretion plus bioturbation was on average the largest source of NH_4^+ in this system (mean of 274 μmol NH_4^+ m^{-2} h^{-1}). Many of the nekton in the intertidal creeks were feeding on benthic invertebrates or detritus, and thus translocating benthic-bound nutrients into the water column via regeneration (see below). Fish are also a significant nutrient source,

via their defecation and excretion, to coral reef communities (Meyer and Schultz, 1985; Meyer *et al.*, 1983). For example, juvenile french and white grunts (*Haemulon flavolineatum and H. plumieri*) were capable of doubling the N supplied to corals from other sources and stimulating coral growth and likely biological activity in reef benthos (Meyer and Schultz, 1985). Diel periodicity in N excretion and defecation by reef-dwelling fish (Polunin and Koike, 1987) may also have important effects on nutrient cycling and phytoplankton communities in reef ecosystems.

The importance of fish as a vector for biotic nutrient transport (or translocation) of biomass or dissolved nutrients from one habitat or ecosystem to another has been explored in a several studies. The migration of gulf menhaden (*Brevoortia patronus*) results in the transport of N and P (as biomass) from an estuary into the Gulf of Mexico that is of the same order of magnitude as passive export of nutrients by tides and freshwater flow (Deegan, 1993). Planktivorous fish (the blacksmith, *Chromis punctipinnis*) feeding in the water column on zooplankton excrete NH_4^+ within the subtidal rocky reef while sheltering at night (Bray *et al.*, 1986). The amount of NH_4^+ excreted by these sheltering fish is about one order of magnitude higher than the total amount excreted by macroinvertbrates and fish foraging mainly within the reef (Bray *et al.*, 1988). Hjerne and Hansson (2002) found the removal of nutrients in fish biomass by the fishery in the Baltic Sea was 1.4% of the total annual N load (and 7% of the P load). The fishery removed a more significant proportion of the estimated anthropogenic fraction of the total nutrient load that reaches the open Baltic Sea (2.5% of the anthropogenic N load and 18% of the P load), constituting a significant flux of nutrients from the ecosystem. They suggest that the fishery may ''counteract eutrophication in the open Baltic Sea by removing considerable amounts of nutrients through fish landings,'' although they caution that ''other effects of fishing may counterbalance this positive effect.'' Fish feeding on benthic prey (or on organic detritus and algae associated with sediments) but excreting metabolized nutrients into the open water column is another mode of N transport. In freshwater systems this release of sediment-bound nutrients into the water column can be an important source of nutrients compared to inputs from the watershed (e.g., Gido, 2002; Schaus *et al.*, 1997). This process has been little studied in marine systems (although see Haertel-Borer *et al.*, 2004, discussed above).

Finally, as described in the preceding section 3.5.3. for zooplankton, vertically migrating nekton in the open ocean may also actively transport regenerated N below the euphotic zone through diel vertical migration, although data are scarce for nekton active transport (Longhurst and Harrison, 1988; Longhurst *et al.*, 1989, and see Angel and Pugh, 2000, and Hidaka *et al.*, 2001 for C transport by micronekton). The fecal matter of vertically migrating myctophids in the western equatorial Pacific was found to be high in amino acids (equal to 37–42% of fecal organic C) and could provide a source of essential amino acids for mesopelagic animals (Hidaka *et al.*, 2001).

3.7. Corals

Corals are known to release relatively large amounts of particulate organic C (POC) and DOC largely in the form of mucus (e.g., Crossland, 1987). The release of DOC-rich mucus has been hypothesized to serve a number of roles including as an aid in

defense and feeding, a protection from dessication and sediment, and as a sunscreen. It has also been suggested that the high C:N ratio of mucus could result from a diet rich in C (Brown and Bythell, 2005).

A review of analyses of the composition of mucus indicated that protein makes up 4–49% of the coral organism with total N making up 0.04–5.2% of mucus (Brown and Bythell, 2005). The primary constituents of the mucus matrix are glycoproteins or mucins. In a recent model of the mucus layer, organic exudates and organic N are released from the coral surface and go on to support a dynamic microbial community within the mucopolysaccharide layer around the coral (Rohwer and Kelley, 2004).

In comparison, relatively little is known about N release. Two studies of DON release found that up to 50% of the total N requirement of the coral colony is released (Bythell, 1988). Rates of DON release were measured in the zooxanthellate coral *Galaxea fascicularis* over a 24-h cycle (Ferrier-Pagès *et al.*, 1998a). There was a diel periodicity inherent in DON release from both fed (on *Artemia*) and unfed organisms with large pulses of DON release observed in mid-morning and mid-afternoon. Daily release rates were 0.5–0.6 µmol DON (mg protein)$^{-1}$ for unfed organisms, 1–3 µmol DON (mg protein)$^{-1}$ for fed organisms, and 0.2–1.3 µmol DON (mg protein)$^{-1}$ for organisms supplemented with N and P. DON did not persist in the media, however, but was rapidly reincorporated, likely by free-living epibiotic and/or intracellular bacteria. The rapidity of measured reincorporation suggests that the release rates measured are likely significantly underestimated. During the pulses of DON release the C:N ratio of the material was very low (2.5–4.5) but reached as high as 13 in the non-peak times. A new chromatographic/mass spectrometric method of measuring DON release (see Chapter 28 by McCarthy and Bronk, this volume) was used to estimate DON release from the hermatypic coral *Porites cylindrica* (Miyajima *et al.*, 2005). Over the course of a four day experiment $^{15}NO_3^-$ was taken up by the coral endo-symbiont and DON was produced at a surface-area specific rate of 0.58 nmol N cm^{-2} day^{-1}.

3.8. Detritus and marine snow

One source of DOM release that is particularly difficult to quantify is release from detritus or marine snow. In an inverse modeling study of C and N in the South California Bight, Jackson and Eldridge (1992) found evidence that the detrital pool was a key intermediate between primary production and release of DOM. The problem with quantifying release from detritus in the field is defining what is meant by detritus. When a phytoplankter dies, does it instantly become part of the detrital pool? A suite of analytical techniques have been brought to bear on defining what constitutes a living cells versus what is detritus (e.g., Minor and Nallathamby, 2004 and references therein). Fecal material is another important component of the detrital pool, which raises questions as to whether one considers DON release from fecal pellets (see Chapter 26 by Steinberg and Saba, this volume) to come from zooplankton or from detritus.

The release of DOM by bacteria solubilizing sinking particles has been of considerable interest in investigations of particle flux to the ocean's interior. Smith *et al.* (1992) showed that amino acids associated with particulates were rapidly

hydrolyzed by exoenzymes secreted by bacteria associated with marine snow aggregates, suggesting that sinking particles may be more rapidly solubilized than previously thought. The hydrolyzed amino acids were not taken up by the attached bacteria, indicating release of DON into surrounding waters. Marine aggregates also have pore fluids that can be enriched (often orders of magnitude over surrounding seawater) with dissolved inorganic and organic nutrients such as NH_4^+ (Gotschalk and Alldredge, 1989; Shanks and Trent, 1979), silicic acid (Brzezinski *et al.*, 1997), and DOC (Alldredge, 2000) that could be released into the surrounding seawater when grazed or otherwise disrupted.

3.9. Sediments

Due to space limitations we confine our discussion of sediments to a review of their role as a source of regenerated N to the water column. For a more thorough treatment of N cycling in sediments see Chapter 19 by Joye and Anderson (this volume), for a review of DON in sediments see Burdige (2002), and for more detailed reviews of N regeneration from sediments see Burdige (2006), Klump and Martens (1983) and Nixon (1981).

In sediments there are three principle microbial processes that affect N regeneration—denitrification ($NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$; Chapter 6 by Devol, this volume), nitrification ($NH_4^+ \rightarrow NO_2^- \rightarrow NO_3^-$; Chapter 5 by Ward, this volume) and ammonification. In addition to classical denitrification, the recently discovered anammox (anaerobic ammonium oxidation) is another denitrifying process (Chapter 6 by Devol, this volume). In the anammox reaction NH_4^+ is combined with NO_2^- to yield N_2 and water. The production of N_2 makes anammox another form of denitrification. Ammonification is the release of NH_4^+ from organic matter. The direct link with organic matter makes ammonification distinct from other processes that regenerate NH_4^+ such as grazing. Ammonification is difficult to quantify, however, because it is difficult to determine the source of NH_4^+. Though most ammonification is thought to originate with bulk DON, some individual compounds have been shown to be important. Urea, which can be quickly hydrolyzed to NH_4^+ by bacterial ureases, is an important source of NH_4^+ in sediments, particularly in those with high macrofaunal biomass. For example, in the sediments on the shelf of the Bering Sea up to 80% of the NH_4^+ production was attributed to urea hydrolysis (Lomstein *et al.*, 1989). To these microbial processes we must also add release from macroalgae, microphytobenthos, and benthic fauna in general (discussed below).

As in the water column one must also consider simultaneous N utilization when discussing N regeneration in sediments. Two sets of processes in particular can remove N from sediments, without transferring fixed N to the water column. The first is denitrification (e.g., Laursen and Seitzinger, 2002) and anammox, where N is lost from the system as N_2 gas., The second is chemical adsorption, including the binding of DON to particles, which protects it from microbial breakdown (e.g., Hedges and Keil, 1999), and NH_4^+ adsorption to clays through association with ion exchange sites (see Burdige, 2006; Klump and Martens, 1983).

A survey of rates of N release from sediments in ocean, coastal and estuarine environments is presented in Table 8.5; we note that this is not an exhaustive

Table 8.5 Rates of nitrogen (N) release from sediment. Rates were quantified by measuring concentration changes (CC) in either sediment cores (SC) or benthic chambers (BC)

[a] Rates were measured using ^{15}N isotope dilution.
[b] Rates were measured in a flow through experimental chamber for 33 days in cores with eel grass added to the surface and in controls without eelgrass.
[c] Rates were measured over the first 17 days after the eel grass addition.
[d] Measurements were taken at a mainland tidal creek, mid-lagoon shoals, at Hog Island (a back barrier island) and Willis Wharf in Virginia
[e] Experiments were conducted in October 1998, and May, July, and August 1999.
[f] Rates measured at Castle Forbes and Port Cygnet; DON release rates only reported for Castle Forbes.
[g] Rates were measured during May, July, August, October, and December 1978 and March 1979.
[h] Study included flux measurements at sites characterized by six different sediment–plant types: Enteromorpha sp., phytoplankton detritus, seagrass + epiphytes, seagrass, Gracilaria sp., and benthic microalgae. Incubations were done in the light and dark; net release rates are reported.
[i] Measurements were taken in the upper estuary (fine grained), mid estuary (organic rich), and lower estuary (marine sands) of the Brunswick, Simpsons, and Sandon estuaries.
[j] Rates were measured twelve times between June 1987 and May 1989.
[k] Rate measured in the control sediment (sandy).
[l] Measurements were taken at a mainland tidal creek, mid-lagoon shoals, and Hog Island (a back barrier island) in Virginia.
[m] Experiments were conducted in October 1997, and May, July, and August 1998.
[n] Incubation days 0–10.
[o] Incubation days 10–29.
[p] Incubation days 10–29 after algal material was added to the top of the core to simulate deposition from an algal bloom.
[q] Data represent the range for cores with and without added eel grass.
[r] Rates were presented as mmol urea but were converted to mmol N for presentation here.
Data are presented as mean ± standard deviation. When data from a given site were reported with several averages and standard deviations, the data were pooled for an overall site average and a new estimate of the standard deviation was calculated using propogation of errors. Negative rates indicate uptake by the sediment. Rates are confined to those measured in situ in papers published since 1990; for a summary of earlier rates see Burdige (2006).

survey…though preparing it was exhausting. These rates were measured using a number of approaches. Generally some form of a chamber is placed over the sediment and then the change in N concentrations within the chamber is monitored over time (e.g., Burdige and Zheng, 1998). Similarly, sediment cores are collected and the change in N concentrations in the overlying water monitored over time (e.g., Tyler et al., 2003). Alternatively a flux is calculated based on the gradient in N concentrations in pore water down a core (e.g., Burdige and Martens, 1990; Landén and Hall, 2000). In some cases the calculated rates are underestimated relative to measured rates (e.g., Landén and Hall, 2000). One possible reason for the discrepancy could be that production or consumption of N is occurring right at the sediment surface rather than within the sediment (Burdige, 2001, 2006). We discuss sedimentary regeneration rates with respect to the types of N released and the variables that control these rates below.

3.9.1. Types of nitrogen regenerated from sediments

Both inorganic and organic N can be released from sediments with release of inorganic N having received considerably more attention. Of the inorganic forms, release of NH_4^+ is generally much larger than release of NO_3^- and NO_2^-. In fact, sediments are more commonly a sink for oxidized forms (e.g., Sundbäck et al., 2004; Tyler et al., 2001). In general, benthic DON fluxes are highly variable, can be into or out of the sediment, and are usually small when compared to total net N flux from sediments (Burdige, 2006; Burdige and Zheng, 1998; Devol and Christensen, 1993). Of the individual organic compounds, urea and amino acids have received the most attention. Urea was 36–70% of the TDN released from sediments in the north Bering Sea (Lomstein et al., 1989) and ~30% in a coastal bay in France (Boucher and Boucher-Rodoni, 1988). Some exceptions where rates of DON release from sediments rivaled or exceeded the release of inorganic N include work in Arctic sediments (Blackburn et al., 1996), a Swedish fjord (Sundbäck et al., 2004), continental margin sediments (Landén-Hillmeyr, 1998), and in a temperate Australian estuary (Cook et al., 2004).

Analogous to DON in the water column, DON in sediment pore water is a heterogeneous mixture of compounds, though we know relatively little about its composition. Total DON concentrations tend to increase with depth into sediments (Burdige, 2002). The bulk of porewater DON is <3 kDalton, representing 80–90% and 60–70% of total DON in estuarine and continental margin sediments, respectively (reviewed in Burdige, 2006). In describing the general composition of porewater DON, Burdige and Gardner (1998) proposed that POM in the sediments initially hydrolyzes to high MW (HMW) compounds and through continued remineralization results in pore water characterized by LMW refractory compounds; this idea builds on the size reactivity continuum model put forth to describe water column DOM (Amon and Benner, 1996). Patience et al. (1992) found evidence that DON in sediment pore waters has a higher proportion of heterocyclic components (N in aromatic rings), which are generally considered more refractory. While the presumably refractory LMW DON, believed to be largely humic in character, increases with depth, concentration of labile LMW material tends to decrease. This LMW material is composed of compounds such as total hydrolysable amino

acids (THAA), DFAA, and urea (e.g., Henrichs *et al.*, 1984; Landén and Hall, 2000). In one study off the coast of Denmark, pore water DON was 9.2 mmol m^{-2} and was composed of 26.8% THAA, 10.1% DFAA, and 1.8% urea, with the remainder uncharacterized (Lomstein *et al.*, 1998). Turnover times of these LMW compounds near the surface can be surprisingly short. In the Lomstein *et al.* (1998) study, turnover times were 7–52 h for THAA, 3–4 h for DFAA, and 1–3 h for urea.

3.9.2. Variables that affect sediment nitrogen regeneration

The direction and magnitude of net N flux is dependent on a number of variables including the type and amount of organic matter delivery, light, temperature and seasonality, sediment oxygen concentration, and the presence and type of vegetation, macroalgae and microphytobenthos, and benthic fauna. Rather than any single variable, however, the key to understanding sediment N regeneration often lies in the interactive feedback loops of one variable to another.

The amount and quality of the organic matter delivered to the sediment surface will determine the amount and form of the N remineralized from the sediment (e.g., Lomstein *et al.*, 1989). A number of studies have shown a positive correlation between increases in OM delivery to the sediment and N regeneration (Enoksson, 1993; Jensen *et al.*, 1990; Sloth *et al.*, 1995; Therkildsen *et al.*, 1996; Tyler *et al.*, 2001). The quality of organic matter is also important. For example, phytoplankton detritus would be expected to have a much lower C:N ratio than seagrass detritus or organic matter transported from the terrestrial environment (e.g., Enriquez *et al.*, 1993), such that more N regeneration would likely occur as a result of phytoplankton detrital deposition relative to deposition of seagrass detritus.

When material hits the sediment surface it has two basic fates in the short term. It can be incorporated into biomass, primarily of bacteria, or it can be remineralized. Evidence for this split is seen in studies where increases in benthic biomass are inversely proportional to DIN flux from the sediment (e.g., Van Duyl *et al.*, 1993). The rate at which N is transported from the sediment to the water column is further dependent on the processes of diffusion and bioturbation (see review by Herbert, 1999).

Sources of organic matter to the sediments include terrestrial organic matter and pelagic and benthic primary producers, including the secretion of organic matter by the roots and rhizomes of macrophytes (e.g., Jensen *et al.*, 1990). Once the organic matter is deposited at the sediment surface, there are several potential sources of N to the water column from the benthos including excretion by meiofauna, macrofauna, N$_2$ fixation, and benthic organic matter remineralization. The presence or absence of plants can also be an important determinant of the magnitude and direction of N flow (e.g., Caffrey and Kemp, 1992).

With respect to environmental variables, light and temperature have been shown to affect sedimentary regeneration (e.g., Eyre and Ferguson, 2002; Sundbäck *et al.*, 2004). The affect of light and temperature is partially responsible for the distinct seasonal patterns often observed in sedimentary processes. For example, in a study in Concepción Bay, Chile, benthic fluxes were negative in the winter but positive in the spring and summer (Graco *et al.*, 2001). In the Gullnar Fjord in Sweden, DIN flux was dominated by NH$_4^+$ in the spring and by NO$_3^-$ in the fall (Sundbäck *et al.*, 2004). Higher fluxes of DFAA were observed in coastal sediments from Cape

Lookout Bight, NC in the summer relative to winter (Burdige and Martens, 1990). Many other factors that affect release can also vary with the season, such as rainfall, which can also affect organic matter delivery.

Whether the sediment is oxic or anoxic is also an important determinant of sedimentary N fluxes as well as the forms of N released. In sediments with significant organic matter deposition, oxygen does not generally penetrate far into the sediments such that reduced compounds like NH_4^+ or N_2 tend to dominate remineralization (e.g., Pedersen *et al.*, 1999). Similarly, efflux of NO_3^- is also heavily dependent on oxygen penetration.

One important variable controlling oxygen levels in sediment is the presence and type of primary producers. Primary producers with low C:N ratios (i.e., phytoplankton and macroalgae) can fuel rapid bacterial decomposition, which can severely reduce the concentration of oxygen. The reduced oxygen can lower the rate of denitrification, via limitation of the source of available NO_3^- through nitrification, and ultimately result in an increase in NH_4^+ release from sediment. In contrast, seagrasses and benthic microalgae can oxygenate the upper sediments reversing the process (Caffrey and Kemp, 1990; Risgaard-Petersen and Jensen, 1997). In general, rates of ammonification and NH_4^+ release tend to be substantially higher in sediments colonized by seagrasses relative to bare sediments (e.g., Boon *et al.*, 1986; Caffrey and Kemp, 1992; Dennison *et al.*, 1987). Nitrification rates tend to be higher in vegetated sediments, likely as a result of the O_2 released by roots (Caffrey and Kemp, 1990). Likewise, denitrification rates also tend to be higher in vegetated areas (Caffrey and Kemp, 1990), likely as a result of increased substrate availability due to the higher rates of nitrification.

3.9.3. Sources of regenerated nitrogen associated with sediments

In addition to the microbial community present in all sediments other organisms can substantially alter the nature of N release from sediment, particularly macroalgae, microphytobenthos, and benthic fauna.

In some coastal systems, the most important primary producers are macroalgae (Peckol and Rivers, 1996). This is particularly true in some highly eutrophied areas (Peckol *et al.*, 1994) where macroalgae can often out-compete seagrasses under high nutrient conditions (Duarte, 1995). Most macroalgal production enters the detrital food web. Macroalgae tend to be high in labile biomass such that they rapidly decompose following senescence, which makes direct release a potentially large source of regenerated N during isolated periods (e.g., Duarte, 1995; Enriquez *et al.*, 1993). Macroalgae at the sediment surface can also limit N regeneration to the water column by taking up the N released from the sediment (e.g., McGlathery *et al.*, 1997; Valiela *et al.*, 1992). Macroalgae can release DOM directly or during grazing (e.g., Branch and Griffiths, 1988; Duggins *et al.*, 1989; Mann, 1988). Potential reasons for direct release include release of proteinaceous enzymes (e.g., Weich and Granéli, 1989), to attract epiphytes like N_2 fixers (e.g., Penhale and Capone, 1981; Thomsen *et al.*, 2006), and release of defensive allelopathic chemicals such as polyphenolic compounds to inhibit the growth of other algal species (e.g., Hay and Fenical, 1988; Lobban and Harrison, 1994). Grazing on macroalgal biomass can also result in N regeneration during sloppy feeding on the

macrophyte and excretion or fecal pellet dissolution after feeding. In general, an estimated 34% of macroalgal net primary production is grazed (Duarte and Cebrián, 1996). Presumably release can also result from parasitic or viral infection of macroalgae though we are unaware of any studies of these routes of release.

A number of studies have measured DOC production from macroalgae and an estimated 30–45% of macroalgal production is released as DOM (e.g., Mann, 1982; Sieburth, 1969). Relatively little is known, however, about release of N containing compounds specifically. Nitrogen release can take several forms including NH_4^+, urea, DCAA, and a suite of different free amino acids (Tyler et al., 2003). The high recovery of ^{15}N added, as either $^{15}NH_4^+$ (96% recovery) or $^{15}NO_3^-$ (99% recovery), in studies with Ulva fenestrata and Gracilaria pacifica, indicates that if substantial DON release occurs it is rapidly reincorporated or remineralized (Naldi and Wheeler, 2002). Branch and Griffiths (1988) found that DOM actively released by kelp consisted of only 5% protein with the remaining made up of C-rich moieties. One of the few studies to quantify N release from macroalgae was done in a shallow back-barrier lagoon in Virginia using Gracilaria vermiculophylla (Tyler and McGlathery, 2006, Table 8.6). In this system, an average of 67% of gross N uptake was released each day (Tyler and McGlathery, 2006); areal rates of N release range from 0.008 to 17 mmol m^{-2} day^{-1} (Table 8.6). Other studies found that release of DON and urea from macroalgae and sediments was higher in the light while NH_4^+ regeneration was higher in the dark (Tyler et al., 2001, 2003).

Different species of macroalgae would be expected to have different N release rates. For example, some macroalgae are known to have large intracellular inorganic N storage pools (e.g., McGlathery et al., 1996). Release of NH_4^+, as measured with isotope dilution, was observed in Ulva fenestrata (0.08–11.27 μmol N g^{-1} h^{-1}) and Gracilaria pacifica (0.12–0.77 μmol N g^{-1} h^{-1}) when $^{15}NH_4^+$ was added to the medium. However, no net NH_4^+ release, over uptake, was observed. Small pulses of free amino acids were released and then rapidly reincorporated (Naldi and Wheeler, 2002), but no protein release was detectable.

It is also known that desiccation is a main stressor for macroalgae and that DOM release increases after desiccation and reimmersion (Carlson and Carlson, 1984). Desiccation and reimmersion likely changes the suite of compounds that are released, resulting in release of more complex moieties such as polypeptides as a result of cell wall damage (Pregnell, 1983). Some algae are also known to release organic compounds as a form of allelopathic protection (Gross, 2003).

Microphytobenthos are another significant source of N from sediments that can also be an important barrier to sedimentary N release (e.g., McGlathery et al., 2001; Stimson and Larned, 2000). This is particularly true in northern microtidal regions where microphytobenthos are active all year long (e.g., Risgaard-Petersen, 2003; Sundbäck and Miles, 2000). In a Swedish fjord, there was a significant negative correlation between gross primary production of microphytobenthos and DIN fluxes, with microphytobenthos removing ∼35% of the remineralized N (Sundbäck et al., 2004); no correlation was observed with DON fluxes. In contrast, in another system with significant amounts of microphytobenthos, Cook et al. (2004) found that fluxes of urea and total dissolved primary amines were insignificant. Rates

Table 8.6 Rates of nitrogen (N) release from macroalgae measured using ^{15}N wet chemical techniques (^{15}N-WC) or changes in concentration (CC). Data are presented as the mean ± standard deviation. When data from a given site were reported with several averages and standard deviations, the data were pooled for an overall site average and a new estimate of the standard deviation was calculated using propogation of error. Negative rates indicate uptake by the plant or sediment

[a] Measurements were taken at a mainland tidal creek, mid-lagoon shoals, and Hog Island (a back barrier island) in Virginia; no net N release of NH_4^+, urea, or DCAA was observed at a fourth site, Willis Wharf.
[b] Experiments were conducted in October 1997, and May, July, and August 1998.
[c] Experiments were conducted in October 1998, and May, July, and August 1999.
[d] When all sites and dates were averaged, there was no net DIN, DON, urea or DFAA release measured.
[e] Experiments were conducted in October 1999, and February, April, and July 2000.

of DON dominated over DIN fluxes and were highest where the highest micro-phytobenthos biomass, production, and respiration occurred (Cook *et al.*, 2004). The link between high microphytobenthos and high DON release has also been shown in an Australian lagoon (Eyre and Ferguson, 2002).

In systems with high abundance of microphytobenthos and macroalgae, DON is often the major form of N released (Cook *et al.*, 2004; Eyre and Ferguson, 2002; Tyler *et al.*, 2001). One possible reason for this is uptake of DIN by the micro-phytobenthos and then release of DON through direct release or release mediated by grazing (Eyre and Ferguson, 2002). The production of DON occurs right at the surface, as pore water DON profiles do not indicate DON accumulation within the sediment (Cook *et al.*, 2004).

Although most NH_4^+ and DON release from sediments is attributed to bacterial remineralization, benthic fauna can also play an important but hard to quantify role (see reviews by Aller, 1988 and Burdige, 2002). Benthic infauna can contribute to N leaving the sediment through excretion or bioturbation (Aller, 1988; Gilbert *et al.*, 2003; Lomstein *et al.*, 1989). They also facilitate oxygen penetration far deeper into the sediments through irrigation and bioturbation thus potentially impacting the form, oxidized or reduced, of the N released (Aller, 1988). In sediments of the open Skagerrak, DFAA fluxes tended to be into the sediment when meio- and macro-fauna were in low abundance but tended to flux out of the sediment, along with NH_4^+, when sedimentary fauna were in higher abundance (Landén and Hall, 2000). Even in continental margin waters of greater than 100 m, macrobenthic irrigation is an important mechanism for transferring N into and out of the sediment (Devol and Christensen, 1993).

Beggiatoa is a large, sulfate-oxidizing bacteria that produces extensive mats at the sediment surface similar to another large marine bacteria, *Thioploca* (e.g., Schulz *et al.*, 1996). Both of these large bacteria are known to accumulate large stores of NO_3^- intracellularly (up to 500 mM) (Fossing *et al.*, 1995). *Beggiatoa* has been shown to release substantial amounts of NH_4^+, likely as a result of dissimilatory NO_3^- reduction to NH_4^+. In one study in Concepción Bay, Chile, NH_4^+ flux from *Beggiatoa* was estimated at 5 mmol m^{-2} day^{-1} or 17% of the total NH_4^+ release from the sediments in the summer (Graco *et al.*, 2001).

4. METHODS TO MEASURE NITROGEN REGENERATION

Regeneration rates are generally determined using bioassays or ^{15}N tracer methods (Chapter 31 by Lipschultz, this volume, Chapter 28 by McCarthy and Bronk, this volume). With the bioassay method, the accumulation of a compound is measured over time (e.g., Steinberg *et al.*, 2002). Bioassays have the advantage that they are relatively easy to perform. However, they can only provide net release rates, will only produce a rate at all if the release rate is greater than any uptake rates, and can suffer from bottle affects if long incubations are needed to see a signal.

The alternative to bioassays is to use tracer methods of which there are two general approaches. In the first, the dilution of an isotopically labeled pool is measured over time (NH_4^+ regeneration, Glibert *et al.*, 1982). In the second, the flow of ^{15}N is followed into a regenerated N pool directly (e.g., DON release, Bronk and Glibert, 1991).

Rates of NH_4^+ regeneration are most commonly measured using isotope dilution. In this approach, ^{15}N-labeled NH_4^+ is added to a sample at $\sim <10\%$ of the ambient concentration. At the end of the incubation the NH_4^+ pool is isolated via distillation (e.g., Glibert *et al.*, 1982), solid phase extraction (e.g., Selmer and Sorensson, 1986), or direct diffusion (Slawyk and Raimbault, 1995). The isotope dilution method assumes that any NH_4^+ released during the incubation is $^{14}NH_4^+$, which will dilute the $^{15}NH_4^+$ added at the start of the experiment. The rate of regeneration is then measured by monitoring the dilution of the labeled ^{15}N-labeled NH_4^+ pool over time (Blackburn, 1979; Caperon *et al.*, 1979). Urea regeneration can be measured in an analogous fashion (e.g., Slawyk *et al.*, 1990). Urea regeneration can also be measured using ^{14}C and ^{15}N-labeled urea with a method described by Hansell and Goering (1989).

Nitrogen regeneration can also be measured by monitoring the flow of a labeled compound from a source pool to a target pool. In the case of DON release, ^{15}N-labeled NH_4^+ or NO_3^- is added to a sample and the appearance of ^{15}N in the DON pool is monitored over time (Bronk and Glibert, 1991). To measure a DON flux, DON must be isolated prior to mass spectrometric analysis. There are three basic approaches used to isolate DON: (1) wet chemistry (e.g., Axler and Reuter, 1986; Bronk and Ward, 1999; Slawyk and Raimbault, 1995), (2) ion retardation (Bronk and Glibert, 1991; Nagao and Miyazaki, 1999), and (3) dialysis (Feuerstein *et al.*, 1997); all three approaches are discussed in more detail in Chapter 28 by McCarthy and Bronk (this volume).

There are two basic approaches to calculate rates of DON release. First, is to directly measure the passage of ^{15}N from the intracellular organic N (ON) pool to the extracellular DON pool (Bronk and Glibert, 1991, 1993) and is specified the intracellular pool (IP) DON release rate. Isolating the intracellular DON pool gives the added bonus of allowing the calculation of a transformation rate, which is a measure of the transformation of NH_4^+ to ON intracellularly (Bronk, 1999). Second, is to monitor the change in the ^{15}N atom % enrichment of the extracellular DON pool only and is the more commonly reported rate. The DON release rate is calculated as the difference between the gross N uptake rate (ρ_G) and the net N uptake rate (ρ). The second method of measuring DON is less labor intensive and requires fewer assumptions and so is more robust.

When measuring any release process one must be aware of three potential artifacts—filtration stress (e.g., Goldman and Dennett, 1985), incubation stress (e.g., Venrick *et al.*, 1977), and loss of DON during the isolation process (Bronk and Ward, 2000); see Chapter 28 by McCarthy and Bronk (this volume) for a more detailed discussion.

> ## 5. Rates of Nitrogen Regeneration in the Water Column

Here we review published rates of NH_4^+ regeneration and DON release in the water column. In general, these rates were measured in small volume incubations (<4 L) run for 1–24 h and could represent release due to many of the mechanisms discussed above for phytoplankton, bacteria, zooplankton, viruses and detritus. There have been two recent reviews of DON release rates in the field (Bronk, 2002 and Berman and Bronk, 2003) and so here we focus on the literature of the last ten years. There have been no similar reviews for NH_4^+ regeneration, however, and so we extend coverage back to the 1980s, when the isotope dilution technique to measure NH_4^+ regeneration was introduced (Glibert *et al.*, 1982).

5.1. NH_4^+ regeneration

Ammonium is the primary form of N released in the water column. Rates of NH_4^+ regeneration are often tightly coupled with uptake such that concentrations of NH_4^+ can be near the limit of detection even in systems that are running largely on NH_4^+ (e.g., McCarthy and Goldman, 1979). Though related, there is seldom a strong correlation between NH_4^+ uptake and NH_4^+ regeneration measured simultaneously because of the large number of processes that can result in NH_4^+ release (e.g., Bode and Dortch, 1996).

5.1.1. NH_4^+ regeneration versus DON release

Rates of NH_4^+ regeneration generally exceed DON release as observed in studies in Chesapeake Bay (Bronk *et al.*, 1998; Ward and Bronk, 2001), Monterey Bay (Bronk and Ward, 1999; Ward and Bronk, 2001), the Gulf of Lions (Diaz and Raimbault, 2000), shelf and oceanic waters off Northwest Spain (Varela *et al.*, 2003a), and the Southern California Bight (Bronk and Ward, 2005). In the water column, rates of NH_4^+ regeneration are often significantly correlated ($p < 0.001$) to rates of DON release as observed in Monterey Bay (Bronk and Ward, 1999; Ward and Bronk, 2001), the Southern California Bight (Bronk and Ward, 2005; Ward and Bronk, 2001), and in the oceanic and coastal waters off of Spain (Varela *et al.*, 2003a). To compare NH_4^+ regeneration to DON release, literature values were used to calculate a total DON release rate, defined as the sum of the rates of DON release due to both NH_4^+ uptake and NO_3^- uptake. Total DON release is plotted against the rate of NH_4^+ regeneration for studies in coastal and open ocean systems (Figs. 8.2 and 8.3, Table 8.7); comparable data for estuarine systems were not available due to a lack of DON release rates resulting from NO_3^- uptake. The slope of the linear regression indicates that across several studies, DON release was approximately 24% of the rate of NH_4^+ regeneration (Fig. 8.2 and Table 8.7). Clearly more data are needed at the higher regeneration rates to define the relationship.
Figure 8.2 The relationship between total DON release, which is defined as the sum of DON released as a result of both NH_4^+ and NO_3^- uptake, and NH_4^+ regeneration in coastal and ocean systems. Model II regression parameters are reported in Table 8.7. The line for a hyperbolic function yields the following parameters: $y = 9.429Ln(x)$, $r^2 = 0.53$, $n = 56$. The graph includes data from Monterey Bay, CA (Bronk and Ward, 1999; Ward and Bronk, 2001), the Southern California Bight, CA (Bronk and Ward, 2005; Ward and Bronk, 2001), and the Gulf of Lions, Mediterranean (Diaz and Raimbault, 2000).
Figure 8.3 The log–log relationship between total DON release, which is defined as the sum of DON released as a result of NH_4^+ and NO_3^- uptake, and NH_4^+ regeneration in coastal and ocean systems. Model II regression parameters are reported in Table 8.7. The graph includes data from Monterey Bay, CA (Bronk and Ward, 1999; Ward and Bronk, 2001), the Southern California Bight, CA (Bronk and Ward, 2005; Ward and Bronk, 2001), and the Gulf of Lions, Mediterranean (Diaz and Raimbault, 2000).

Table 8.7 Regression parameters for Figs. 2–4

[a] Rates from coastal and oceanic systems.
[b] Rates from estuarine, coastal and oceanic systems.

5.1.2. Rates of NH_4^+ regeneration in the field

A literature survey of NH_4^+ regeneration rates in oceanic, coastal, and estuarine systems is presented in Table 8.8. Only those rates measured on whole water or the smaller size fraction (i.e., <202 or 370 μm) were used in the calculation of means. In a survey of literature values, the lowest rates were measured in oceanic systems (mean 0.036 μmol N L^{-1} h^{-1}). Within a given study, however, this trend was not always observed. For example, along an ocean to coastal continuum off the coast of Spain, rates of NH_4^+ regeneration tended to be higher in oceanic, relative to coastal, waters (Varela *et al.*, 2003a). Comparisons between systems suggest that rates are highest in coastal waters (0.138 μmol N L^{-1} h^{-1}; note that the very high rates measured in coastal Louisiana (Dortch *et al.*, 1992) were excluded from this average), which is approximately twice that of the mean rate in estuarine waters (0.079 μmol N L^{-1} h^{-1}). Within estuarine systems NH_4^+ regeneration can vary widely along the salinity gradient (e.g., Cotner and Gardner, 1993), but not always. For example, rates of NH_4^+ regeneration measured along a salinity gradient from the Mississippi River to the mid-shelf region of the Gulf of Mexico did not vary with salinity in one study (Bode and Dortch, 1996), while in an earlier study in the same region, NH_4^+ regeneration rates were highest in higher salinity waters (Dortch *et al.*, 1992). Many parameters can affect NH_4^+ regeneration, which could also vary along a salinity gradient, such as phytoplankton standing stock, temperature, and plankton community structure. As a result it is difficult to tease apart the role of salinity itself.

5.1.3. Variables that affect NH_4^+ regeneration rates

A large number of variables can affect NH_4^+ regeneration. As a result it is there are few robust trends across as illustrated below. The size structure of the phytoplankton community can be an important determinant of N regeneration. Larger cells tend to occur in more turbulent areas with higher new N inputs, such as upwelling zones. Smaller cells, in contrast, are more common in stratified environments where primary production runs largely on regenerated N, mainly NH_4^+ (Legendre and Rassoulzadegan, 1995). During periods of low input of new N, grazing by micro and macrozooplankton affects primary production through N regeneration, which can enhance primary production (Gasol and Morán, 1999) as well as consume phytoplankton biomass. As discussed above, large zooplankton can add another level of complexity because they graze on the protozoa, which can be the primary regenerators of N thereby decreasing total N regeneration rates (Caron, 1991).

Due to the close association with grazing, N regeneration is likely to have a diel periodicity associated with the rates. For example, in the Southern California Bight in April, NH_4^+ regeneration rates were higher at night than in the day (Bronk and Ward, 2005). This trend was also observed in three out of four size fractionation experiments in April and five out of six experiments in October in the Southern California Bight (Ward and Bronk, 2001). Day/night differences also likely impact how NH_4^+ regeneration may vary with depth. While some studies observe the highest rates of regeneration near the surface (e.g., Probyn, 1987 in an upwelling zone, Diaz and Raimbault, 2000) other studies show higher release deeper in the water column (e.g., Bode *et al.*, 2002). When NH_4^+ regeneration is measured in the

	Mean	*0.079 ± 0.030*	*Whole water*			

[a] Rates were meausured in April 1997, August and September 1998, and October 1999.
[b] Rates were averaged; when a rate was below the level of detection (0.4 nmol L^{-1} h^{-1}) a zero was included in the calculation.
[c] Rates were measured using 24 h incubations and converted to per hour.
[d] Rates were measured based on concentration changes then the rate of NH_4^+ uptake was added.
[e] Rates were measured in December 1983, October 1984, and March and July 1985.
[f] Extremmely high values from Dortch *et al.* 1992 were excluded from mean. If they were included the mean would be 0.357.
Data are presented as mean ± standard deviation. When data from a given site were reported with several averages and standard deviations, the data were pooled for an overall site average and a new estimate of the standard deviation was calculated using propogation of error. Rates are confined to those measured *in situ* in papers published since 1980. NDL = near detection limits. Many rates were estimated from figures.

light and the dark, in parallel, rates are often higher in the light incubation (e.g., Gardner *et al.*, 1997; Hanson and Robertson, 1988) although, again, this trend is not always observed (e.g., Lipschultz *et al.*, 1986).

Rates of NH_4^+ regeneration can also vary seasonally with higher rates in the spring and summer and lower rates in the fall and winter (e.g., Maguer *et al.*, 1999). In a seasonal study in Chesapeake Bay, however, the highest rates of NH_4^+ regeneration were measured in the fall, relative to the spring and summer, although the rates were highly variable ranging from extremely high (>1.2 µmol N L^{-1} h^{-1}) to unmeasurable (Bronk *et al.*, 1998).

5.2. DON release

The number of studies that have quantified DON release is finally increasing to the point that general trends are emerging, particularly with respect to DON release resulting from NH_4^+ uptake. Here we focus on DON release and the percent of uptake released across systems, release resulting from NH_4^+ versus NO_3^- uptake, and how DON release varies with respect to N uptake, water depth, and diel and seasonal cycles.

5.2.1. Rates of DON release in the field

A literature survey indicates that rates of DON are highly variable but that the average rate of DON release (resulting from NH_4^+ uptake) appears to be lowest in oceanic systems (0.006 µmol N L^{-1} h^{-1}), higher in coastal systems (0.044), and higher still in the one estuary for which there are measurements, Chesapeake Bay (0.074, Table 8.9). This same trend was observed in a transect north and south through the central Atlantic, where rates of DON release, resulting from NH_4^+ uptake, were higher in shelf waters relative to oceanic waters farther offshore (Varela *et al.*, 2006). In contrast, another study along a continuum of stations from coastal to oceanic found that rates of DON release tended to be higher at offshore stations relative to stations nearer shore (Varela *et al.*, 2003a).

5.2.2. DON release versus nitrogen uptake

DON release rates can be compared to two types of uptake rates—gross and net. The rate of gross N uptake is the total amount of N taken up by cells regardless of whether its ultimate fate is PON production or DON production (Bronk *et al.*, 1994). The net N uptake rate is the rate traditionally measured with ^{15}N tracer techniques that only includes PON production (Bronk *et al.*, 1994). As a percentage of gross N uptake, termed percent extracellular release (PER) in many studies, DON release appears similar but slightly higher in coastal (39 to 48%) versus oceanic environments (29–45%; Table 8.9). A similar trend was observed in a north-south transect through the central Atlantic where a larger percentage of gross NH_4^+ uptake was released as DON in shelf relative to oceanic waters (Varela *et al.*, 2006; a gross uptake rate was calculated as the sum of the published NH_4^+ uptake and DON release rate). Within the oceanic sites, however, a higher percentage of NH_4^+ uptake was released as DON at sites classified as oligotrophic (14%), defined as areas

Table 8.9 Rates of dissolved organic nitrogen (DON) release published and ratios of DON release to gross nitrogen (N) uptake, expressed as a percent, in the field. Rates were determined using ^{15}N tracer techniques (^{15}N) or changes in concentrations (CC)

[a] Rates were measured in April 1997, August and September 1998, and October 1999.
[b] Rates were calculated by taking the mean euphotic zone integrate rate and dividing by the mean integration depth.
[c] Percentage was recalculated using gross nitrogen uptake rates.
[d] Percentate was calculated using raw data from manuscript and equations in Slawyk *et al.* (1998).
[e] <10 μm size fraction.
[f] < 202 μm size fraction.
[g] Rate was calculated from uptake and percent release data.
[h] Release was mediated by grazers.
[i] Gross uptake rates were calculated from original data.
Tracer methods include ion retardation columns (IRC) and wet chemical (WC) isolation. Data are presented as mean ± standard deviation. When ranges are presented, the mean % release was calculated using the median value in the range. When data from a given site were reported with several averages and standard deviations, the data were pooled for an overall site average and a new estimate of the standard deviation was calculated using propogation of error. NP = not presented. Many rates were estimated from figures.

with <0.25 µg Chl L^{-1}) relative to those classified as productive (11%; Varela *et al.*, 2006). Similarly, within the shelf sites, the percent of NH_4^+ released as DON was higher at the low productivity sites (23%) relative to high productivity sites (18%; Varela *et al.*, 2006).

Using ^{15}N tracer techniques, rates of DON release are often measured as a result of either NH_4^+ or NO_3^- incorporation. One trend emerging from field data is that a higher percentage of gross NO_3^- uptake is released as DON relative to incubations where NH_4^+ is the substrate (Table 8.9). In oceanic systems 45% of NO_3^- uptake was released as DON while only 29% of NH_4^+ was released, although the errors are large (Table 8.9). The value for DON release from NH_4^+ agrees well with the 27% cited in a review table in Varela *et al.* (2006). In coastal systems 48% of NO_3^- uptake was released as DON relative to only 39% of NH_4^+, but again the errors are large (Table 8.9). Note that the 39% is almost twice that of the 20% cited in the review table of Varela *et al.* (2006). The reason for the discrepancy is the inclusion of estuarine data in their coastal mean. They also included three very low averages from a study in Akkeshi Bay where grazers were purposely excluded (Hasagawa *et al.*, 2000b) that were not included in Table 8.9 because they did not represent *in situ* rates.

Within individual studies this trend of higher percent extracellular release when NO_3^- is used is even more apparent. At six providences in the central Atlantic, the mean percentage of NO_3^- uptake released as DON was 1.7–2.7 times greater than the mean percentage of NH_4^+ uptake released as DON (Varela *et al.*, 2005 and Table 8.9). A higher percentage of NO_3^- uptake was also released as DON, relative to NH_4^+ uptake, in Monterey Bay (Bronk and Ward, 1999) and the Southern California Bight (Bronk and Ward, 2005). This trend is not universal, however, and the reverse was seen in the Gulf of Lions (Diaz and Raimbault, 2000) and in a culture study with *Scenedesmus quadricauda* and *Microcystis novacekii* (Nagao and Miyazaki, 2002). Although published DON release rates are most commonly the result of NH_4^+ uptake, followed by NO_3^- uptake, theoretically DON release could result from uptake of any N substrate—inorganic or organic. Varela *et al.* (2005) used an isotope dilution approach to measure DON release due to urea uptake. Percent release when urea was used tended to be similar to the percent release observed in parallel NH_4^+ incubations (Varela *et al.*, 2005). Most importantly, the fact that multiple substrates can contribute to DON release means that DON release rates measured as a result of just one or two substrates (i.e., NH_4^+ and NO_3^-) likely underestimates the true rate of DON release *in situ*.

Rates of DON release usually correlate well with N uptake. For example, rates of DON release (from NH_4^+) were linearly related to rates of NH_4^+ uptake in the waters off of Spain (Bode *et al.*, 2004b). In a similar fashion, net and gross uptake was positively correlated (linearly) to each other in the Gulf of Lions for both NH_4^+ ($r^2 = 0.93$) and NO_3^- ($r^2 = 0.95$) uptake (Diaz and Raimbault, 2000); the difference between net and gross nitrogen uptake is DON release. This relationship, however, is a function of the methods used to measure DON release. Using the ^{15}N approaches published to date (e.g., Bronk and Glibert, 1991, Slawyk and Raimbault, 1995) the cell must first take up the ^{15}N label thereby making a
Figure 8.4 The log-log relationships between DON release and gross nitrogen uptake for (A) DON release as a result of NH_4^+ uptake and gross NH_4^+ uptake and (B) DON release as a result of NO_3^- uptake and gross NO_3^- uptake. Model II regression parameters are reported in Table 8.7. Graphs include data from Monterey Bay, CA (Bronk and Ward, 1999; Ward and Bronk, 2001), the Southern California Bight, CA (Bronk and Ward, 2005; Ward and Bronk, 2001), the Gulf of Lions, Mediterranean (Diaz and Raimbault, 2000), and six sites in the Central Atlantic (Varela *et al.*, 2005). Graph A also includes data from Chesapeake Bay (Bronk *et al.*, 1998).

release rate measurement dependent on prior N utilization. When data from a number of different studies were combined, log-transformed DON release rates from NH_4^+ and NO_3^- were positively correlated with their respective log-transformed gross uptake rates at the $p < 0.001$ level (Fig. 8.4 and Table 8.7). Varela *et al.* (2006) included a log-transform plot of DON release, from NH_4^+ uptake, and net NH_4^+ uptake for 180 incubations performed in ocean and shelf waters in the Atlantic (data not included in Fig. 8.3). The equation of their regression was log DON release = 0.84 log net NH_4^+ uptake-0.56, $r^2 = 0.76$, $p < 0.001$. Note that their plot used net uptake rates, as opposed to the gross uptake rates used in Fig. 8.4.

5.2.3. Variables that affect DON release rates

Rates of DON release also vary with depth in the water column. DON release rates were generally higher in surface waters and lower at depth in the Gulf of Lions, from both NH_4^+ and NO_3^- uptake (Diaz and Raimbault, 2000), and in the Central Atlantic Ocean when NH_4^+ was the substrate (Varela *et al.*, 2005). In contrast, the reverse was true for DON release resulting from both NH_4^+ and NO_3^- uptake in the Southern California Bight (Bronk and Ward, 2005). When expressed as a percentage of uptake, however, DON release is generally higher deeper in the euphotic zone indicating that deeper in the water column a smaller percentage of the N taken up is incorporated into cells and therefore sinking particles (Bronk and Ward, 1999). This was also observed in rates of DON release measured when NO_3^- was the substrate in the Central Atlantic Ocean (Varela *et al.*, 2005) and as a result of NH_4^+ uptake in the waters off of Spain, where greater than 50% of the NH_4^+ taken up was released as DON deep in the euphotic zone, as compared to surface waters where the percent extracellular release was generally less than 20% (Bode *et al.*, 2004b). This trend was also seen in the cross system comparison conducted for this review. In four coastal and open ocean studies, for which complete data sets were available, there was a higher percentage of gross NH_4^+ and NO_3^- uptake released as DON at the base of the euphotic zone, relative to near surface waters. In near surface waters, the slopes of the regression lines indicate that 13% and 57% of the NH_4^+ and NO_3^- taken up, respectively, was released as DON (Table 8.7). Deeper in the euphotic zone, the percentages increase to 86% and 93% for NH_4^+ and NO_3^- uptake respectively (Table 8.7). Similarly, high rates of urea release are also observed at the base of the euphotic zone (Cho and Azam, 1995).

The question is why would cells lose or release so much of the N that was recently taken up. Bronk and Ward (1999) suggested possible mechanisms that could contribute to higher measured DON release. Higher grazing pressure deeper in the euphotic zone could increase release rates. Similarly, greater rates of viral–induced release or cell death could also enhance release rates. Lower rates of incorporation of recently release DON at the base of the euphotic zone could also lead to higher measured release rates. Bacterial production tends to be lower deeper in the water column (e.g., Carlson and Ducklow, 1996) and concentrations of inorganic N are higher such that reincorporation of recently release DON would not be as likely. Most troublesome is the possibility of a photoprotective futile cycle (Lomas and Glibert, 1999). Cells in a NO_3^-–rich environment, as is common at the base of the euphotic zone in or near the nitracline, may rapidly take up NO_3^- and release reduced compounds as a way of protecting their photosystems when exposed to high light levels. The high light exposure could have occurred when the incubations were being assembled on deck. If this mechanism was operating, high rates measured at the base of the euphotic zone could be an artifact of the experimental protocol. A similar circumstance could occur in nature during deep mixing events, however, when cells in low light, high NO_3^- waters could be mixed up into higher light environments.

The question of a diel periodicity in rates of DON release is still an open one. In the Southern California Bight, rates of DON release from both NH_4^+ and NO_3^- uptake were generally higher at night deeper in the water column, but higher during

the day nearer the surface (Bronk and Ward, 2005). In cultures of both *Scenedesmus quadricauda* and *Microcystis novacekii*, DON release increased in the light relative to the dark (Nagao and Miyazaki, 2002). In Chesapeake Bay, DON release rates in surface waters were highest at dawn and dusk, than during the day, although the difference was not statistically significant (Bronk *et al.*, 1998). Based purely on physiology, phytoplankton do not synthesize the organic C component of DON in the dark, which should lead to lower rates of direct DON release from cells. As a result, when higher rates of DON release are observed in the field at night, it is likely more a function of trophic dynamics, such as zooplankton sloppy feeding or excretion, than direct release by cells.

The fate of N uptake also appears to change seasonally. In Monterey Bay, the primary fate of N uptake is particle production in March but DON production in September, suggesting that the DON pool acts as an intermediate between DIN assimilation and the net formation of particles for export (Bronk and Ward, 1999). In a seasonal study of DON release off the coast of Spain, the percentage of NH_4^+ uptake released as DON was highest during the winter and fall, when rates of primary production were relatively low, and lower during the higher productivity periods during seasonal upwelling (Bode *et al.*, 2004b). Measured rates of DON release are also affected by simultaneous uptake of DON. As a result, this pattern of lower percent DON release during upwelling could be enhanced to some extent by relatively low rates of bacterial DOM consumption during the upwelling period (Varela *et al.*, 2003b). In another study, upwelling appeared to largely control the seasonal and spatial variability in regeneration rates (Varela *et al.*, 2003a). Rates of NH_4^+ regeneration and DON release, integrated throughout the euphotic zone, were at a minimum during upwelling conditions in the summer and at a maximum in early fall (Varela *et al.*, 2003a). With respect to seasonal, temporal, and spatial differences in NH_4^+ and DON release rates, the only statistically significant source of variability was a seasonal component to NH_4^+ regeneration (Varela *et al.*, 2003a). This suggests that in general these rates are governed by biological processes on relatively small spatial and temporal scales.

5.3. Individual organic compounds

In addition to the bulk DON pool, rates of release have also been measured for a suite of individual compounds including urea, DFAA, DCAA and proteins, and nucleic acids. In many respects urea behaves similarly to NH_4^+ though it can be much more variable (e.g., Bronk *et al.*, 1998). Rates of uptake and release of urea can be tightly coupled, as observed in the Bering Sea (Hansell and Goering, 1989). They also tend to be lower than NH_4^+ regeneration, though in one study in Chesapeake Bay urea release rates were high enough to supply over 100% of the phytoplankton N requirement (Bronk *et al.*, 1998). A review of urea regeneration rates in Chesapeake Bay found that mean Bay-wide surface urea regeneration rates are highest but most variable during the fall (Lomas *et al.*, 2002). In the Southern California Bight, urea release in the bacterial size fraction was very high at the base of the euphotic zone (Cho and Azam, 1995). These data suggest that urea is an important intermediate between sinking particles and release of NH_4^+ mediated by bacteria.

Elevated concentrations of dissolved amino acids are often measured during and after phytoplankton blooms (e.g., Børsheim et al., 1999). The copepod *Eucalanus pileatus* was shown to release bursts of DFAA when fed (Gardner and Paffenhöfer, 1982). In another study DFAA release was found to be higher in the presence of copepods (Roman et al., 1988) and bactivory can also result in DFAA release (Ferrier-Pagès et al., 1998b). A number of culture studies have investigated DFAA release. In general, DFAA often accumulate in the media with the highest concentrations present during stationary phase (Poulet and Marin-Jezequel, 1983) while diatoms showed the highest rates of DFAA release during exponential growth (Myklestad et al., 1989). The types of amino acids released from the diatom *Chaetoceros affinis* also changed during exponential growth relative to stationary growth (Myklestad et al., 1989). Marsot et al. (1991) observed an accumulation of glycine, threonine, and serine in cultures of *Phaeodactylum tricornutum*. Sea ice can be a large reservoir for DFAA due largely to their production by ice algae. Concentrations of DFAA in ice were as high as 1.83 µM, which represented 21% of the total DOC in the sea ice (Amon et al., 2001).

Meon and Kirchman (2001) measured DCAA production and degradation rates during phytoplankton blooms in two mesocosms—one with nutrient enrichment and one without. Concentrations of DCAA increase in the enriched mesocosm but not in the unenriched. They concluded that degradation processes, not production, were more important in governing the composition of the DCAA pool. In another study, *Paraphysomonas imperforata* grazing on bacteria released DCAA (Nagata and Kirchman, 1991).

Nucleic acids are another ON pool that has received attention recently. In the North Pacific Subtropical gyre 11–35% of total enzymatically hydrolyzable dissolved DNA (ehD-DNA) production was due to lysis of bacteria (Brum, 2005) indicating that other processes contribute significantly to the ehD-DNA pool; likely candidates were bacterial exudation, bacterial autolysis, and bactivory. Rates of D-DNA production from viruses were lowest at the surface (5 m, 0.019–0.042 ng ml^{-1} h^{-1}), fairly constant within the upper 45 m, and highest at the deepest station sampled (75 m, 0.062–0.120 ng ml^{-1} h^{-1}, Brum, 2005).

5.4. Linking DON release with DOC flux

Release of DON and DOC in short-term incubations is ultimately dependent on primary production and so a positive relationship between DON release and primary production and DOC release could be expected. Similarly, bacteria are often considered the primary users of DON and so an inverse relationship between measured DON release and bacterial production is also likely. To date few studies have investigated these relationships directly, although studies linking DON with DOC release are becoming more common.

A study off northwest Spain measured DON release and primary production in parallel (Bode et al., 2004b). A model II regression of log-transformed data indicated only a weak positive relationship between rates of DON release and primary production (slope = 0.55, r^2 = 0.14, p = 0.023, n = 36) or chlorophyll a concentrations (slope = 1.01, r^2 = 0.13, p = 0.028, n = 36). Log-transformed DON release rates (from both NH_4^+ uptake, NO_3^- uptake and both combined) were plotted

against log-transformed chlorophyll *a* concentrations for the studies used in Fig. 8.4 but no significant relationships were observed.

Similar to DON release, release of DOC as a fraction of particulate and dissolved C production is highly variable in many systems (reviewed in Carlson, 2002), with rates of DOC release generally being higher at the surface (e.g., Bode *et al.*, 2004b). A seasonal study in Chesapeake Bay showed that the ratio of DOC:DON release (from NH_4^+ uptake only) was quiet low in May, August, and October, ranging from 3.4 to 4.5. These low ratios suggest release consisting primarily of N-rich compounds such as DFAA. In a study off northwest Spain, the slope of a linear regression between rates of DOC and DON release (from NH_4^+ uptake only) was 7.4 ($r^2 = 0.867$, $p < 0.001$) again suggesting the release of relatively N-rich compounds (Bode *et al.*, 2004b). At any given depth, however, the DOC:DON release ratio varied widely from ∼5 to 23 at the 100% light depth to ∼1 to 5 at the 1% light depth (Bode *et al.*, 2004b). In another study off the coast of Spain, which experiences seasonal upwelling, the ratio of DOC:DON release (from NH_4^+ uptake only) always exceeded 30 indicating the release of C-rich compounds such as mono-or polysaccharides. High DOC:DON release ratios could also be the result of an underestimation of DON release rates because only release as a result of NH_4^+ uptake was measured. DOC:DON release ratios could also increase due to a rapid reincorporation of the released DON during the course of the incubation; if DON was reincorporated it would not be included in the measured DON release rates. Several studies suggest that DOC release, as a percentage of primary production (i.e., PER), is higher in oligotrophic, relative to more productive, systems (Morán *et al.*, 2002; Nagata, 2000). In a transect through the central Atlantic, a similar trend was observed where the PER of DON release, resulting from NH_4^+ uptake, was higher in oligotrophic waters relative to shelf waters (Varela *et al.*, 2006).

Similar to the situation with primary production, relatively few studies have measured DON release and bacterial production simultaneously. In a transect through the central Atlantic, DON release accounted for <15% of the variability observed in bacterial production rates. In this study, rates of DON release were in excess of the bacterial N requirements in oceanic waters but not in shelf waters. The calculations assumed that only 20% of the recently released DON was labile. While it is true that a large fraction of the DON pool could be composed of refractory compounds (reviewed in Chapter 3 by Aluwihare and Meador, this volume and Bronk, 2002) the DON released in short-term incubations would likely be composed predominantly of labile biomolecules such as amino acids, proteins, nucleic acids, and enzymes. For example, in a study with *Trichodesmium* virtually all of the recently released DON (Glibert and Bronk, 1994) was in the form of amino acids, based on amino acid release measurements performed in parallel (Capone *et al.*, 1994).

6. RECOMMENDATIONS FOR FUTURE RESEARCH

We are only beginning to understand the who, what, and where of regeneration—both in the water column and sediment. With respect to the who—studies are needed that determine the magnitude of release from different trophic levels. In the

water column we need new approaches that will allow researchers to separately quantify release due to direct release by phytoplankton from release mediated by viruses and the various pathways whereby grazers affect release (excretion, sloppy feeding, fecal pellet dissolution). Along these lines, only a handful of studies have examined changes in plankton community trophic structure and resultant changes in N regeneration. While experimentally challenging, the use of mesocosms and other approaches have proved useful in several studies. With respect to the what—more studies are needed to characterize the organic pools released. Though there has been substantial effort directed at characterizing HMW DON, we know relatively little about the range of organic N compounds produced during the different regeneration processes. Studies that address the stoichiometry of release are also needed as we work to define how the different elemental cycles of C, N, and P interact. In particular more studies are needed that measure inorganic and organic release simultaneously. With respect to the where—it is no surprise, given sampling constraints, that rates of N regeneration are best known for coastal surface waters of coastal and near-shore sediments. Little is known of the relative role of different trophic levels in N regeneration in mesopelagic waters, and DON flux rates from sediments, particularly deep sea sediments, are still few and far between. Quantifying sediment DON fluxes is particularly important for accurate N budgets in coastal and estuarine systems because they help constrain processes that are much more difficult to quantify like denitrification.

Land-Based Nitrogen Sources and Their Delivery to Coastal Systems

Sybil P. Seitzinger *and* John A. Harrison

Contents

1. Introduction

Inputs to terrestrial systems of newly fixed N_2 (the conversion of relatively inert N_2 gas to more bioavailable N forms) have more than doubled as a result of human activities including synthetic N fertilizer production, cultivation of legume crops, and combustion of fossil fuels (Galloway *et al.*, 2004; Vitousek and Matson, 1993). A portion of this chemically combined N is transported to coastal waters where it can lead to changes in coastal ecosystem function (e.g. Chapter 18 by Boynton and Kemp, this volume; Deegan *et al.*, 2002; Glibert *et al.*, 2005a; Nixon, 1995; Rabalais *et al.*, 2002; Valiela *et al.*, 1997; Carpenter *et al.*, 1998). Changes in phytoplankton species composition,
Figure 9.1 Land-based sources of N to coastal and marine waters from natural (grey arrows) and anthropogenic (black arrows) sources. Sources of N that contribute to river N export are represented including non-point inputs from atmospheric deposition from natural sources (soil emissions and lightning) and fossil fuel combustion, non-agricultural and agricultural biological N_2-fixation, and synthetic fertilizer and livestock manure; point sources include wastewater treatment facilities. Some portion of watershed N inputs can enter coastal regions directly with submarine groundwater discharge. Atmospheric deposition directly to the surface of coastal and oceanic waters also is a transport pathway of land-based N. Figure created using the IAN symbol library (http://ian.umces.edu).

alteration and loss of seagrass habitats, and increases in carbon fixation, extent and duration of anoxic and hypoxic water, harmful algal blooms, and coral reef degradation are some of the effects associated with excess N inputs to coastal systems (e.g., Anderson et al., 2002; Carpenter et al., 1998; Diaz, 2001; Nixon, 1995; NRC, 2000; Rabalais, 2002) as reviewed in Chapter 11 by Paerl and Piehler (this volume).

Rivers are the major pathway for delivery of land-based N sources from watersheds to coastal systems (Fig. 9.1). In addition, submarine groundwater discharge and direct atmospheric deposition can be important pathways for delivery of land-based N sources. This chapter focuses on export of N by rivers to the coastal zone (i.e., estuaries, bays, continental shelves) and includes investigations of: (1) spatial patterns of river N export, by N form; (2) N sources (natural and anthropogenic) and other factors controlling the form and magnitude of N transport by rivers from watersheds; (3) temporal patterns in river export of N (e.g., inter-decadal, inter-annual, seasonal, events); and (4) effects of human modification of discharge (dams, consumptive water use) on N export. We also include brief discussions of coastal N loading via submarine groundwater discharge and direct atmospheric N deposition to coastal waters. Site specific case studies as well as regional and global perspectives are presented.

We specifically address land-based inputs of N to the coastal zone in this chapter. Biological N_2-fixation occurring within coastal and open ocean regions can contribute substantial additional inputs of N at some times and locations (Chapter 4 by Carpenter

and Capone, this volume; Chapter 22 by Hopkinson and Giblin, this volume). Of particular note is N from oceanic N_2-fixation which is transported onto continental shelves from advection of open ocean waters and can considerably exceed land-based N sources to continental shelves (e.g., Fennel et $al.$, 2006; Seitzinger and Giblin, 1996).

2. Spatial Patterns in Amount and Form of River Nitrogen Export

Biologically available N transported by rivers to coastal systems occurs in several forms. These forms include dissolved inorganic nitrogen (DIN), dissolved organic nitrogen (DON), and particulate nitrogen (PN). DIN is made up of three major components: nitrate (NO_3^-), nitrite (NO_2^-), and ammonium (NH_4^+). DON is operationally defined as organic N that can pass through a filter with a minimum pore size of 0.2–1 µm. PN is the N that is retained by the filter. DON and PN each are composed of complex mixtures of specific N-based compounds, most of which are chemically uncharacterized at the molecular level, although considerable advances are being made (Chapter 3 by Aluwihare and Meador, this volume; Benner, 2002; Bronk 2002; Chapter 8 by Bronk and McCarthy, this volume; Koch et $al.$, 2005; Seitzinger et $al.$, 2005a).

From a nitrogen mass balance perspective, understanding total N export from watersheds to coastal systems may be sufficient. However, information about the various forms of N transported by rivers is important in order to understand factors controlling N export and effects of N inputs on coastal systems. This is because factors controlling export of N from watersheds are not the same for all N forms, as discussed below. Furthermore, different forms of N have different ecosystem effects. For example, all of the DIN pool is generally considered to be bioavailable, while only a portion of river transported DON is readily available for uptake by micro-organisms, including bacteria and some phytoplankton (Bronk, 2002; Seitzinger et $al.$, 2002a). In particular DON is implicated in the formation of some coastal harmful algal blooms (Berg et $al.$, 1997; Glibert et $al.$, 2005a,b; Granéli et $al.$, 1999; Paerl, 1988; 2003). Particulate and dissolved species can have very different impacts on receiving ecosystems. Of course, it is also not sufficient to understand N alone; other bioactive elements (e.g., phosphorus, silica, carbon, etc.) must also be considered in order to fully understand effects of nutrient inputs to coastal systems (Conley et $al.$, 1993; Turner et $al.$, 1998). In this chapter we focus on only N, while recognizing the importance of other elements. Recent global perspectives on river export of P and C can be found in Harrison et $al.$ (2005a,b), Mackenzie et $al.$ (1998), Smith et $al.$ (2003), and Van Drecht et $al.$ (2005).

2.1. Approaches

During the last several decades there have been many studies quantifying and characterizing N export by individual rivers to the coastal zone through direct measurements of N concentrations and water discharge (e.g. Boynton et $al.$, 1995;

Eyre and Pont, 2003; Jordan *et al.*, 2003; Nixon *et al.*, 1995; Wollast, 1983; Table A1). In addition, a number of relatively complex, deterministic models of river nitrogen flux have been developed and applied to individual rivers (e.g., GWLF, Haith and Shoemaker, 1987; Lee *et al.*, 1999; HSPF, Bicknell *et al.*, 1997; Filoso *et al.*, 2004; SWAT, Srinivasan *et al.*, 1993). Several of these, as well as other models, have been described recently in Alexander *et al.* (2002).

However, syntheses of results from individual studies have been rarer. One of the first global syntheses of measurements of river N export, by N form, was by Meybeck (1982). Since then, several databases have been created documenting measured N export from rivers for specific regions (e.g., Alexander *et al.*, 1996—U.S.; Lewis *et al.*, 1999—South America; Holmes *et al.*, 2000—Arctic; UNEP/MAP, 2003—Mediterranean; EEA, 1998—Europe; Table A1) and globally (GEMS-Water Triennial Reports; LOICZ; Meybeck and Ragu, 1995; Peierls *et al.*, 1991; Smith *et al.* 2003). The creation of these databases has highlighted the large variation among rivers, both in terms of N yield (kg N km^{-2} watershed yr^{-1}) and N load (kg N watershed^{-1} yr^{-1}; Table A1), and made it possible to develop a more refined understanding of patterns of N export at local, regional and global scales. For example, regional syntheses of measured N fluxes have characterized rates of N export in the Northeast US (Boyer *et al.*, 2002), Eastern and Gulf US (Castro *et al.*, 2001), and in relatively unimpacted rivers in the Americas (Lewis *et al.*, 1999). These studies have shown that fluxes of TN to the coastal zone can vary substantially on a regional scale and that TN export correlates reasonably well with N inputs to watersheds (Sources contributing to N export are discussed in detail in Section 3).

Development of databases for a wide range of rivers also has made it possible to develop models that are widely applicable without tuning to individual basins. This is particularly important because in many basins around the world there is inadequate observational data on surface water quantity and quality. In some regions, such as the US, the number of river locations monitored (e.g., by the US Geological Survey) for water quality and discharge has decreased dramatically in the past decades; in some other world regions open access to data is still very limited. Progress continues to be made in the development of remote-sensing-based measurements for rivers and streams to obtain continuous data on water discharge (Brakenridge *et al.*, 2005) and automated sensors capable of measuring concentrations of dissolved and particulate constituents (e.g. Johnson and Coletti, 2002). However, until these techniques are substantially improved and widely implemented, we must rely on models to estimate N export from watersheds which have few or no available measurements of nutrient export.

Significant progress has been made in the development and application of spatially explicit regional and global models of N export by rivers to the coastal zone as a function of watershed N inputs and biogeophysical properties (e.g., Alexander *et al.*, 2000; Beusen *et al.*, 2005; Boyer *et al.*, 2006; Caraco and Cole, 1999; Green *et al.*, 2004; Harrison *et al.*, 2005b; Howarth *et al.*, 1996; Jordan and Weller, 1996; Seitzinger and Kroeze, 1998; Smith *et al.*, 2003; Van Drecht *et al.*, 2003). One of the first models to explain N export by a wide range of rivers globally related human population to nitrate export (Peierls *et al.*, 1991). That model was further developed with additional parameters, including nonpoint sources related to agricultural fertilizer use and atmospheric N deposition, point source sewage inputs, and hydrological parameterization (Caraco and Cole, 1999). Global databases of input parameters were then applied which resulted

in the first spatially explicit, global view of DIN export as a function of N inputs to watersheds (Kroeze and Seitzinger, 1998; Seitzinger and Kroeze, 1998; Seitzinger *et al.*, 2002b). A model describing TN export by rivers as a function of atmospheric deposition and net anthropogenic N inputs (NANI model) was developed using data from rivers in the North Atlantic Basin (Howarth *et al.*, 1996). A modified version of the NANI model has now been applied to global databases (Boyer *et al.*, 2006). The SPARROW model (Spatially Referenced Regression on Watershed attributes; Smith *et al.*, 1997) relates TN export by rivers with spatial data on watershed N sources, landscape characteristics, and stream properties. The SPARROW model has been applied to a range of rivers in the US and New Zealand (e.g., Alexander *et al.*, 2000, 2001; McBride *et al.*, 2000). A non-spatial, global model has examined changes in the biogeochemical cycles N, P, C, and S over decadal to century time scales (Mackenzie *et al.*, 1998).

A system of spatially explicit, global nutrient export models has recently been developed by the Global **N**utrient **E**xport from **W**atersheds (Global NEWS) working group (Seitzinger *et al.*, 2005b). The Global NEWS system of models includes models that predict annual average export of DIN, DON, and PN for individual river basins globally (P and C forms are also included). These sub-models are referred to as NEWS-DIN, NEWS-DON and NEWS-PN, respectively. The NEWS-DIN model predicts DIN yield (kg N km^{-2} yr^{-1}) as a function of water runoff, inorganic N fertilizer application, manure N excretion, sewage N inputs, atmospheric N deposition, and biological N_2-fixation (described in detail in Dumont *et al.*, 2005). NEWS-DIN also includes N retention and loss terms such as N retention in river networks, N retention in dammed reservoirs, N loss via consumptive water use, and N removed from a watershed via harvesting and grazing. The NEWS-DON model predicts DON yield (kg N km^{-2} yr^{-1}) as a function of water runoff, inorganic N fertilizer application, manure N excretion, sewage N inputs, and biological N_2-fixation (described in detail in Harrison *et al.*, 2005b). It contains many of the same retention and loss pathways as NEWS-DIN. NEWS-PN is somewhat different in that it predicts PN yield (kg N km^{-2} yr^{-1}) as a function of land-use, precipitation intensity, landscape rugosity, and lithology (described further in Beusen *et al.*, 2005).

2.2. Patterns

According to global model predictions, total N export by rivers at the global scale is approximately 40–65 Tg N yr^{-1} under 1990s conditions (Boyer *et al.*, 2006; Galloway *et al.*, 2004; Green *et al.*, 2004; Seitzinger *et al.*, 2005b; Van Drecht *et al.*, 2003). It is remarkable how small the range of estimates is, given the uncertainties in modeling approaches, global input data bases, and availability and quality of measurements of river TN export. Though this consistency is encouraging, some of it may result from the fact that there is considerable overlap between TN-export datasets used to calibrate each of these models, and some overlap in the input data sets used to apply the models (Van Drecht *et al.*, 2005).

Relatively few large rivers account for a large proportion of the N exported to coastal zones globally for all N forms, based on NEWS model predictions. For example, the 25 rivers with the greatest water discharge globally (<0.5% of the rivers with a watershed >2500 km^2) account for approximately half of the exported DIN and DON, and about a quarter of the exported PN, globally (Table 9.1). Some of

Table 9.1 The largest 25 rivers (in order of decreasing annual discharge; Meade 1996 Milliman and Meade 1983), river watershed areas, river discharge estimates, and NEWS-model-estimated DIN, DON, PN, and TN (Total exports from the 25 largest rivers and the percent of total global export for which these rivers account are also shown, $Tg = 10^{12}$ g)

the highest rates of TN export (>100 Gg N yr^{-1}) by individual rivers occur in Europe and southern and eastern Asia, although high export is also predicted for a number of rivers in North America, Africa, and South America (Fig. 9.2). The highest rates of TN export are often, although not always (e.g., Amazon), estimated to occur in large rivers with substantial anthropogenic N inputs.

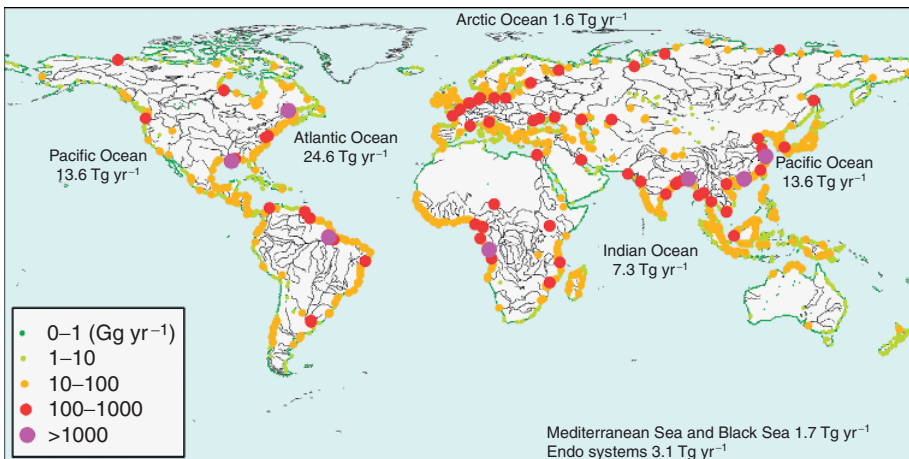
If we distinguish N export by form, at the global scale, DIN and PN export are approximately equal in magnitude ($\sim$25 Tg yr^{-1} and 30 Tg yr^{-1}, respectively), with


Figure 9.2 Modeled river TN export to coastal areas from Van Drecht *et al.* (2003). Gg = 10^9 g and Tg = 10^{12} g.
Figure 9.3 Globally, approximately 270 Tg of newly fixed N enters terrestrial soils each year from biological N_2-fixation (natural and agricultural), lightning, combustion of fossil fuels (leading to increased atmospheric N deposition), and synthetic fertilizer use as of the mid-1990s (Galloway *et al.* 2004). According to NEWS-model-predictions, 65 Tg N yr^{-1} of the N entering soils is exported by rivers to coastal systems as DIN, DON, and PN (Beusen *et al.*, 2005; Dumont *et al.*, 2005; Harrison *et al.*, 2005b). We estimate that ∼15 Tg of the river N is discharged by large rivers directly to the continental shelves. The other 50 Tg of river N enters estuaries, of which ∼38 Tg is then exported to continental shelves. Units: Tg N yr^{-1} (Tg = 10^{12} g).

each accounting for approximately 40% of the global TN export, according to NEWS-model-predictions (Fig. 9.3). In contrast, global DON export is substantially less (∼12 Tg yr^{-1}), and accounts for approximately 20% of TN export. (The C exported in the dissolved organic and particulate matter amounts to 170 and 197 Tg C yr^{-1}, respectively, according to NEWS model predictions—Harrison *et al.*, 2005b; Beusen *et al.*, 2005). There is, however, substantial spatial variability in both the magnitude and form of N exported to the coastal zone (Table A1; Fig. 9.4).

There are a number of hot-spots and cold-spots for N yield (N export per km^2 watershed) that are consistent across all N forms. For example, regions with high runoff such as northern South America, tropical West Africa, and Indonesia have high predicted yields for DIN, DON, and PN (Fig. 9.4) (Seitzinger *et al.*, 2005b). Conversely, arid regions such as the southwestern US, Northern Africa, and Australia all have low predicted yields for all N forms.

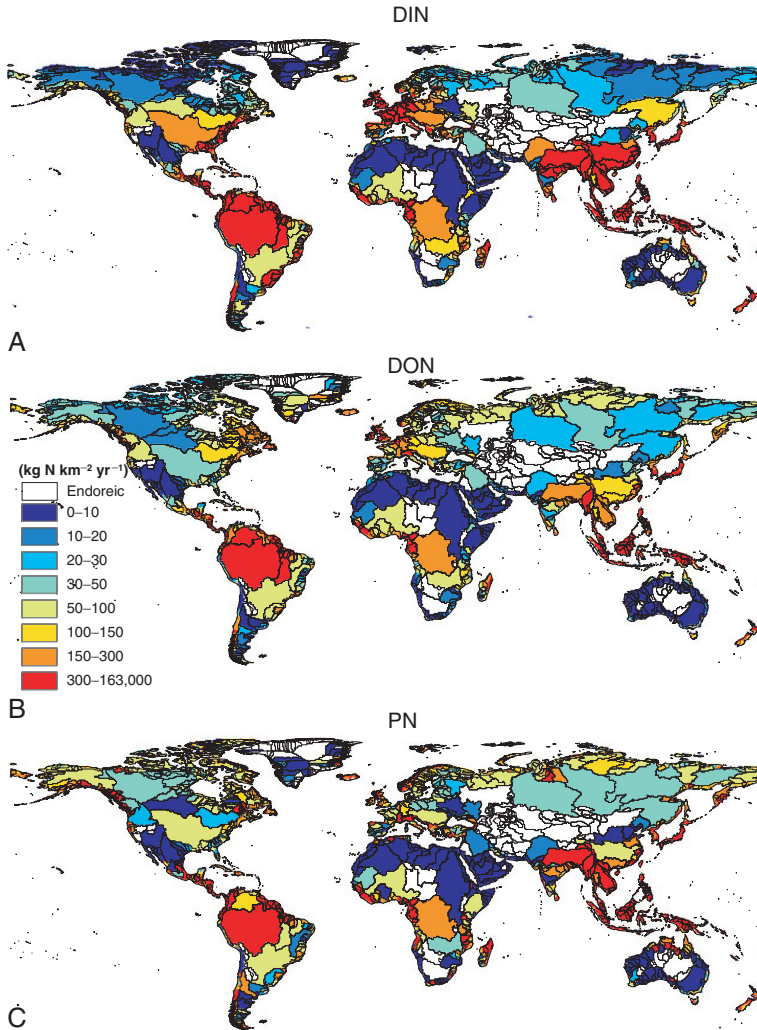
Substantial differences in the magnitude of export of the N forms are observed in many regions. For example, regions with high rates of human activity such as the NE US, Western Europe, and China all have high predicted rates of DIN export, but relatively lower predicted rates of DON and PN export (Fig. 9.4). South Asia and Southeast Asia have high predicted rates of DIN and PN export, but generally lower


Figure 9.4 NEWS–model–predicted (A) DIN, (B) DON, and (C) PN yield (kg N km^{-2} yr^{-1}) for 0.5 × 0.5 degree (latitude × longitude) or larger river basins globally for mid-1990's conditions. Model output replotted from Beusen *et al.* (2005), Dumont *et al.* (2005), and Harrison *et al.* (2005b).

predicted rates of DON export. High predicted DIN yields in these regions are likely due to the high rates of human activity in these regions and the high predicted PN yield is likely due to the mountainous nature of the region. Basins where DON constitutes the largest pool of exported N are widely distributed, with a slight tendency to occur more frequently in northern boreal basins (Figs. 9.4 and 9.5).

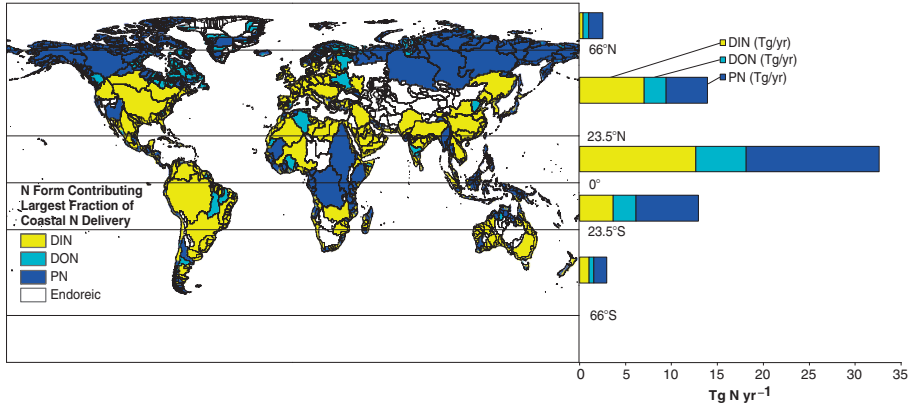
When we aggregate predicted N export by latitude, several interesting patterns emerge. DIN constitutes the largest single form of N exported to coastal zones in north temperate regions, but PN constitutes the largest fraction of exported N from the rest of the world's latitudinal regions (Fig. 9.5; Table 9.2). The greatest fraction


Figure 9.5 DIN, DON, and PN export to the coastal zone by latitude (mid-1990s). Dominant forms are shown by basin in map, and magnitudes of coastal TN export are represented by size of bars to right of map. Global map has been slightly distorted to make room for bar graph to right. Model predictions taken from Beusen *et al.* (2005), Dumont *et al.* (2005), and Harrison *et al.* (2005b).

Table 9.2 DIN, PN, DON, total N (TN) export (Tg N yr^{-1}) by rivers, and exoreic land surface area (10^6 km^2) for tropical (0°–23.5°), temperate (23.5°–66°), and polar (66°–90°) latitude bands and global totals, based on Global NEWS model predictions for mid-1990s (for spatially explicit representation of data, see Figs. 6.4 and 6.5)

Latitude band	DIN (Tg N yr^{-1})	DON (Tg N yr^{-1})	PN (Tg N yr^{-1})	Total N (Tg yr^{-1})	Surface area (10^6 km^2)
Arctic (66°N–90°N)	0.4	0.6	1.6	2.5	17.0

North Tropical (0°–23.5°N)	12.6	5.7	14.5	32.6	27.6
South Tropical (0°–23.5°S)	3.7	2.5	6.8	12.9	15.0
South Temperate (23.5°S–66°S)	1.0	0.6	1.4	2.9	10.8
Totals	24.8	12.1	28.6	64.9	114.1

of exported N occurring as DON is in arctic latitudes, where approximately a quarter of the exported N is DON. DON constitutes a somewhat smaller proportion of N exported from other latitudinal bands (17–20%). Although most of the exoreic land surface area is located in the north temperate latitude band, the greatest rates of N export for all N forms occur in the north tropical latitude band (Table 9.2; Figs. 9.4 and 9.5). This is due largely to the high rates of water runoff in tropical

regions, though in many regions high levels of human activity also play an important role (Seitzinger *et al.*, 2005b). The above discussion of the differences in the spatial patterns of river export of the various N forms demonstrates the need to explicitly include parameterization of the different N forms in watershed N export models.

Where does the river N enter the coastal zone? Some rivers discharge into estuaries while others (primarily large rivers) discharge directly to continental shelves (e.g., Mississippi, Zaire). Of the river N entering estuaries, a portion is permanently removed within the estuary by denitrification or burial, with the remainder exported to continental shelves. How much of river transported N enters estuaries and how much reaches continental shelves? Using NEWS model predictions of global river TN export (DIN + DON + PN = 65 Tg TN yr^{-1}) and arguments presented in Seitzinger *et al.* (2006), we estimate the following distribution. Rivers discharge 50 Tg N yr^{-1} to estuaries and 15 Tg N yr^{-1} (from large rivers) directly to continental shelves (Fig. 9.3). Estuaries export 38 Tg N yr^{-1} of their river N to continental shelves, bringing total inputs of river N to continental shelves to 53 Tg N yr^{-1}. Therefore, estuaries (directly) and continental shelves (directly plus indirectly) receive about equal amounts of river N. Most of the river transported N does not enter the open ocean, but is denitrified in estuarine and continental shelf sediments (reviewed in Seitzinger *et al.* 2006).

3. Sources of Nitrogen and Factors Controlling Nitrogen Export

Both natural and anthropogenic factors are important in controlling among-watershed differences in DIN, DON, and PN export. Natural N sources include N$_2$-fixed by lightning and biological N$_2$-fixation (Fig. 9.1). Prior to recent anthropogenic increases in N fixation, the amount of naturally fixed N washed into surface waters was likely controlled by a mixture of biological N$_2$-fixation rates and hydrology, with high rates of runoff transferring a relatively large proportion of the naturally fixed N into surface drainage waters. The tight coupling between runoff and N export in relatively unimpacted tropical and temperate rivers supports this conceptual model (Lewis *et al.*, 1999). Major anthropogenic sources of fixed (bioavailable) N inputs to watersheds include inputs of newly fixed N from agricultural sources (inorganic fertilizers and biological N$_2$-fixation by crops) and atmospheric N deposition, as well as recycled N from animal manure, human sewage, and industrial sources.

3.1. Approaches

Nitrogen isotope studies and watershed modeling are two approaches that have been used to identify the contribution of different watershed sources of N to river N export. For example, differences in the δ^{15}N signature of biogenic (plants, soils) and lithogenic (rock) PN has been used to infer that biogenic sources accounted for only ~10% of the total PN exported from the mainstem of the Lanyang-His River in Taiwan (Kao and Liu, 2000). The δ^{15}N signature of nitrate has been used to indicate differences in N

sources in watersheds (e.g., Billen *et al.*, 2005; Böhlke *et al.* 1997; Mayer *et al.*, 2002). For example, increases over time in the δ^{15}N signature of nitrate in groundwater beneath agricultural land were used to relate increases in groundwater nitrate concentration to a change in the sources of N for crops from biological N_2-fixation plus mineralization to primarily synthetic fertilizer (Böhlke 2002). δ^{15}N signatures were used to demonstrate a strong link between N in estuarine organisms and land-based anthropogenic N sources in several shallow coastal systems in the Northeast US (Martinetto *et al.* 2006; McClelland and Valiela, 1998; see also Montoya, this volume).

Another approach to estimating the relative importance of N sources within a watershed entails the use of models. Models have been used to estimate the relative importance of various land-based N sources at basin, region and global scales. Numerous models have been developed for use in individual watersheds (e.g., Alexander *et al.*, 2000; Billen *et al.*, 2001; Donner *et al.*, 2004; Lee *et al.*, 1999; Valiela *et al.*, 2000). Though these models are useful for the watersheds to which they have been tuned, it is problematic to apply these models to address regional and global scale questions as the input data required for these models are often unattainable at regional and global scales. Furthermore, they often require coefficients to be tuned to specific system types through sampling programs that would be resource-prohibitive at the regional or global scale.

Regional scale modeling analyses have been done for 15 watersheds in the NE US (Boyer *et al.*, 2002), 31 watersheds in the eastern and Gulf coasts of the US (Castro *et al.*, 2001), and for the coterminous US divided into 15 regions (Jordan and Weller 1996). These analyses were limited to predicting export of TN only or nitrate only, not individual N forms, and examined the magnitude of various N sources to those watersheds but did not explicitly estimate the contribution of each source to the river export. Due to different rates of retention of N sources in watersheds, relative inputs of different N sources are not equal to their relative contributions to N export. However, insights from these studies are still quite useful. In addition to these regional studies, the recent development of global nutrient export models (such as the NEWS and some of the other models described in section 2) has made it possible to estimate the spatial distribution of the contributions of various land-based N sources to coastal N export globally.

3.2. Patterns

In their regional modeling analysis, Boyer *et al.* (2002) found that TN sources to watersheds varied substantially throughout the NE US. However, averaged across all the 15 study watersheds, atmospheric N deposition constituted the greatest N input (31% of total N inputs); net inputs of food and feed constituted the second largest source of N to these watersheds (25%), followed by agricultural N_2-fixation (24%), fertilizer use (15%), and forest N_2-fixation (5%) (Boyer *et al.*, 2002; Driscoll *et al.*, 2003). Castro *et al.* (2001) found similar patterns for TN sources to NE watersheds, but also found that sources of TN to watersheds differed substantially by region, with N fertilizer being substantially more important in mid-Atlantic, Southeastern, and Gulf Coast watersheds than in Northeast US watersheds.

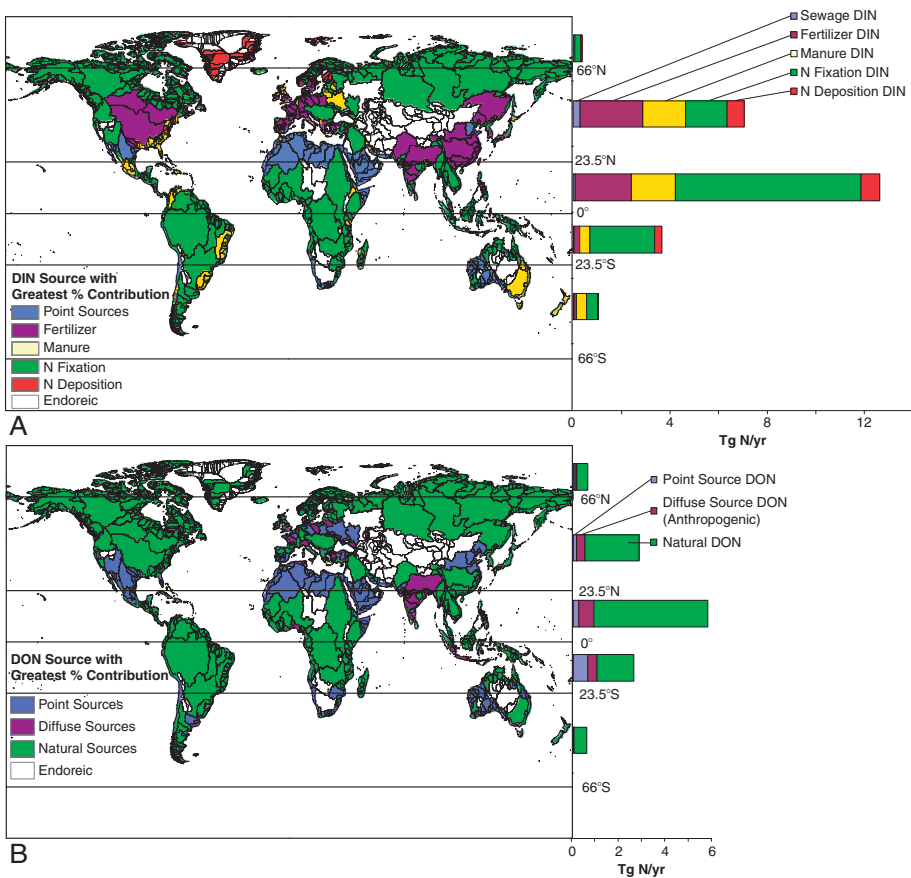
At the global scale, it is possible to use NEWS models to make several predictions regarding watershed N sources driving the regional patterns of N export. First, human activity is estimated to be responsible for approximately 60% of the global export of DIN to coastal zones and has significantly increased DON export in many regions as well (Dumont *et al.*, 2005; Harrison *et al.*, 2005b) (Fig. 9.6; Tables 9.3 and 9.4). Total anthropogenic point and non-point sources of DON in rivers are estimated to be over three times greater in the tropics (1.85 Tg N yr^{-1}) than temperate latitudes (0.51 Tg N yr^{-1}) and account for a larger proportion of total DON (Table 9.4). Despite the massive scale of human intervention in the N cycle that has altered the input and transport of N by rivers (and the atmosphere) to coastal zones, natural sources still dominate the export (i.e., are the single largest


Figure 9.6 Dominant sources of N to the coastal zone by 0.5 × 0.5 degree or larger basin and relative contributions of sources of exported DIN and DON by latitude band as predicted by NEWS-DIN (A) and NEWS-DON (B). Global maps have been compressed horizontally to fit both map and bar graph in same figure. For actual values of predicted DIN and DON, see Tables 9.3 and 9.4. Model predictions have been reprocessed from Dumont *et al.* (2005) and Harrison *et al.* (2005b).

Table 9.3 DIN sources: contribution of N sources in watersheds to the global DIN export by rivers by latitude bands and global total, as predicted by Global NEWS models for mid-1990s (Units: Tg N yr^{-1})

source) of DIN, DON, and PN from many watersheds in Arctic regions and in much of South America and Africa (Fig. 9.6). In the case of DON, natural sources still account for approximately 80% of export globally (Harrison *et al.*, 2005b).

Fertilizer is estimated to be the single most important source of exported DIN in north temperate latitudes, contributing 37% of the exported DIN, according to

NEWS-DIN (Fig. 9.6; Table 9.3). N_2-fixation was estimated to be the largest contributor in tropical and Arctic regions, responsible for over half of the exported DIN in each region. N_2-fixation is estimated to contribute the smallest proportion of exported N in the industrialized north temperate range (~24%). Manure was estimated to contribute a relatively small fraction of exported DIN (11–25%) in most latitude bands, but was estimated to contribute a substantial proportion (39%) of the exported DIN in the south temperate range. N deposition was most important in the Arctic, contributing an estimated 14% of the exported DIN, and least important in the south temperate range (5%). When examined at the level of large latitudinal regions, sewage point sources constituted a fairly small fraction of exported DIN and DON (<5% and <10%, respectively). However, in individual basins, sewage point sources can dominate DIN and DON export (Fig. 9.6). Most of the point-source-dominated basins are arid, and therefore have very small predicted rates of diffuse source (natural or anthropogenic) N input (Fig. 9.6).

It is important to note that often only a relatively small percentage of the total N inputs to the landscape are exported by rivers to the coast. Data from a variety of coastal watersheds throughout the world, indicate that, on average, approximately 25% of total net nitrogen inputs from anthropogenic plus natural sources is exported by rivers as TN to the coast (Boyer et al., 2006; Fig. 9.3). Similarly, estimates for watersheds throughout the North Atlantic Basin suggest that about 25% of anthropogenic N inputs are exported by rivers (Howarth et al., 1996). There can be considerable variation among basins in the percentage of N inputs that are exported by rivers. For example, the percentage of N loaded onto basins from point and non-point sources (both anthropogenic and natural) that is exported as DIN ranged from 0.0001% to 43%, based on NEWS-DIN model predictions (Dumont et al., 2005). Rivers which exported the largest fraction of their watershed N inputs had high water runoff (>1 m yr^{-1}); rivers exporting the smallest fractions had extensive damming or very low annual precipitation and runoff. According to NEWS-DIN, in exoreic dry areas of Africa, Asia, Australia, and North America where runoff is less than 0.1 m yr^{-1} (30% of the exoreic world), only 5% (on average) of N applied to watersheds is exported to coastal waters as DIN. Export from these arid systems is predicted to be low because there is very little runoff to transport soluble nitrogen (nitrate) from the soil and unsaturated zone to streams.

A number of caveats must be considered in the discussion of large–scale patterns of N sources. There is considerable variation among watersheds in a region in the relative importance of various N sources. Global models primarily focus on relatively large basins (25,000 km^2). These large watersheds account for ~72% of global water discharge and 79% of exoreic land area and thus likely a large proportion of N export. However, small coastal watersheds drain most of the coastline globally. For example, out of 6152 watersheds identified globally in a simulated topological network (STN-30p), 93% of them are entirely contained in coastal grid cells (0.5° latitude × 0.5° longitude) that are immediately adjacent to an ocean (Vörösmarty et al., 2000). Therefore, while small coastal watersheds may not appear to contribute much coastal N at regional and global scales, they are very important in determining rates and patterns of N delivery to many of the world's estuaries, and thus important in affecting coastal ecosystems and water quality where much of the world's population lives.

4. Temporal Patterns in River Export of Nitrogen

Temporal variability of river N export spans a range of scales from geological (e.g., glacial, inter-glacial) to hourly. On human time scales, long-term trends occur over decades associated with changes in anthropogenic N inputs to watersheds (Meybeck, 2003), inter-annual variability can be associated with differences in weather patterns, and intra-annual variability occurs on seasonal, diurnal and event (e.g. storm) scales. Variability on all of these scales can affect the response of coastal ecosystems to N inputs (Deegan *et al.*, 2002; Grenz *et al.*, 2000; Chapter 11 by Paerl and Piehler, this volume).

4.1. Long-term trends

Long-term (multi-decadal) records of N export from watersheds are rare and generally limited to nitrate (see also Boynton and Kemp, this volume). In general, human-impacted rivers demonstrate higher NO_3^- loads than non-impacted rivers, and the NO_3^- loads increase over time as anthropogenic N inputs to those watersheds increase. For example, an approximately 30-year record for the Yangtze River (Changjiang River), China, demonstrates a more than ten-fold increase in NO_3^- export as human population and agricultural activity have increased in the watershed (Yan *et al.*, 2003) (Fig. 9.7). Several-fold increases in NO_3^- export have also been observed in the Mississippi (Goolsby and Battaglin, 2001), Seine (Billen *et al.*, 2001), Scheldt (Billen *et al.*, 2005), and Susquehanna (Hagy *et al.*, 2004) basins associated with changing anthropogenic watershed activities (Fig. 9.7). In contrast, as expected, relatively stable NO_3^- export is observed in basins with relatively low and stable levels of human activity, such as in the Yukon and S. Dvina Rivers (Alexander *et al.*, 1996; Holmes *et al.*, 2000) (Fig. 9.7).

At the global scale, TN river export to coastal systems is estimated to have approximately doubled between 1860 and 1990, due to anthropogenic activities on land (Galloway *et al.*, 2004). Over the next 50 years the human population is predicted to increase markedly in certain world regions, notably Southern and Eastern Asia, South America, and Africa (United Nations, 1996). Growing food to feed the expanding world population will require increased use of nitrogen and phosphorus fertilizers (Alcamo *et al.*, 1994; Bouwman, 1997; Bouwman *et al.*, 1995). Increased industrialization, with the associated combustion of fossil fuels and NO_x production, is predicted to increase atmospheric deposition of N (Dentener *et al.*, 2006; IPCC, 2001). Thus, unless substantial technological innovations and management changes are implemented, increasing food production and industrialization will undoubtedly lead to increased export of N to coastal ecosystems (Galloway *et al.* 2004), with resulting water quality degradation. For example, inorganic N export to coastal systems is predicted to increase 3-fold by the year 2050 (relative to 1990) from Africa and South America (Fig. 9.8) (Kroeze and Seitzinger, 1998; Seitzinger *et al.*, 2002b). Substantial increases are predicted for Europe (primarily from eastern Europe) and N. America. Alarmingly large absolute increases are predicted for eastern and southern Asia; almost half of the total global increased N export is predicted for those regions alone.
Figure 9.7 NO_3^- yield (kg N km^{-2} yr^{-1}) trends for three human-impacted rivers (Seine, Mississippi, and Yangtze), and two relatively non-impacted rivers (Severnaya Dvina and Yukon). (Alexander *et al.*, 1996; Billen *et al.*, 2001; Goolsby and Battaglin, 2001; Holmes *et al.*, 2000; Yan *et al.*, 2003).
Figure 9.8 Predicted increases in DIN export to coastal systems between the years 1990 and 2050 under a business–as–usual (BAU) scenario. Modified from Kroeze and Seitzinger (1998).

Increases in river N export over time often correlate relatively well with increases in N inputs to watersheds. However, the response of river N export to *decreases* in watershed N inputs is not necessarily as rapid or well understood. In at least one case, the Patuxent River (MD, USA), point source reductions in N resulted in rapid reductions in N export (Boynton *et al.*, 1995; Jordan *et al.*, 2003). However, N export is generally dominated by non-point sources, not point sources (Carpenter *et al.*, 1998; Dumont *et al.*, 2005; Seitzinger *et al.*, 2005b; others), so substantially reducing N export often requires a reduction in non-point N inputs. Reductions of non-point nutrient inputs have been attempted in a number of systems, but response of river N export to these reductions is often much slower and less predictable than responses to reductions in point sources (Stålnacke *et al.*, 1999).

The complex response of N export to nonpoint reductions is well illustrated by Eastern European rivers. Despite a drastic reduction in fertilizer use and animal production as a result of the economic decline in the former Soviet Union and in Eastern Europe in the early 1990's, DIN concentrations showed statistically significant downward trends in only 4 of 12 sites studied in Latvian Rivers (study period 1987–1998) (Stålnacke *et al.*, 2003). No decreases were reported in nitrogen export from major Eastern European rivers such as the Vistula and Oder Rivers in Poland (1989–1995) (Stålnacke, 2005) or the Danube River (at Reni; 1995–2000) (Behrendt *et al.*, 2005a). Only moderate decreases in TN or nitrate export by the Elbe River to the North Sea were measured (1985–2000) (Hussian *et al.*, 2004). A number of factors have been proposed to explain the weak response of river N export to decreases in diffuse sources of N in the watersheds, including the long-water transit times of water in soils and in aquifers and continued mineralization of the large pools of organic N which have accumulated over time in soils. The above examples demonstrate the uncertainty in our knowledge of the response of river N export to decreases in N inputs to watersheds after prolonged periods of high inputs and the need for future research.

4.2. Interannual variability

In addition to long-term trends, there is also substantial inter-annual variation in N export (Fig. 9.7). There are several potential causes for this inter-annual variability, including: year-to-year variation in climate, variation in N inputs, changes in land-use, or changes in the relative timing of N application and runoff events. For example, inter-annual variation in climate is a major factor affecting river water discharge, and discharge is an important variable controlling non-point N (natural or anthropogenic) export. This is observed in the long-term pattern (1945–2001) of nitrate export by the Susquehanna River to Chesapeake Bay which was strongly affected by inter-annual and inter-decadal differences in river discharge (Hagy *et al.*, 2004). Similarly, in the Odra River inter-annaual variation (1960–2000) in DIN load and discharge showed similar patterns (Behrendt *et al.*, 2005b). It is not clear whether the positive relationship between discharge and N export is simply due to increased hydrologic connectivity between potential N sources and flowing surface waters under wetter conditions or whether higher discharges also reduce N removal by denitrification in the river and on the landscape. The overall effect of water

discharge on DIN, DON, and PN export is indicated by the importance of water discharge as an explanatory variable in models that predict N export (TN as well as each of the N forms) across a wide range of rivers/watersheds globally (Caraco and Cole, 1999; Dumont et al., 2005; Harrison et al., 2005b; Smith et al., 1997; Smith et al., 2003). This is consistent with analysis of data from 16 major watersheds in the Northeastern US in which watersheds with higher discharge exported a greater fraction of the net anthropogenic N inputs (Howarth et al. 2006). Future changes in water discharge in various world regions are predicted in response to changing climate (due to natural and anthropogenic effects). Already, increases in water discharge in the 6 largest Eurasian Arctic rivers which appear to be related to global warming have been documented (7% from 1936 to 1999) (McClelland et al., 2004; Peterson et al., 2002); the effect of such changes in river flow on N export in these rivers is under investigation. A preliminary estimate of the effect on TN export of increases in precipitation and discharge due to future climate change indicated that TN export by the Susquehanna River to Chesapeake Bay might increase by 3–17% by 2030 and by 16–65% by 2095 (Howarth et al., 2006).

It is possible to examine the relationship between climate and N export by de-trending long-term data and evaluating the strength of the relationship between de-trended N export and water discharge via regression analysis. When this analysis is done, we find that discharge exerts a relatively strong effect on NO_3^- export in some rivers, explaining approximately half of the variability in NO_3^- export from the Mississippi and Yukon River basins. This is similar to what others have found for the Mississippi using other approaches (Goolsby and Battaglin, 2001). However, curiously, in other rivers (e.g. the Yangtze, Seine, and Severnaya Dvina), there is little or no detectable relationship between water discharge and NO_3^- export through time, even when changes in N inputs are accounted for.

4.3. Seasonal variability

The response of coastal ecosystems to river nutrient inputs depends, in part, on the seasonal pattern of the N delivery, including seasonal changes in the form of N delivered (e.g., DIN, DON, and PN). Most studies of river nutrient export only report annual rates and often only report TN export. Where seasonal patterns of N export by individual river basins have been reported, a number of patterns have been observed, and the different forms of N can exhibit different patterns of export (e.g., Alexander et al., 1996; Eyre and Pont, 2003; Lesack et al., 1984) (Figs. 9.9 and 9.10). Seasonal patterns are observed in both N concentration and in N export (Fig. 9.10).

One might expect that river nutrient export from point sources would show a constant export rate, with concentration varying inversely with discharge, while rivers dominated by diffuse N sources would show an export rate more directly related to discharge with less variation in concentration with discharge (Billen et al., 2005). However, to our knowledge this dynamic has not yet been demonstrated across a broad range of rivers, or with consideration of the N form. Seasonal patterns of river nutrient export may be complicated by seasonal variations in biological retention (plant uptake) or removal (e.g. denitrification) within soils or within the
Figure 9.9 Mean annual N load for the Mississippi River at Belle Chase, LA (1979–1981), by N form, including total nitrogen (closed triangles), dissolved inorganic nitrogen (open circles), dissolved organic nitrogen (closed circles), and particulate nitrogen (open triangles) (Alexander *et al.*, 1996). Units: metric Ton N day^{-1}.

river network. Extremes of river discharge with season, such as occur in monsoonal regions, would be expected to greatly affect river N export. The natural seasonal cycle of N export can also be markedly dampened by dams such as demonstrated in California's Mokelumne River, as compared to a similar, but undammed neighboring river (Ahearn *et al.*, 2005). In this case, dams shifted the pulse of nitrate export from winter to summer, and distributed the winter pulse of TN evenly throughout the year.

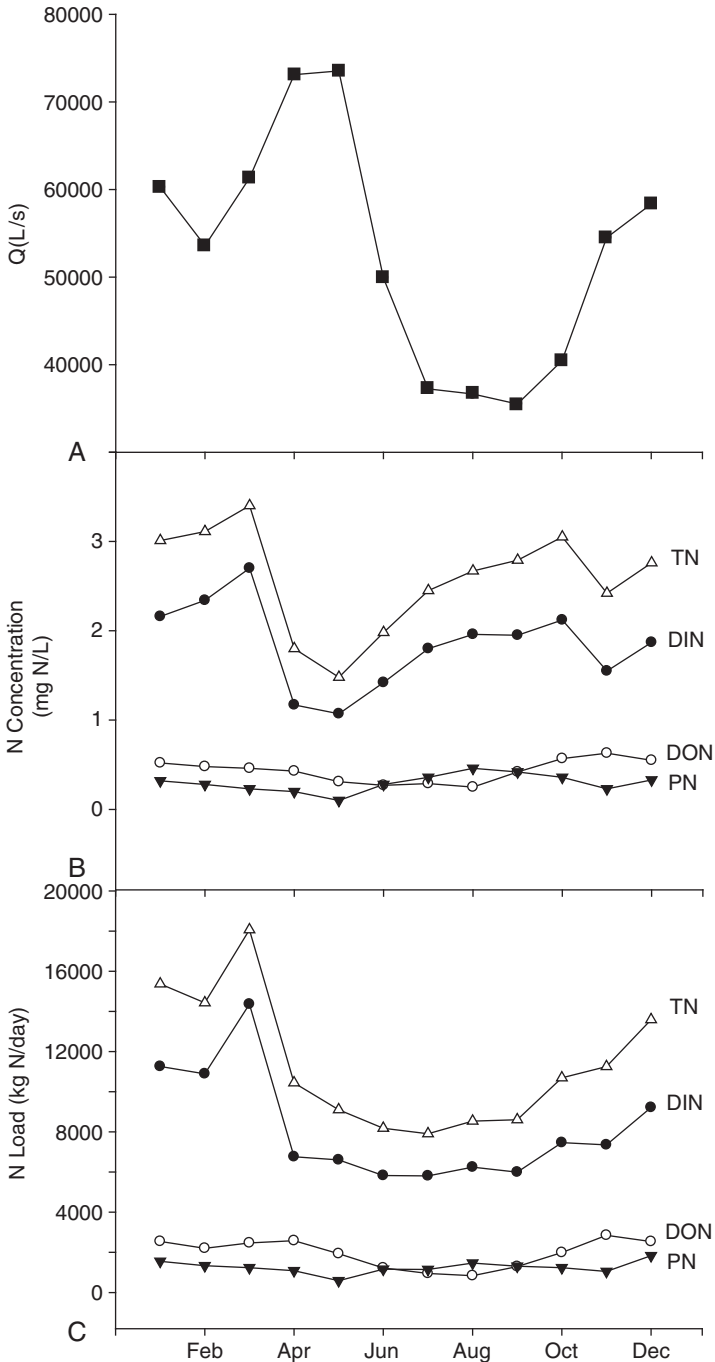
Despite a general lack of synthetic understanding regarding seasonal dynamics of N export from rivers, some initial work has been done at the global scale to estimate seasonal patterns of TN export by world rivers. Green *et al.* (2004) simply distributed annual river TN export for individual rivers based on the pattern of monthly water discharge (Fig. 9.11). This approach suggests that Arctic rivers exhibit the largest TN export during the summer (June–August). Many Northern Hemisphere temperate latitude rivers are predicted to have highest TN export during winter (December–February) or spring (March–May), according to this approach. A comparison of the seasonal pattern of model predicted TN export for the Mississippi River (Fig. 9.11) with measured export (Fig. 9.9) suggests that, at least for this river, discharge alone can capture the major patterns in seasonal variation of TN export. Additional analyses we have conducted for the Sacramento, San Joaquin, and Yukon Rivers are consistent with the above, suggesting that, while the absolute magnitude of N export is highly dependent upon watershed N inputs, the overall seasonal patterns in TN export can be relatively well predicted from the seasonal pattern in river water discharge. However, the pattern in other rivers is not as straight forward and will require more comprehensive analyses.


Figure 9.10 Seasonal discharge and N dynamics in the San Joaquin River (California, USA). Monthly average discharge (A), DIN (closed circles), DON (open circles), TN (open triangles), and PN (closed, inverted triangles) concentrations (B), and loads (C) are shown. Data from 2001–2002 (Kratzer *et al.*, 2004).
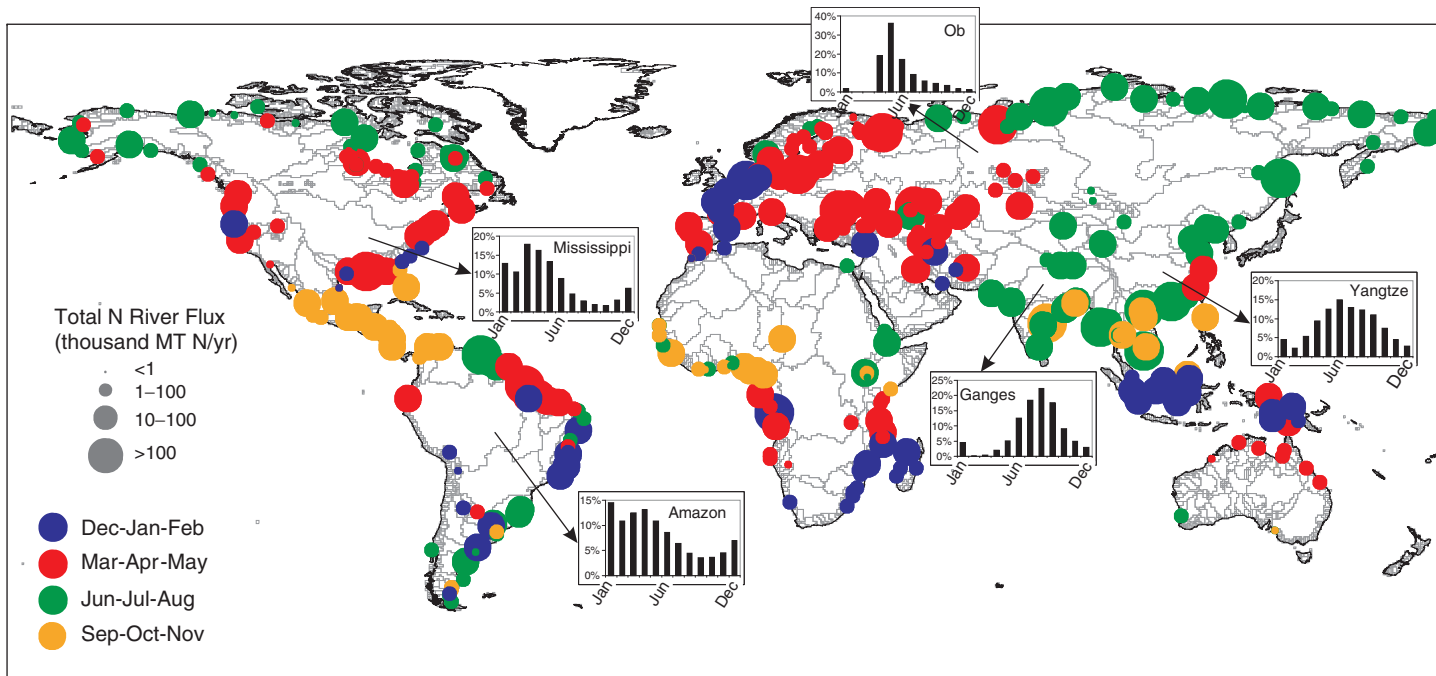

Figure 9.11 Global seasonal patterns of N export as predicted using hydrology alone. Hydrographs of five large, representative rivers are shown. Reprinted with permission from Green *et al.* (2004).

4.4. Diel variability

Shorter term variations in nutrient export due, for example, to diel variations in N processing, can also be significant and may affect coastal ecosystem processes. A study in the highly productive, subtropical Yaqui Valley region in Mexico suggests that night-time anoxia can shut down nitrification and coupled nitrification–denitrification, thereby substantially changing the amount and form of exported N on a time-scale of hours (Harrison *et al.*, 2005c). Similarly, a study of three rivers in the Midwest US showed a decrease in denitrification during the night (Laursen and Seitzinger 2004). The San Joaquin River, a highly productive river in California, also exhibits pronounced diel fluctuations in N concentrations and dynamics (Dahlgren, personal communication). In the case of the Mexican stream, the authors estimated that failing to measure night-time N fluxes would lead to a 17–38% underestimate of N export during their 24-h study period (Harrison *et al.*, 2005c). However, understanding the impact of diel variation in N cycling on longer term (seasonal and annual) patterns and magnitudes of N flux will require additional work. Also, the effects of diel variation on downstream ecosystems have yet to be explored.

4.5. High intensity, low frequency events

Tropical storms, typhoons, or hurricanes, depending on their strength and geographical context, often deliver torrential rains. Increased river flow during such high intensity, low frequency rainfall events can transport a major portion of annual river N load to coastal systems. Historically, there has been a paucity of data on such events due to their irregular and extreme nature and the generally manual nature of water sample collection for nutrient analyses. However, with the use of *in situ* automatic water samplers and nutrient analysis systems, data from such events can now more readily be captured.

Large increases in river nutrient export associated with hurricanes have been documented in rivers in the Chesapeake Bay watershed and in the Neuse River watershed (North Carolina, USA) (Chesapeake Research Consortium, 1976; Paerl *et al.*, 2005). In years with hurricanes that travel inland and deposit large amounts of rain (e.g., hurricanes Fran 1996 and Floyd 1999), the annual DIN load to Pamlico Sound from the Neuse River can be twice as large as during non–hurricane years (Paerl *et al.*, 2005 Chapter 11 by Paerl and Piehler, this volume). DON load is also elevated (Paerl, pers comm.). In the Lanyang-His in Taiwan, a small subtropical river with a forested watershed, as much as 90% of the annual load of suspended matter can be transported during a single typhoon, although water discharge is often <10% of the annual total runoff (Kao and Liu, 1996, 2000).

In arid regions the majority of water and nutrients in un–dammed rivers can be exported during a few major storms. In a study of 7 subtropical, Australian rivers, approximately 75% of the annual TN load was delivered in 20% of the time (two 10-day flood periods during 1996; Eyre and Pont, 2003). This contrasts with a number of temperate systems in which it takes 23–52% of the time to deliver 75% of the annual TN load (Eyre and Pont, 2003). Different N forms also exhibited different patterns of export in this study of Australian rivers, with DON typically accounting

for a relatively constant proportion (60–80%) of the total N load in each non–flood month and PN increasing in importance during flood months (Eyre and Pont, 2003).

5. EFFECTS ON NITROGEN EXPORT OF LONG-TERM HUMAN MODIFICATION OF DISCHARGE

Human modification of water discharge associated with dams and consumptive water use can greatly decrease river N export. Both dissolved and particulate N forms are affected. Dams trap particulates and also can increase water residence time, which can increase the proportion of N inputs that are denitrified or buried. Consumptive water use (e.g. irrigation) transfers N out of the river system to terrestrial soils where it can be assimilated by crops, fixed by soils, or denitrified, and therefore not transported downstream. Consumptive water use also can influence PN export by decreasing water flow, which increases suspended sediment trapping within the river system.

Over 45,000 dams at least 15 m high are in operation today around the world (Vörösmarty et al., 2003; World Commission on Dams, 2000). There are many additional smaller dams. For example, there are more than 79,000 registered dams in the US alone (National Inventory of Dams), and an estimated >500,000 globally (Downing et al., 2006). While soil erosion due to anthropogenic activities has increased sediment transport by global rivers by over 2 billion metric tons yr, the amount of sediment reaching the world's coast has decreased by about 1.4 billion metric tons, due to retention in reservoirs (Syvitski et al., 2005). Globally, trapping of suspended sediments behind dams is estimated to have decreased the modern sediment transport to coastal systems by about 26% (Syvitski et al., 2005; Vörösmarty et al., 2003). PN data are often not available for pre and post dam conditions. However, there is a reasonably strong, non-linear relationship between total suspended sediment (TSS) and PC, PN, or PP based on data from a wide range of world rivers, so that PN and PC can be estimated based on TSS export (Beusen et al., 2005; Ittekkot and Zhang, 1989). Globally, approximately 4–7 Tg yr^{-1} of PN are estimated to be buried with sediments in large reservoirs alone (about 600), which is equivalent to a reduction of 14–23% of the current global export of PN (Beusen et al., 2005; Seitzinger et al., 2002b). Substantial additional PN is undoubtendly trapped in the tens to hundreds of thousands of small reservoirs around the world (Smith et al., 2001).

Dams can increase water residence time in a river, thereby increasing denitrification and decreasing N export to coastal systems (Dumont et al., 2005; Seitzinger et al., 2002c). Globally, denitrification is estimated to remove about 31 Tg N yr^{-1} in lakes and reservoirs, with about 11 Tg N yr^{-1} in large lakes and reservoirs and 20 Tg N yr^{-1} in small lakes (Seitzinger et al., 2006). These estimates are associated with considerable uncertainty, but (given that global N export by rivers is about 60 Tg yr^{-1}; Bouwman et al., 2005; Boyer et al., 2006; Seitzinger et al., 2005b) suggest that human modification of rivers may significantly impact river N export.

The degree to which dams increase N removal by denitrification in a given river depends on a number of factors, such as placement of dams within the watershed, reservoir water residence time, reservoir depth, and the proportion of the river N that passes through reservoirs. Analysis of 16 rivers in the Northeastern US suggested that while any one reservoir could remove a substantial portion of the N input to that reservoir, at the scale of the whole river, the total amount of N removed in all dams within a watershed decreased the export of N to the coastal zone by less than 10% (Seitzinger *et al.*, 2002c). In general, a relatively small proportion of the N inputs to those rivers passed through reservoirs. However, reservoirs with long water residence times, which intercept a large proportion of a basin's water and N load, can have a marked effect on export of N to coastal systems. The Nile provides a dramatic example. Nitrate export is estimated to have decreased by more than a factor of ten due to closure of the high dam at Aswan in 1965 (Nixon, 2003). Denitrification in reservoirs is predicted to also have a marked effect on N export in a number of other rivers heavily influenced by dams such as the Colorado, Rio Grande, Orange, and Huang He (Dumont *et al.*, 2005). Interestingly, N export by the Nile is estimated to now exceed the pre–dam export due to increased fertilizer use, changes in agricultural draining, increasing human population, and marked extensions of urban water and wastewater systems, and the Nile delta fishery now surpasses that immediately preceding the dam (Nixon, 2003).

6. Groundwater

Submarine groundwater discharge (SGD) is a potentially important but as yet poorly quantified source of nutrients to coastal systems (Burnett *et al.* 2003; Slomp and Van Cappellen, 2004). The discharge of groundwater into the sea has been known since Roman times, when offshore springs were used as a source of freshwater (reviewed by Burnett *et al.*, 2003). However, recognition of the potential importance of SGD as a source of nitrogen to coastal systems has been relatively recent (e.g., Burnett *et al.*, 2003; Capone and Bautista 1985; D'Elia *et al.*, 1981; Johannes, 1980; Slomp and Van Cappellen, 2004; Valiela and D'Elia, 1990; Valiela *et al.*, 2002). Coastal systems in which SGD is an important source of N tend to be those characterized by shallow, permeable (sand, limestone) coastal aquifers with high rates of groundwater recharge (Slomp and Van Cappellen, 2004).

Nitrogen concentrations in submarine groundwater are influenced by many of the same natural and anthropogenic watershed characteristics that control river water concentrations. A model that predicts total dissolved N loads in groundwater to shallow estuaries for watersheds underlain by unconsolidated sands, has been developed and successfully applied to a number of systems on Cape Cod, MA (USA) (Valiela *et al.*, 2000, 2002). Inputs to the model include N in wastewater (via septic systems), fertilizer use, and atmospheric deposition. Quantifying N inputs to coastal waters, however, is complicated by high spatial and temporal variability. In addition to geologically determined preferential flow-paths, large changes in nitrogen concentrations can occur during groundwater movement through the aquifer and

coastal sediments. In particular, groundwater nitrate can be removed by denitrification, and diagensis of organic matter in the coastal sediments can add nitrogen or change the composition of nitrogen species in the groundwater (Capone and Slater, 1990; Nowicki *et al.*, 1999; Valiela *et al.*, 1990).

Despite difficulties, there are a number of studies at both local and regional scales in which SGD of nitrogen (generally only nitrate measurements) has been quantified within the context of whole system N budgets. SGD has been shown to be an important N source in some coral reefs areas (e.g., Corbett *et al.* 1999; D'Elia *et al.* 1981; Umezawa *et al.* 2002), shallow coastal lagoons and bays (Capone and Bautista 1985; Capone and Slater, 1990; Gobler and Boneillo, 2003; Moser, 1997; Valiela and D'Elia, 1990; Valiela *et al.*, 1990; 2002), and salt marsh dominated systems (Krest *et al.*, 2000). In a number of systems, N inputs from SGD equal or exceed river inputs (Table 9.5).

At regional scales, there are also examples in which SGD of nitrogen equals or exceeds river fluxes. For example, DIN fluxes in groundwater discharges through salt marshes along the South Carolina coast are estimated to be equivalent to input from major rivers in this region ($\sim 60 \times 10^6$ mol yr^{-1}) (Krest *et al.*, 2000) (Table 9.5).

Regional and global scale budgets of SGD and nutrients are very difficult to formulate with confidence. However, most estimates of SGD at the global scale range from about 6–10% of surface water inputs (reviewed by Burnett *et al.*, 2003), with large variations in time and space. If we assume that the water budget is a rough proxy for dissolved N inputs, then SGD could transport approximately 4 Tg N yr^{-1} to coastal systems (10% of global river DIN plus DON transport). While at the global scale, SGD may be a relatively small source of N to coastal systems, it is becoming

Table 9.5 Comparison of estimated N fluxes through submarine groundwater discharge (SGD) relative to river fluxes (modified from Slomp and Van Cappellen, 2004; sites with relatively large SGD inputs relative to river inputs were specifically selected for this table)

increasingly clear that at local and regional scales it can be a very important term in some cases (Table 9.5). There is a need for greater understanding of SGD as a coastal N source and for the formulation and application of spatially explicit models of groundwater N inputs.

7. ATMOSPHERIC DEPOSITION DIRECTLY TO COASTAL WATERS

Atmospheric N deposition can be an important source of N to coastal and open ocean ecosystems. The potential importance of N in atmospheric deposition has been recognized for over twenty years (e.g., Correll and Ford, 1982; Duce, 1986; Paerl, 1985). Recognition of the importance of atmospheric deposition as a source of N to coastal waters increased rapidly following the analysis by Fisher and Oppenheimer (1991) for a number of coastal systems, including Chesapeake Bay. Atmospheric deposition to watersheds contributes to diffuse N loads in rivers as discussed previously in this chapter. In this section we are specifically referring to N deposited (wet and dry) directly to the surface of coastal and open ocean waters.

N in rainwater includes both DIN (nitrate, nitrite, ammonium) and DON. Gas phase N species in the atmosphere contributing to dry deposition include ammonia, nitric acid and organic N compounds. Particulate N can also be associated with dust and organic debris, and deposited either as dry deposition or with rainfall. Globally, anthropogenic sources account for over 70% of NOx and 65% of ammonium deposition (Galloway et al., 2004). Sources of organic N compounds are not well known although a significant fraction (up to 80%) is available to plankton communities as a nitrogen source (Peierls and Paerl, 1997; Seitzinger and Sanders, 1999; Timperley et al., 1985).

In some estuaries and coastal embayments, atmospheric deposition directly to the water surface can account for a substantial fraction of N input (as much as 40% of the N inputs from river plus atmospheric inputs; Table 9.6). However, the relative importance of atmospheric deposition as an N source varies considerably among coastal systems and depends on a number of factors, including the nature of watershed N sources and the relative sizes of the contributing watershed and receiving estuary (Valigura et al., 2001).

In continental shelf regions, there is also a wide range in the relative magnitude of atmospheric N deposition. For example, in North Atlantic shelf regions, direct atmospheric deposition can account for from as little as 5% to more than half of the land-based N input (rivers plus direct atmospheric deposition; Table 9.6). The proportion of land-based N inputs that are from atmospheric deposition depends not only on the magnitude of river N export, but also the area of shelf over which atmospheric N is deposited (Nixon et al., 1996; Seitzinger and Giblin, 1996). At the global scale, atmospheric N deposition to continental shelves ($\sim$8 Tg N yr^{-1}) is estimated to account for about 17% of total N inputs from land-based sources (Table 9.6). This is based on estimated N inputs to global continental shelves from rivers that includes river N exported from estuaries and N delivered from large rivers that discharge directly to shelves (Fig. 9.3 and Seitzinger et al., 2006). These atmospheric deposition estimates do

[a] Wet and dry deposition.
[b] Inorganic and organic N.
[c] Wet deposition only.
[d] Nitrate only.
[e] Inorganic only.
For open ocean regions atmospheric deposition is calculated as a percent of biological N_2-fixation plus atmospheric deposition, assuming river N inputs are removed within coastal and shelf sediments. For continental shelves the range includes uncertainties in river N inputs; for open ocean estimates, the range is that calculated with and without including DON in rainwater. See Fig. 6.6 for the contribution of atmospheric deposition in watersheds to river N export.

not include DON, as we know of no measurements for DON in rainwater collected directly from continental shelf locations. However, we estimate that DON may comprise anywhere from 20% to 80% of the total dissolved N in rainwater (Cornell *et al.*, 1995, 2001, 2003; Mace *et al.* 2003; Valigura *et al.*, 2001).

Open ocean regions receive significant amounts of land-based N from atmospheric deposition ($\sim$25 Tg N yr^{-1} Dentener pers. comm.). This estimate of atmospheric deposition does not include dissolved organic nitrogen (DON), which may account for from 20% to as much as 80% of the total dissolved N in rainwater in remote marine locations (Cornell *et al.*, 1995, 2001, 2003; Mace *et al.* 2003). Keeping in mind that this estimate of DON is uncertain because of the

limited number of measurements, including DON could increase current estimates of N deposition to oceanic regions by a factor of 1.25–5 or to 31–125 Tg N yr^{-1}, increasing it to the range of estimated oceanic biological N_2-fixation (57–152 Tg yr^{-1}; Mahaffey *et al.* 2005; Chapter 4 by Carpenter and Capone, this volume).

8. Summary and Future Directions

In the past several decades, considerable progress has been achieved toward a comprehensive understanding of land–based N inputs to coastal waters (estuaries, bays and continental shelves). Local studies of patterns and controls of N export have been carried out and synthesized. These syntheses have, in turn, been used to develop spatially explicit regional and global models that can be used to estimate the patterns and magnitudes of N input to coastal ecosystems, as well as the N sources in watersheds and other factors controlling N export. We now have reasonable, though still quite uncertain, estimates of land–based N inputs to coastal waters globally via a number of different pathways, including rivers ($\sim$60 Tg N yr^{-1}), submarine groundwater discharge (roughly 4 Tg N yr^{-1}) and direct atmospheric deposition ($\sim$8 Tg N yr^{-1}). A better understanding of the magnitude of transport of different forms of N is also developing. Globally, DIN and PN each account for approximately 40% of river transported N is in the form of DIN and PN, with DON comprising approximately 20%.

There is substantial variability in the magnitude of N inputs to coastal regions, as well as the contribution of different sources driving that export, that is starting to be addressed by spatially explicit models. There are now many watersheds throughout the world with high yields (i.e., kg N exported by rivers to the coastal zone km^{-2} watershed yr^{-1}). Some of the highest TN yields occur in watersheds in Europe and southern and eastern Asia. These are watersheds with high anthropogenic N inputs and N export from these systems is dominated by DIN, with fertilizer being the single largest N source of that DIN. Anthropogenic factors, however, are not always responsible for high rates of N yield from watersheds, and high yields are not always dominated by DIN. Watersheds with high water runoff, such as the Amazon and Congo, are estimated to have high yields of all N forms (DIN, DON, and PN). In much of Oceania, a combination of high water runoff and anthropogenic activity lead to high yields of all N forms. Throughout most of the world, non-point sources (natural and/or anthropogenic) dominate N export, regardless of N form. This includes fertilizer which is estimated to be the single most important source of exported DIN in many north temperate latitude watersheds; manure is estimated to contribute a substantial portion of the exported DIN in a number of watersheds scattered throughout temperate and tropical latitudes. Except for some watersheds in the Eastern United States, atmospheric deposition does not appear to be the dominant N source driving DIN export. Despite the massive scale of human intervention in the N cycle which has affected transport of N by rivers, natural sources (N_2-fixation) are still the single largest contributor of DIN, DON, and PN from many watersheds in the Arctic, South America, and

Africa. PN export may be one of the largest uncertainties in river N export. Its potential importance is suggested by current estimates that PN accounts for about 40% of global river TN export, and that it constitutes the largest fraction of exported N from all regions, except the north temperate zone, when information is aggregated at the larger scale of major latitudinal zones (tropical, temperate, and arctic regions). Within a region, all the patterns noted above can vary among individual watersheds. Differences in the spatial patterns of river N export among N forms, in combination with differences in coastal ecosystem effects of these different N forms, highlight the need to explicitly include parameterization of the different N forms in watershed N export models.

Often only a relatively small proportion of the total N inputs to a watershed are exported by rivers to the coast, although the range is considerable (e.g., <1% to >40%). Much of the N is denitrified within soils and freshwater ecosystems. Hydrology has a large impact on the proportion of N exported by rivers with the largest proportion exported from watersheds with high water runoff (>1 m yr^{-1}) and lowest from basins with extensive damming or very low annual precipitation and runoff.

There is still much important work that needs to be done to understand patterns and controls of different N forms delivered to coastal waters. Below we highlight a few of these needs. At present, there is considerably more information on DIN inputs than other forms of N. The ability to predict seasonal or event driven changes in export, by N form, is largely limited to intensive studies in individual watersheds, as at present most regional and global N export models are only able to predict mean annual river export from large river basins. A comprehensive synthesis of seasonal patterns of river nutrient export that includes different N forms, as well as the factors contributing to those seasonal patterns, is needed. Such an analysis should include rivers across a wide range of geographic, hydrological, geological, and human disturbance regimes. These studies should also include small coastal watersheds which drain a large portion of the land immediately adjacent to the coastline globally, but which have often received less attention than larger watersheds. There is also a need for better integration of terrestrial biogeochemistry and ecosystem models with river nutrient export, including multiple element interactions. All the above are particularly pressing needs in tropical and subtropical systems, which are simultaneously the most poorly understood and subject to the greatest anticipated increases in N loading. While there has been relative success relating increases in N inputs to watersheds to increases in N export by rivers, there is considerable uncertainty in our knowledge of the response of river N export to decreasing N inputs to watersheds after prolonged periods of high inputs. Given the suggested large magnitude of N entering marine systems from atmospheric DON deposition, research is needed to obtain better quantitative information DON deposition and to determine whether the source of that DON is from land-based processes in which case it is an input of new N to the oceans, or whether it is from volatilization of DON from the oceans, in which case it would not represent new N, but rather recycled N.

Phototransformations of Dissolved Organic Nitrogen

Waldemar Grzybowski *and* Lars Tranvik

Contents

1. Introduction

Within the last decade it has become obvious that photochemical reactions play an important role in the transformations of organic matter. Most studies in this respect have focused on organic carbon. However, photochemical reactions are not restricted to carbon, but also affect other elements including nitrogen (see below), sulfur (e.g. Brugger *et al.*, 1998; Dierdre *et al.*, 2003; Hatton, 2002), phosphorus (observations limited to humic-rich lake water—see Mopper and Kieber, 2002), and metals (see Zepp, 2003).

The interest in environmental photochemistry is additionally stimulated by the awareness of an increasing flux of harmful UVB radiation due to stratospheric ozone depletion (e.g. Crutzen, 1992; Smith *et al.*, 1992). As a consequence, there has been a sizable increase in the number of publications concerning interactions between sunlight and both biotic and abiotic components of aquatic environments (Fig. 10.1).

The data that have accumulated so far are summarized and discussed in several excellent reviews. Of those, information on the impact of sunlight on aquatic nitrogen compounds can be found in Bronk (2002), Kieber (2000), Mopper and Kieber (2002), Moran and Covert (2003), and Zepp (2003). A reader interested in mechanisms behind the reported phenomena is advised to turn to more chemistry-oriented works by Boule *et al.* (1999) and Mopper and Kieber (2000). The present chapter is a supplement and update of the above-mentioned studies, specifically focusing on phototransformations of dissolved organic nitrogen (DON).
Figure 10.1 Development of publications on UV and the aquatic ecosystem between 1949 and 2003 (Web source: Ruben Sommaruga, http://homepage.uibk.ac.at/homepage/c719/c71986/).

2. PHOTOCHEMICAL PRODUCTION OF INORGANIC NITROGEN

Organic carbon and organic nitrogen differ in the environmental role of their final photoproducts. The ultimate product of photochemical oxidation of organic carbon is carbon dioxide and its dissolved forms. Although intermediate organic photoproducts are important substrates for heterotrophic bacteria (e.g. Bertilsson and Tranvik, 1998), the product of complete photomineralization of organic carbon is of little ecological importance. Inorganic carbon is highly abundant in marine waters, and its photochemical formation can hence cause only minor relative changes in concentration. Complete photochemical mineralization of organic nitrogen compounds, however, results in production of ammonium, the most easily assimilated nitrogen species, used by both auto- and heterotrophs.

Despite the conceptual simplicity of the phenomenon, the first proof of production of ammonium via photodegradation of natural dissolved organic matter was presented relatively recently, when Bushaw *et al.* (1996) showed that short-term irradiation of water with high concentrations of UV-absorbing natural organic matter resulted in a significant increase in ammonium concentration. Biotic mechanisms were ruled-out by these authors (and by their followers) by exclusion of bacteria by filtering through $0.2\ \mu m$ pore-size membrane filters.

Since most of the organic nitrogen is of limited bioavailability to autotrophs, photochemical transformation of recalcitrant DON into bioavailable forms implies an important (and unaccounted for) potential source of assimilable nitrogen. The study of Bushaw *et al.* (1996) was followed by several investigations containing

data on photoammonification in different aquatic environments. The results published so far, however, are not consistent (Table 10.1), and include positive results as well as decreased ammonium concentrations upon light exposure, and studies where no change in ammonium concentrations could be detected. The great potential significance of photoammonification, combined with the relatively low number of follow-up studies that were able to corroborate the initial results of Bushaw *et al.* (1996), suggest that there may be a "file drawer effect" (Bachau, 1997), i.e. an accumulation of conflicting results that have remained unpublished.

Since only absorbed light can initiate phototransformations, it may be expected that samples of different optical properties show different photoproduction rates. For comparative purposes, the rates are thus usually absorbance-normalized. However, the inconsistency when comparing results from different studies is not resolved by such normalization and the variability of normalized rates exceeds an order of magnitude (Table 10.1). An attempt to find a correlation between available bulk characteristics (DON, DOC, pH, absorbance) and irradiation effects proved unsuccessful (Grzybowski, 2003). Additional confusion is introduced by reports on lack of ammonium release and even its removal during irradiation, observed in apparently similar samples (Table 10.1).

The method descriptions in most of the published experiments are not detailed enough to allow us to elucidate whether differences in experimental setup are responsible for the observed variability. For example, data on radiation intensity at the surface of the irradiated water layer are not sufficient in the case of optically thick samples where a significant fraction of the light is absorbed within the upper layer of the sample. Accordingly, differences among samples that differ in the fraction of incident light that is absorbed may not be proportional to the photochemical reactivity of the organic matter.

The published results are commonly normalized against absorbance at 350 nm (UVA range). Since the total energy absorbed in the water column is usually higher in the UVA than in the UVB range, UVA normalization may be a reasonable approximation. However, it should be noted that UVB radiation is suggested to be most important for photoammonification (Buffam and McGlathery, 2003; Bushaw *et al.*, 1996). Data normalization limited to the UVA range may be misleading, since a highly energetic, singular UVB photon can not be directly substituted by numerous (but less energetic) UVA photons. So far, no comprehensive study has been presented on the relative importance of different wavelengths of radiation for photoammonification and other DON photoreactions.

Another factor responsible for the observed variability in "positive" results may be adsorption of ammonium and other nitrogen compounds onto humic substances (the main photoreactive fraction of DOM). Hence, detection of photoammonification may to some extent reflect photochemically induced desorption of ammonium from large organic molecules, rather than the mineralization of organic nitrogen. This phenomenon, however, would be limited to fresh and low salinity waters, since at higher salinities ammonium ions are replaced by cationic macroconstituents of seawater.

Table 10.1 Results of experiments on ammonium release due to photochemical transformations of dissolved organic matter

Irradiated sample	Irradiation conditions	Photoproduction rate (μM h^{-1})	DOC (μM)	DON (μM)	Absorption coefficient (m^{-1})	Absorbance normalized photoproduction rate (μM m h^{-1})	Reference
Boreal pond water, pH = 7.6	Artificial (Wavelength >290 nm), exposure time 18 h	0.15 ± 0.01	3000	55	a$_{350}$ ~43	0.0035	Bushaw *et al.* (1996)
	Wavelength >320 nm	0.11					
	Wavelength >360 nm	0.08					
Boreal pond inlet (fulvic acid), pH = 6.5	Artificial (wavelength >290 nm), exposure time 6.6 h	0.065	1133	24	a$_{350}$ ~20	0.0025	Bushaw *et al.* (1996)
Swamp water, pH = 3.9	Artificial (wavelength > 290 nm), exposure time 18 h	0.34	3840	86	a$_{350}$ ~106	0.032	Bushaw *et al.* (1996)
	Wavelength >320 nm	0.22					
	Wavelength >360 nm	0.059					
	Wavelength >425 nm	0.040					

Suwannee River water	Artificial (wavelength >320 nm), exposure time 36 h	0.36	not available	74	Not available		Bushaw et al. (1996)
Fluka humic acid solution	Artificial (wavelength >290 nm), exposure time 18 h	0.23	1942	51	a_{350} ~127	0.018	Bushaw et al. (1996)
Satilla River water	Artificial, exposure time 4 h	0.1	2100	40	a_{350} ~90	0.001	Gao and Zepp (1998)
Lake water	Artificial (UV range), exposure time 12 h	No photo-production	~880 and ~1000	~6 and ~15	Not available		Jørgensen et al. (1998)
Maracaibo Lake water, pH = 7.72	Sunlight	0.22	not available	Not available	Not available		Gardner et al. (1998)
Concentrate of Satilla River fulvic acids	Sunlight, exposure time 7 h	0.058	2200	40	a_{350} ~86	0.001 (corrected for internal shading)	Bushaw-Newton and Moran (1999)
Boreal rivers and groundwater, pH = 5.1–7.1	Artificial (UV range) exposure time 12 h	No photo-production	200–2192	14–47	a_{365} 0.1–34.7		Bertilsson et al. (1999)

Elemental nitrogen in humic compounds include structural nitrogen as well as different chemical moieties bound to the humic structure (Schnitzer, 1985). One may reasonably expect different photolability of these fractions, with the structural nitrogen showing bigger resistance to photorelease and the associated nitrogen sensitive to ionic strength and/or pH. In fact, increasing photoammonification rates with decreasing pH were reported by Wang *et al.* (2000), but this finding does not hold true for some of the data presented in Table 10.1.

The reverse process, i.e. decrease in ammonium during irradiation, was observed in some studies (Jørgensen *et al.*, 1999; Koopmans and Bronk, 2002). During long-term irradiation fluctuations in factors such as pH and temperature may affect the results. There may be a shift of the NH_4^+/NH_3 equilibrium towards ammonia (NH_3) if there is an increase in pH, and enchanced temperature during irradiation would favor volatilization of ammonia. Another reason for ''negative'' results may be irreversible binding of ammonium to other components of natural waters in a way that renders it undetectable, as has been reported for solutions of humic substances (e.g. Thorn and Mikita, 1992). It is conceivable that irreversible binding takes place also during irradiation, simultaneously with ammonium production from photodegraded DOM. The net formation of free, analytically available ammonium depends on the relative importance of binding as opposed to new formation of ammonium. The significance of ammonium binding (and its apparent removal) should be higher in samples of high initial ammonium concentration. This can actually be implied from observations in irradiated ground water samples (Fig. 10.2).
Figure 10.2 Change in ammonium (NH_4^+) concentration after an exposure of unmanipulated (◆), NH_4^+ removed (□), and DON concentrated (Δ) groundwater samples to natural or artificial sunlight (xenon arc lamp, 1000 μE m^{-2} s^{-1}), plotted against the initial NH_4^+ concentration. Means ± SD shown, $n = 3$ (Koopmans and Bronk, 2002).
Figure 10.3 Possible mechanisms of photochemical ammonia formation from amides/peptides. The ketone is listed as a possible photosensitizer (Wang *et al.*, 2000).

Most of the published results on photammonification were obtained via a ''black box'' approach, i.e. without detailed inquiry of underlying mechanisms. The few exceptions are papers by Wang *et al.* (2000) and Tarr *et al.* (2001). These authors proposed chemical reactions behind photoammonification (Fig. 10.3), which include a ketone as a photosensitizer.

One remarkable finding is an initial increase in ammonium in river water immediately after the end of irradiation of water followed by a decrease during prolonged incubation (Wang *et al.*, 2000). Since ammonium concentration did not change in nonirradiated samples, authors suggest an abiotic mechanism, involving long-lived, photo-induced transients. However, since these authors used glass fiber filters with a nominal 0.5-μm cut off, that is not effective in bacteria removal, an alternative explanation to their result may be a biotic process. Still, a similar phenomenon (initial increase and subsequent decrease in ammonium concentration) was observed by Kieber *et al.* (1997), upon addition of ammonium after irradiation of seawater enriched with fatty acids. In this case, the samples were filter sterilized with 0.2-μm membrane filters (Fig. 10.4).

In addition to reports on ammonium changes due to photodegradation of DON there is an intriguing study by Kieber *et al.* (1999) demonstrating formation of nitrite during photodegradation of dissolved organic matter. An important implication of this finding is the existence of oxidized (+3), i.e. nonproteinaceous nitrogen within structures of natural, biogenic matter. The possibility that the observed nitrite is a result of photo-oxidation of organic nitrogen seems unlikely since this would generally require semi-conductor catalysis (e.g. Hidaka *et al.*, 1997; Nohara *et al.*, 1997). Kieber *et al.* (1999) found that nitrite photoproduction increased with the addition of humic substances to Gulf Stream water, suggesting an organic origin of the nitrite. Spokes and Liss (1996) noted in irradiated solutions of nitrate that increased humic substances concentrations resulted in an increase in nitrite. In this case the authors postulated both enhancement of nitrate reduction by reactive by-products of photodegradation of humic substances and/or release of nitrite from organic matter.
Figure 10.4 Comparison of changes in ammonia concentration observed during post–photolysis in sea water enriched with fatty acids (A) (after Kieber *et al.*, 1997) and river water (B) (Wang *et al.*, 2000) (in this case samples were either kept dark throughout experiment ■, were irradiated □, or were first irradiated and then kept dark ○).

3. PHOTOCHEMICAL TRANSFORMATIONS OF ORGANIC COMPOUNDS AND EFFECTS ON BIOAVAILABILITY

A number of organic compounds have been identified as products of DON photodegradation. In the majority of published papers, they are characterized in bulk as amines measured as fluorescent ortho–phtaldialdehyde derivatives (Lindroth and Mopper, 1979). Figure 10.5 shows one of the few cases where organic products of DON phototransformation are presented as chemical moieties identified at the molecular level.
Figure 10.5 Amino acid photoproduction from Suwannee River fulvic acid (30 mg L^{-1}). Chromatograms are of OPA derivatized samples before (A) and after (B) 31 h irradiation in a solar simulator. Labeled peaks increased in size after irradiation are labeled with names of amino acids having the same retention time (Tarr *et al.*, 2001).

Published results on organic nitrogen products of photodegradation of dissolved organic matter are compiled in Table 10.2. Similarly to the photoammonification data, the publications include observations of increased, unchanged, as well as decreased concentrations of amines.

In addition to chemical analysis of irradiation products, bioassays have been employed to estimate how photochemical reactions change the availability of organic substances for bacterial growth. In this way, information is gained on the environmental role of photoproducts even though their identity and concentration remain unknown. This approach has yielded a large body of results on photochemical effects on dissolved organic carbon bioavailability (see e.g. Mopper and Kieber, 2002 for a review). In general, these effects are positive for DOM dominated

Table 10.2 Published results on photoproduction of amines from dissolved organic matter

Irradiated sample	DOC (μM)	DON (μM)	Absorption coefficient (m^{-1})	Irradiation conditions	Irradiation effects	Reference
Epilimnion lake water	∼800	∼16	Not available	Sunlight, 7 h exposure	Increase in DFAA (0.1 μM) and DCAA (∼0.5 μM)	Jørgensen et al. (1998)
Hypolimnion lake water	∼950	∼6	Not available	Sunlight, 7 h exposure	Increase in DFAA (∼0.05 μM), no change in DCAA	Jørgensen et al. (1998)
Baltic Sea water	Not available	10–30	Not available	Artificial (UV range), 12 h	Up to 59% increase or no change in DCAA; up to 65% increase no change; and up to 45% decrease in DFAA	Jørgensen et al. (1999)
Concentrate of river water humic substances dissolved in artificial seawater – 28 × Skidaway River	2352	56	a$_{350}$ ∼40	Sunlight, 7 h exposure	increase in bulk primary amines ∼0.3 μM	Bushaw-Newton and Moran (1999)

Concentrate of river water humic substances dissolved in artificial seawater—2.8 × Satilla River Estuary	2200	34	a$_{350}$ ~58	Sunlight, 7 h exposure	Increase in bulk primary amines ~0.06 μM	Bushaw–Newton and Moran (1999)
Suwannee River fulvic acid solution	~7200	Not available	Not available	Artificial, ~45 h exposure	0.7 μM increase in serine	Tarr *et al.* (2001)
Satilla River (modified)	4066	107	a$_{350}$ 128	Artificial sunlight, 8 h exposure	No change in primary amines	Koopmans and Bronk (2002)
Ground water	4224	66	Not available	Sunlight, 7 h exposure	0.63 μM increase in primary amines	Koopmans and Bronk (2002)
Ground water	1196	26	a$_{350}$ 21.8	Artificial sunlight, 8 h exposure	0.33 μM decrease in primary amines	Koopmans and Bronk (2002)
Ground water (diluted)	612	37	a$_{350}$ 19.7	Artificial (UV range), 36 h exposure	~0.03 μM increase in glycine and alanine; no change in serine	Buffam and Glathery (2003)

by humic substances, and negative for freshly synthesized algal organic matter (Tranvik and Bertilsson, 2001). Also when it comes to DON, both positive and negative effects of solar exposure on bacterial utilization have been observed.

In a concentrate of DOM from a Sphagnum bog, which was extensively rinsed by a tangential flow ultrafiltration approach to remove inorganic nutrients, Tranvik *et al.* (2000) found that bacterial utilization of DON was stimulated by pre-exposure of the organic matter to simulated sunlight. In bacterial cultures that received either pre-exposed or dark-treated DOM free from inorganic nutrients, together with an additional source of organic carbon (glucose) and inorganic phosphorus, to make the cultures limited by nitrogen and void of any N source other than the DON, bacterial growth was enhanced by light exposure to an extent that could not be explained by photoammonification. Hence, it appears that some DON compounds were transformed by light into more available organic forms.

DON, in addition to structural nitrogen of humic substances and humic-bound proteinaceous matter, consists of highly labile amines, amino acids, and proteins. Proteins generally do not absorb radiation within the solar spectrum that reaches the biosphere (>290 nm). In one of the first bioassays with chemically defined compounds, peptone lost its bioavailability upon irradiation (Naganuma *et al.*, 1996). The results, however, were obtained with unrealistically high substrate concentrations. Similar experiments, but with several orders of magnitude lower organic nitrogen concentrations, were made by Reitner *et al.* (2002). The measurable, negative change in bacterial growth was observed solely in a solution of tryptophan (one of the few amino acids able to absorb solar radiation) while there was no impact of irradiation on light transparent alanine.

This result suggests that phototransformation of biolabile substances proceeds mainly via direct photoreactions, while photo-induced interactions with other light-absorbing constituents of natural waters are of negligible importance. In contrast, in experiments with fresh algal extract irradiated in presence of humic substances (Tranvik and Kokalj, 1998), irradiation decreased susceptibility of the substrate to subsequent mineralization by bacteria. The decreased respiration was demonstrated to be caused by photo-induced, physico-chemical interactions between algal extract and humic substances.

Accordingly, photochemically induced decreased bioavailability of DON and other DOM may result from directly absorbed radiation (e.g. Reitner *et al.*, 2000) as well as indirectly, e.g. via photochemically induced interactions with other substances (e.g. Tranvik and Kokalj, 1998).

Most of the organic nitrogen in natural waters is bound to or built into structural components of humic substances (Bronk, 2002; Schnitzer, 1985). It has been demonstrated both in laboratory experiments and in field observations that proteinaceous matter bound to humic substances becomes bioresistant (Carlson *et al.*, 1985; Hubberten *et al.*, 1994). In pioneering studies on DON phototransformation Amador *et al.* (1989, 1991) showed that a significant part of amino acids associated with humic matter becomes bioavailable after irradiation. On the other hand, long-term irradiation of a mixture of protein and DOM compounds resulted in decreased bioavailability (Keil and Kirchman, 1994). The loss of bioavailability of the protein required presence of DOM, supporting that the DOM either interacted directly

with the protein, or mediated indirect photoreactions. Interestingly, the change in protein quality was detected only as decreased bacterial activity in bioassays, but could not be discerned as a change in amino acid composition of the protein.

4. Recommendation for Future Research

Despite the remarkable efforts put into research on environmental aquatic nitrogen photochemistry there is still no consensus on its environmental role. Published data so far do not allow testing of fundamental issues such as the proportionality between absorbed energy and the extent of photoreactions. The basic necessary data for such studies include spectral characteristics of irradiated samples as well as the quality and dose of light. This is particularly important in experiments using natural sunlight where share of UV radiation changes both quantitatively and qualitatively. In such experiments, data on the length of irradiation and the intensity of radiation determined for the full spectrum are not sufficient.

The observed apparent discrepancies among different studies of nitrogen photochemistry may be an effect of, according to Mopper and Kieber (2002), "limitations in the analytical methodologies used to quantify NH_4^+." In the majority of studies, modifications of the same phenolhypochlorite method (Solòrzano, 1969) were used for ammonium analysis, and the reported standard deviations ranges from 0.01 μM to above 0.5 μM. Progress in the understanding of the ecological role of photo-ammonification depends on careful analytical procedures, including the use of proper controls and methods that allow hing sensitivity and reproducibility in the submicromolar range.

NITROGEN AND MARINE EUTROPHICATION

Hans W. Paerl *and* Michael F. Piehler

Contents

1. INTRODUCTION

The availability of nitrogen (N) most frequently limits autotrophic production of organic matter in the world's estuarine, near-shore coastal and open ocean waters (Dugdale, 1967; Nixon, 1986, 1995; Ryther and Dunstan, 1971). As such, the fertility of these waters is often closely controlled by N inputs, provided either internally by regeneration of pre-existing N and biologically-fixed atmospheric N_2, or supplied externally (i.e., ''new'') as combined N sources delivered via surface runoff, sub-surface groundwater or atmospheric deposition (Fig. 11.1). Because marine ecosystems lose some fixed N via denitrification and burial, ''new'' N supply is essential for compensating for these N losses, and ensuring productive conditions. However, during the past century humans have significantly altered the balance between ''new'' N inputs and N losses in the marine environment through large-scale use of synthetic N fertilizers in agriculture, rapid expansion of industrial and transportation–related fossil fuel combustion and coastal urbanization (Codispoti *et al.*, 2001; Rabalais, 2002; Vollenweider *et al.*, 1992). Over this time frame, terrigenous discharge and atmospheric N emissions have increased 10-fold (Holland *et al.*, 1999; Howarth *et al.*, 1996) and continue to grow as human development expands in coastal watersheds (Vitousek *et al.*, 1997).
Figure 11.1 Schematic diagram illustrating sources, transformations and fates of nitrogen (N) along the estuary to ocean continuum. Surface, subsurface and atmospheric pathways of externally-supplied or new N inputs attributable to anthropogenic activities are shown as are internal N cycling. The combined anthropogenic N inputs are shown as a thick arrow (upstream), which decreases in thickness downstream as a portion of the N inputs settles to the bottom sediments and is buried and/ or denitrified (DNF). NF represents nitrogen (N₂) fixation, a biologically-mediated new N input. The linkage of anthropogenically-enhanced N inputs to accelerated primary production or eutrophication, and its trophic and biogeochemical fate are also shown. In many estuarine and sound systems, primary production and phytoplankton biomass are maximal in mid-system locations, where adequate new N loads and decreasing rates of flushing (increasing residence times) overlap. The resultant chlorophyll *a* maximum (Chl *a* max) is characteristic of estuarine systems in which residence times are long enough to allow periodic phytoplankton blooms to accumulate.

For at least 50 years, researchers have recognized this growing imbalance, especially in estuarine and coastal waters where N over-enrichment has fueled accelerated primary production, or eutrophication, which Nixon (1995) defined as ''an increase in the rate of supply of organic matter to an ecosystem.'' From a food web perspective, eutrophication is a condition where nutrient-enhanced primary production exceeds the ability of higher ranked consumers to utilize it. D'Elia (1987) characterized this condition as ''too much of good thing,'' or over-fertilization of N-limited marine ecosystems with ''new'' N, the bulk of it being anthropogenic (Galloway and Cowling, 2002; Howarth *et al.*, 1986; Vitousek *et al.*, 1997). Symptoms of N–driven eutrophication include: (1) subtle increases in plant production, to (2) changes in primary producer community composition, (3) rapidly accelerating algal growth, (4) visible discoloration or blooms (Jørgensen and Richardson, 1996; Paerl, 1988; Smetacek *et al.*, 1991), (Fig. 11.2), (5) losses in water clarity, (6) increased consumption of oxygen leading to ecosystem–scale oxygen depletion (hypoxia, anoxia) (Hagy *et al.*, 2004) (Fig. 11.3), which is stressful to resident fauna and flora, and can lead to (7) elimination of habitats (Diaz and Rosenberg, 1995; Rabalais and Turner, 2001). Lastly, excessive N enrichment, relative to other nutrient inputs, can alter nutrient input balances and cycling, including shifts to phosphorus and silicon limitation of
Figure 11.2 Estuarine and coastal phytoplankton blooms symptomatic of nitrogen-enhanced primary production or eutrophication. Clockwise, starting with upper left; (A) cyanobacterial blooms in the Gulf of Finland, Baltic Sea (photo courtesy of P. Moisander); (B) dinoflagellete red tide bloom off the coast of Japan (photo courtesy of ECOHAB Program); (C) dinoflagellate/ diatom bloom near the coast of Hong Kong, China (photo courtesy ECOHAB Program), and (D) cyanobacterial bloom on the St. Johns River Estuary, Florida (photo courtesy J. Burns).

primary production in receiving estuarine and coastal waters (Dortch *et al.*, 2001; Lohrenz *et al.*, 1999; Sylvan *et al.*, 2006).

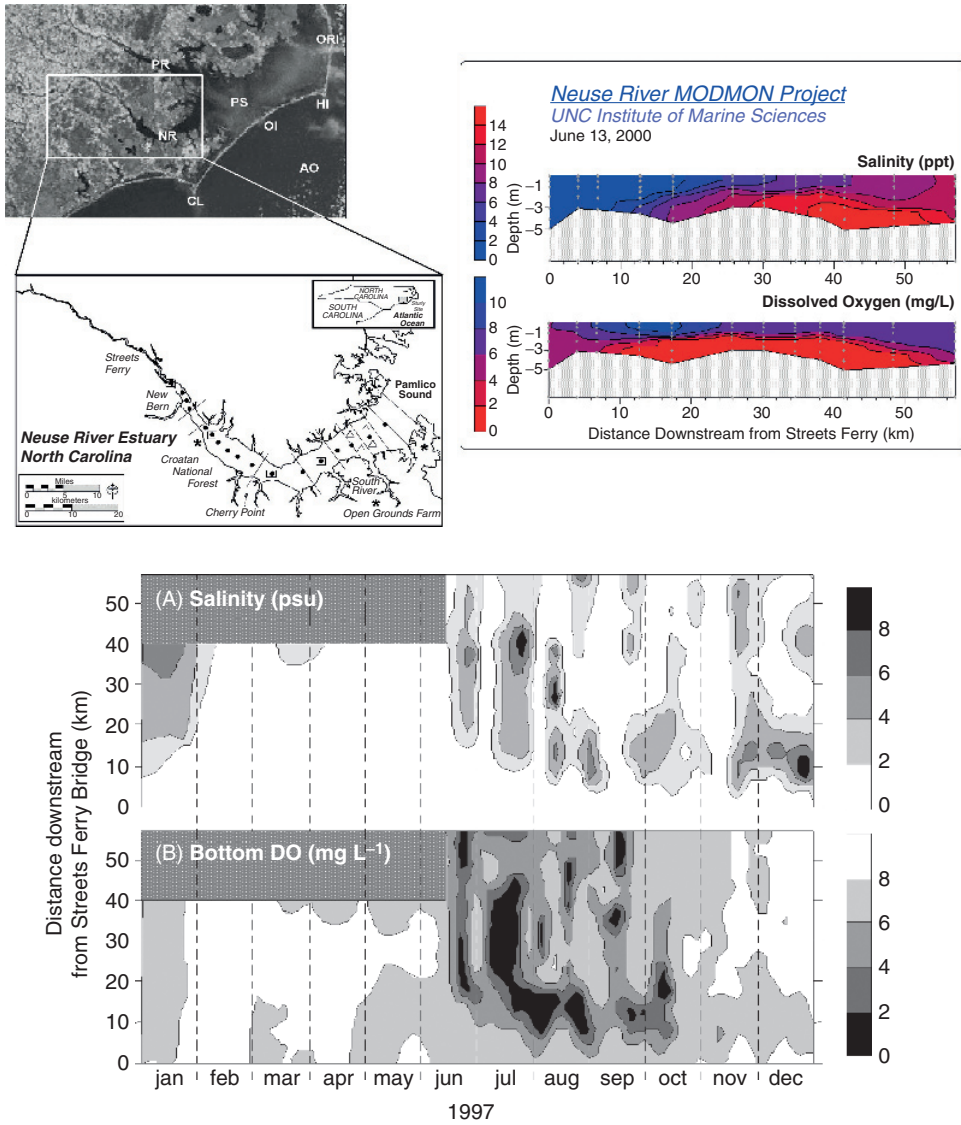
Anthropogenic or cultural eutrophication has been closely linked to population densities in coastal watersheds (Nixon, 1995; Peierls *et al.*, 1991; Vitousek *et al.*, 1997; see also Chapter 9 by Seitzinger and Harrison, this volume; Chapter 18 by Boynton and Kemp, this volume). A significant, and in many instances increasing, proportion of "new" N input can also be attributed to remote sources delivered through airsheds and subsurface aquifers outside the immediate watershed (Galloway and Cowling, 2002; Jaworski *et al.*, 1997; Paerl, 1997). The area of an airshed can greatly exceed that of a watershed for a specific estuary or coastal region. For example, the airshed of the Baltic Sea includes much of Western and Central Europe (Hov *et al.*, 1994), and the airsheds of the US's two largest estuarine ecosystems, the Chesapeake Bay and Albemarle-Pamlico Sound, are from 15 to over 30 times the size of their watersheds (Paerl *et al.*, 2002) (Fig. 11.4). Thus, the airshed of one region may impact the watershed and receiving waters of another (Dennis, 1997) (Fig. 11.4). Furthermore, atmospheric N inputs do not stop at coastal margins. Along the North American Atlantic continental shelf and Mediterranean coast, atmospheric N inputs more than match riverine inputs (Herut *et al.*, 1999; Jaworski *et al.*, 1997; Paerl *et al.*, 2002), underscoring the fact that this is a regional, if not global, issue (Galloway and


Figure 11.3 Low oxygen, hypoxic (less than 2 mg L^{-1} O_2) conditions in the bottom waters of the N-enriched, eutrophic Neuse River Estuary, located in coastal North Carolina (upper left hand side). Upper right hand side shows the lateral extent of hypoxia along the central channel of the estuary during summer (data from the Neuse River Monitoring and Modeling Program, www.marine.unc.edu/neuse/modmon, see Buzzelli et al., 2002). The lower part of this figure shows both the spatial and temporal extent of hypoxia in this estuary (adapted from Buzzelli et al., 2002).

PRINCIPAL OXIDIZED NITROGEN AIRSHEDS FOR:
NARRAGANSETT BAY, CHESAPEAKE BAY,
PAMLICO SOUND, TAMPA BAY, MOBILE BAY,
LAKE PONTCHARTRAIN

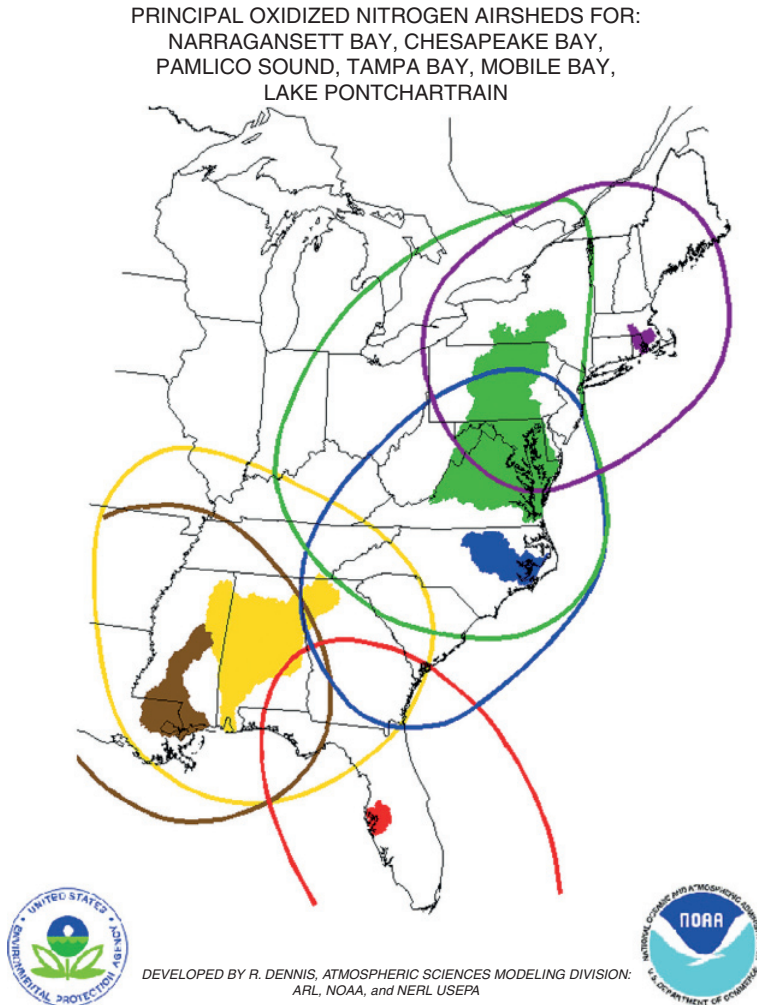
*DEVELOPED BY R. DENNIS, ATMOSPHERIC SCIENCES MODELING DIVISION:
ARL, NOAA, and NERL USEPA*


Figure 11.4 The spatial relationships between selected US Atlantic and Gulf of Mexico Coastal watersheds and airsheds. The airsheds are depicted from modeled depositional patterns of oxidized forms of N, NO$_x$ (*cf.* Paerl et al., 2002). Shown are the air- and watersheds for Narragansett Bay, Chesapeake Bay, Pamlico Sound, Tampa Bay, Mobile Bay, and Lake Ponchartrain. Note that because of their much larger sizes than watersheds, airsheds overlap for these systems. The airsheds also extend over the coastal ocean, indicating that NOx emissions in any of the watersheds have the potential to enrich coastal waters with "new" N. Developed by R. Dennis, Atmospheric Sciences Modeling Division, NOAA/ARL and NERL USEPA.

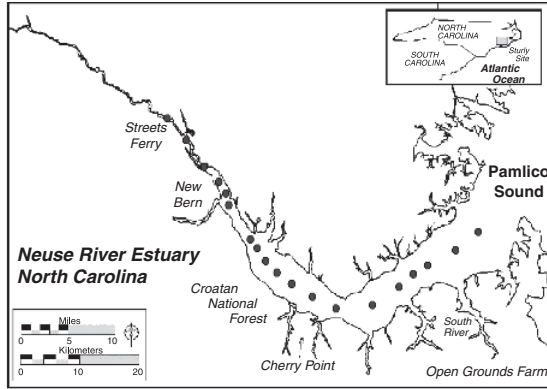
Cowling, 2002). For example, in truly oceanic locations (e.g., Bermuda), North American continental atmospheric N emissions (reduced and oxidized N) are commonly detected and significant (Luke and Dickerson, 1987; Prospero *et al.*, 1996). Likewise, islands in the North and mid Pacific receive N deposition originating on the Asian continent (Prospero *et al.*, 1989).

It has been estimated that riverine and atmospheric N inputs in the North Atlantic Ocean basin are at least equal to and may exceed N inputs by biological N_2 fixation (Howarth *et al.*, 1996; Paerl and Whitall, 1999). Therefore, our understanding of marine eutrophication dynamics needs to consider a range of scales including ecosystem, watershed, regional and global.

2. THE EVIDENCE FOR THE ROLE OF NITROGEN IN MARINE EUTROPHICATION

A vast number of studies conducted over the past 50 years have shown that N enrichment is a primary causative agent of marine (estuarine and oceanic) eutrophication (Dugdale, 1967; D'Elia *et al.*, 1986; Nixon, 1989, 1995; Ryther and Dunstan, 1971; Smetacek *et al.*, 1991). These include:

- *In situ* evidence of the spatial and temporal relationship of N inputs vs. primary production responses (Fig. 11.5)
- Nutrient addition bioassays where N enrichment has been shown to stimulate primary production (D'Elia *et al.*, 1986; Dugdale, 1967; Fisher *et al.*, 1992, 1999; Oviatt *et al.*, 1995; Paerl *et al.*, 1987, 2003; Pennock *et al.*, 1994; Piehler *et al.*, 2004) (Figs. 11.6 and 11.7)
- Paleoecological studies showing that historic increases in anthropogenic nutrient (N–dominated) loading have led to eutrophication (e.g., Chesapeake Bay, Cooper and Brush, 1993)
- Uptake studies which have shown that at ambient concentrations and supply rates, N limitation is widespread (Harrison and Turpin, 1982; Harrison *et al.*, 1987; Syrett, 1988)
- Correlative budgetary studies in which N loading or supply rates were directly related to daily or annual rates of primary production in diverse coastal ecosystems (Nixon, 1986, 1995) (Fig. 11.8)
- Stoichiometric analyses that have shown, relative to the availability of carbon (C), phosphorus (P), silicon (Si) and other nutrients, N often falls below the nutrient supply ratio needed to sustain balanced plant growth (i.e., Redfield ratio of 105:16:1 for C:N:P, Redfield, 1958; Smith, 1990)

Figure 11.5 Relationships, in time and space, between dissolved inorganic N (as nitrate, the dominant new N source), dissolved organic N, inorganic phosphorus (as orthophosphate) concentrations and phytoplankton biomass (as chlorophyll a) along the axis of the Neuse River Estuary, North Carolina. The locations shown on the y axis represent the distance between an upstream location at Streets Ferry Bridge and a downstream location below Cherry Point (both are shown as ◆ on map). Phytoplankton accumulate as distinct concentrations of biomass, which, depending on chlorophyll a levels, may be as visible blooms. During much of the year, nitrate concentrations decreased sharply concurrent with increased chlorophyll *a* concentrations forming the chlorophyll a maxima, while a similar relationship between orthophosphate and chlorophyll a is absent. This serves as in situ evidence that dissolved inorganic N supply is most likely controlling or "limiting" phytoplankton production. Dissolved organic N concentrations appear to closely track phytoplankton biomass, suggesting that phytoplankton may be a source of this form of N.


(For legend see opposite page)
Figure 11.6 Results from seasonal in situ bioassays in the southwest basin of Pamlico Sound. Bars are means of 5 replicates and error bars are on standard deviation. The top panel shows the response of primary productivity of the natural phytoplankton community to the addition of nitrate (+N, 20 μM-N), phosphate (+P, 5 μM-P), nitrate and phosphate (+NP), and the un–amended control. The bottom panel shows the response of chlorophyll a to the same treatments. Relative to controls, strong N limitation was observed in Pamlico Sound despite high load of N to the upstream Neuse River Estuary.

- Specific case studies (e.g., Kaneohe Bay, HI, Chesapeake Bay, Neuse River–Pamlico Sound, Long Island Sound, Narragansett Bay, Baltic Sea, Coastal North Sea, Northern Adriatic Sea, Northern Gulf of Mexico) have shown that increasing N loads are directly linked to accelerated eutrophication (*cf.*, Boesch *et al.*, 2001a,b; Elmgren and Larsson, 2001, Fisher *et al.*, 1999; Nixon, 1995; Paerl *et al.*, 1998, 2004; Rabalais, 2002; Smith *et al.*, 1981; see also Chapter 18 by Boynton and Kemp, this volume)

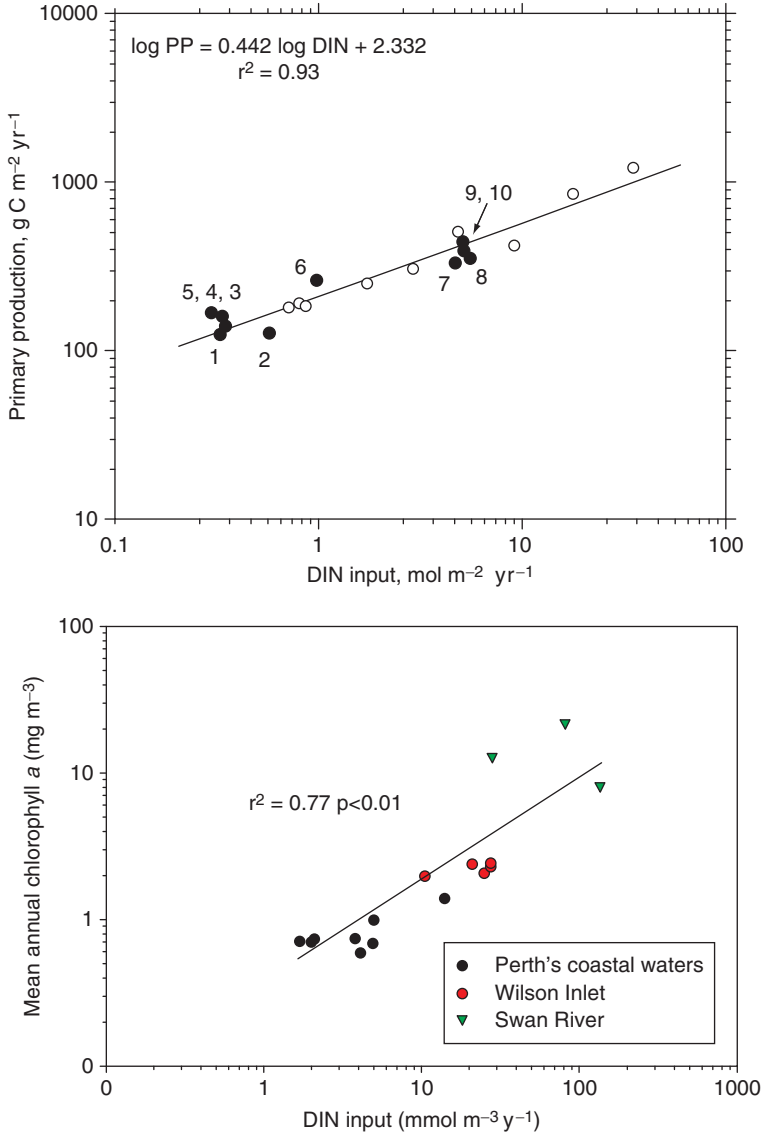
Geochemists have pointed out that theoretically, nitrogen (N_2) fixation should compensate for N-limitation in the worlds oceans. According to this argument, P availability (which is assumed to control N_2 fixation) is ultimately limiting primary production (*cf.*, Doremus, 1982; Tyrell, 1999). This argument operates over geological time scales and requires predictable and consistent biology (i.e., N_2 fixation is solely and consistently controlled by new P inputs). However, the theory does not seem to be compatible with biological time scales and the complex environmental controls of N_2 fixation beyond phosphorus availability (Paerl, 1990; see also Chapter 3 by Carpenter and Capone, this volume and Chapter 7 by Mulholland and Lomas, this volume). In many estuarine and coastal systems, N_2 fixation does not automatically ''turn on'' when P is adequate and N is limiting. Experimental data indicate that other factors, including N:P supply ratios, iron (Fe) limitation, organic matter availability, physical constraints such as turbulence, irradiance, and potentially ''top down'' consumption processes control N_2 fixation (Howarth, 1988; Paerl, 1990). As a result, this argument has limited application to managing coastal eutrophication.
Figure 11.7 Time course of nutrients and chlorophyll *a* in the nutrient-addition bioassay performed on a Chesapeake Bay above-pycnocline water sample from station TF1.5 (Patuxent Tidal Fresh Region) in September 2000. Nutrients were added as one dose just after the initiation of the bioassay (0 days). N was added as NH_4^+ (NH_4Cl) and P was added as PO_4^{-3} (NaH_2PO_4). Added NH_4^+ was rapidly depleted, whereas excess P was present in all treatments except +N. The bioassay was incubated at 60% of surface irradiance. Chlorophyll a responded strongly to any N addition, but not in the control nor to P additions (adapted from Fisher and Gustafson, 2004).


Figure 11.8 Upper frame: Direct relationships between dissolved inorganic N input and primary production in a various estuarine and coastal ecosystems★. Figure adapted from Nixon *et al.*, 1996. Lower frame: Direct relationship between dissolved inorganic N input and phytoplankton biomass, as mean annual chlorophyll *a* content of several Western Australian estuarine systems. Figure adapted from Twomey and Thompson, 2001.
★Details of systems: The open circles are for large (13 m³, 5 m deep) well-mixed mesocosm tanks at the Marine Ecosystems Research Laboratory (MERL) during a multi-year fertilization experiment (Nixon, 1995; Nixon *et al.*, 1986). Natural systems (solid circles) include; (A) Scotian shelf—DIN from Houghton *et al.* (1978), production from Mills and Fournier (1979); (B) Sargasso Sea—DIN from Jenkins (1988), production from Lohrenz *et al.* (1992) mean of 1989 and 1990 values of 110 and 144 g C m⁻² year⁻¹; (C) North Sea—DIN from Laane *et al.* (1993) assuming that the ratio of DIN/TN

Figure 11.8 cont'd in the input from the Atlantic equals that in the Channel, production from Chapter 9 by Seitzinger & Giblin (this volume); (D) the Baltic Sea—DIN and production from Ronner (1985), including DIN flux across the halocline; (E) North Central Pacific—DIN from Platt *et al.* (1984), production from Tupas *et al.* (1993) mean of 1992 and 1993 values of 150 and 185 g C m^{-2} year^{-1}; (F) Tomales Bay, CA, DIN and production from Smith (1991); (G) Continental shelf off New York—DIN and production from Walsh *et al.* (1987); (H) Outer continental shelf off southeastern U.S., DIN and production from Verity *et al.* (1993); (I) Peru upwelling—DIN calculated from annual mean upwelling rate of 0.77 m day^{-1}) and an initial 20 µM concentration of NO$_3$ in upwelled water (Walsh *et al.*, 1980), production off Chimbote from Guillen and Calienes (1981); (J) Georges Bank—DIN from Walsh *et al.* (1987). The equation is a functional regression.

The extent to which N loading promotes eutrophication varies greatly among marine ecosystems. Receiving waters exhibit varying sensitivities to N and other nutrient (P, Fe, Si) loads that are controlled by their size, hydrologic properties (e.g., flushing rates and residence times), morphologies (depth, volume), vertical mixing characteristics, geographic and climatic regimes and conditions. In addition, the magnitude and distribution of N in relation to other nutrient loads can vary substantially. In waters receiving very high N loads relative to requirements for sustaining primary and secondary production, other nutrient limitations may develop. This is evident in estuarine and coastal waters downstream of rivers draining agricultural regions that are highly enriched in N. Examples include the Po (Italy), Rhine (W. Europe), Yangtze (China) and Mississippi (USA), the Ganges (India) and the Nile (Egypt) rivers that over the past century have experienced very large increases in N loading (*cf.* Nixon, 2003; Rabalais, 2002). Here, excessive N loading may be saturating in-shore primary production, leading to either P and Si co-limitation or exclusive P and Si limitation (Conley, 2000; Dortch and Whitledge, 1992; Ferber, 2004; Lohrenz *et al.*, 1999, Sylvan *et al.*, 2006). Further offshore, receiving waters have remained N undersaturated and hence exhibit chronic N limitation (Justić *et al.*, 1995a,b; Rabalais *et al.*, 1996; Smetacek *et al.*, 1991). Because they have remained N limited even in the face of accelerated N loading, off-shore waters can support additional N-driven eutrophication (i.e., they are still in the initial stages of eutrophication) (*cf.* Codispoti *et al.*, 2001; Smetacek *et al.*, 1991).

N-driven eutrophication can exert feedbacks on internal N cycling, which may alter within-system N availability, N budgets and subsequent eutrophication potentials. Numerous studies have shown organic matter loading, sedimentation and the extent of bottom water/sediment hypoxia resulting from eutrophication can regulate key N tranformations, including nitrification and denitrification (Fear *et al.*, 2005; Heggie *et al.*, 1999; Henriksen and Kemp, 1988; Boynton and Kemp, 2000; Seitzinger and Giblin, 1996; Smith and Hollibaugh, 1989, 1998; Twilley *et al.*, 1999). These within-system feedbacks can significantly affect N availability, and hence subsequent eutrophication potentials (Eyre and Ferguson, 2002; Smith and Hollibaugh, 1998). For example, in the Baltic Sea the extent of hypoxia formation is thought to control denitrification rates and hence the ability of the system to depurate itself of fixed N (Elmgren and Larsson 2001; Wulff *et al.*, 2001). Lastly, top down effects such as grazing, and removal of grazers by overfishing (Jackson *et al.*, 2001) can significantly alter the flux, availability, utilization and manifestation of N and other nutrient inputs.

3. Nutrient, Physical and Climatic Controls of Marine Eutrophication

While anthropogenic N enrichment has been linked to N-driven eutrophication of estuarine and coastal waters (*cf.* Boesch *et al.*, 2001a,b; Nixon, 1995; Smetacek *et al.*, 1991), the manner and extent by which eutrophication affects production, nutrient cycling, trophodynamics, and habitat condition are complex products of nutrient inputs, physical features of receiving waters and climatic conditions. In arid regions, the generation, transport and fate of nutrients are quite distinct from wet regions. Similarly, polar, temperate and tropical coastal and oceanic regions can respond in contrasting manners to N and other nutrient inputs. Episodic climatic events, such as large storms and hurricanes, and extreme temperatures strongly modify the degree to which eutrophication is manifested in coastal waters.

As a result, marine waters exhibit highly individualistic responses to N loads over seasonal and longer (multi-annual, decadal) time scales. The degree to which these systems are exposed to tidal exchange and vertical mixing is critical for determining and predicting how they respond to specific N loads (Cloern, 1999, 2001; Nixon, 1995; Vollenweider *et al.*, 1992). Another variable is the manner in which N is delivered, ranging from acute pulsed events such as storms and associated flooding, to longer-term gradual (chronic) increases in N loading associated with more predictive seasonal, annual and interannual hydrologic cycles. There are striking contrasts in estuarine response to N inputs that reflect a range of hydrodynamic, optical and climatic conditions (Cloern, 1999, 2001; Sharp, 1994, 2001). North American examples include the contrast between strong tidally-driven estuarine systems like Delaware Bay and San Francisco Bay, moderately tidally-driven systems like Chesapeake Bay, micro-tidal, lagoonal systems like North Carolina's Pamlico Sound and Texas's Luguna Madre, and semi enclosed coastal systems like Florida Bay and the Long Island Sound (Bricker *et al.*, 1999). While these systems may receive comparable amounts of N, they exhibit differential biological responses. Interactions between the biological response and physical forcing features are significant. If the rate of flushing exceeds the growth and doubling rates of the resident phytoplankton communities, the system may be able to tolerate a relatively high N load without showing symptoms of eutrophication. In contrast, under similar N loading but relatively long residence time conditions, phytoplankton growth rates may be able to keep up with or exceed the rates at which populations are flushed from the system. Under these conditions, symptoms of eutrophication (algal blooms, hypoxia) are most strongly felt within the estuary, while under more highly-flushed, short residence time conditions, eutrophication may manifest itself more in downstream coastal waters (Fig. 11.9).

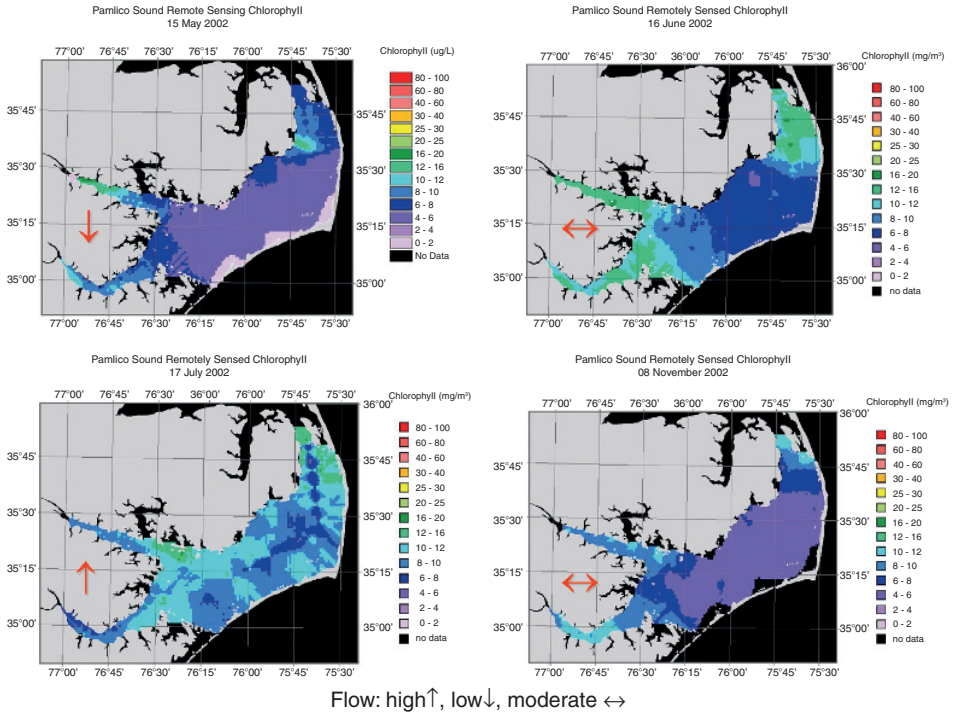
Variation in ecosystem sensitivity and response due to hydrologic variability can be seen in North Carolina's Pamlico Sound, the US's largest lagoonal ecosystem and second largest estuary (1700 km^2), draining numerous sub-estuaries. This system exhibits N limitation from its upstream oligohaline riverine components to the inlets


Figure 11.9 Spatial relationships between the phytoplanton biomass, as chlorophyll *a*, and estuarine freshwater discharge conditions in the Albemarle–Pamlico Sound estuarine system North Carolina, USA. Surface water chorophyll *a* concentrations were estimated using an aircraft-based SeaWiFS remote sensing system (Harding and Perry, 1997), calibrated by field samples that were analyzed fluorimetrically (Paerl *et al.*, 1995). Under relatively low flow and long residence time conditions, phytoplankton biomass is concentrated in the upstream reaches of the estuarine tributaries. Under moderate flow, phytoplankton biomass maxima extend further downstream. Under high flow (i.e., short estuarine residence time) phytoplankton biomass maxima are shifted further downstream into the open Pamlico Sound.

mediating exchange with the Atlantic Ocean (Peierls *et al.*, 2003; Piehler *et al.*, 2004; Twomey *et al.*, 2005). If high flow coincides with the period of maximum productivity (early spring through summer), the zone of maximum phytoplankton biomass accumulation (chlorophyll *a* ''maximum'') tends to be in the downstream estuarine segments (Valdes–Weaver *et al.*, 2006). In contrast, if low flow accompanies maximum productivity, or if drought conditions follow periods of high nutrient discharge, maximum biomass accumulation typically tends to occur in the upstream oligo- to mesohaline regions of the estuaries (Figs. 11.5 and 11.9). In either case, productivity may be enhanced by similar N loads, but depending on the means of N delivery (high vs. low flow discharge), ecosystem responses and impacts vary.

The Baltic Sea exemplifies the strong interactions between physical and chemical forcing features in terms of how eutrophication is expressed. There is general

agreement that excessive P and N loading have led to the eutrophication of this large brackish water system (Larsson *et al.*, 1985), although the history of productivity and algal boom responses to increasing levels of nutrient loading remains unclear (Elmgren, 1989; Elmgren and Larsson, 2001). On interannual and decadal time scales, the magnitudes, duration, biogeochemical and trophic ramifications of eutrophication vary considerably, depending on these interactions. Riverine and atmospheric inputs in the Eastern and the Southern Baltic regions have large impacts on amounts and ratios of new N and P loads controlling productivity (Conley *et al.*, 2002; Elmgren and Larsson, 2001; Savchuk and Wulff, 1999; Turner *et al.*, 1999). Furthermore, the freshwater runoff associated with large rivers draining the eastern, southern and northern Baltic influence both salinity and vertical stratification regimes throughout the sea. On the western side, dense, saltwater inflow from the North Sea is a key determinant of vertical salinity stratification, nutrient fluxes and budgets (Elmgren and Larsson, 2001; Humborg *et al.*, 2002; Savchuk and Wulff, 1999). The interaction of these physical–chemical forcing features in time and space determines the nature, distribution and duration of nutrient limitation, the magnitude and extent of manifestations of eutrophication, and the hypoxic volume of the Baltic basin. This interaction can vary substantially on interannual and decadal time scales (Elmgren and Larsson, 2001; Humborg *et al.*, 2002; Turner *et al.*, 1999). In single or consecutive years of high freshwater runoff combined with high nutrient delivery, productivity and biomass accumulation tends to be relatively high (e.g., spring non-cyanobacterial blooms, followed by large summer cyanobacterial blooms). High delivery of freshwater also maximizes vertical stratification, which in turn favors water column stability and buoyant cyanobacterial bloom species. Under these conditions maximum expression of eutrophication takes place (Wulff *et al.*, 2001). Conversely, relatively dry years tend to reduce N loading, and phytoplankton productivity and biomass accumulation are relatively low. The resultant ecosystem effect is a reduction in eutrophication potential (Conley *et al.*, 2002; Wulff *et al.*, 2001).

Another example of the interaction of physical forcings and nutrients modulating coastal eutrophication was provided by Bledsoe and colleagues (2004). In a 3-year study of the Suwanee River estuary in Florida, excessive phytoplankton growth was controlled by both nutrient loading and residence time. Maximum phytoplankton biomass was recorded during periods when loading from the river was elevated and prevailing on-shore winds decreased the flushing rate from the estuary. Their work illustrated the difficulties of managing nutrients in the context of mitigating natural circumstances such as meteorological conditions.

Very large climatic events, such as hurricanes and associated floods, can overshadow more subtle, longer-term (chronic) trends in eutrophication and water quality decline. The three sequential hurricanes (Dennis, Floyd and Irene) that struck coastal North Carolina during a six week period in fall 1999 and provided a striking example of the interacting effects of anthropogenic N loading and climatic forcing. These storms delivered up to 1 m of rainfall and caused record flooding in the largely agricultural watershed of the Pamlico Sound. The floodwaters rapidly mobilized nutrients and turned the Sound's sub-estuaries into raging rivers,

discharging nutrient enriched floodwaters directly to the Pamlico Sound (Paerl *et al.*, 2001; Peierls *et al.*, 2003). During normal hydrologic years, these N-limited estuaries remove much of the terrigenously-supplied N, either by uptake and assimilation or denitrification and dissimilation, to the extent that only a fraction of the externally supplied new N makes it past the estuarine filter into Pamlico Sound. During these years, symptoms of eutrophication (algal blooms, hypoxia and anoxia, fish kills) are largely confined to the estuaries themselves (Buzzelli *et al.*, 2002; Paerl *et al.*, 1998, 2006a,b,c) (Fig. 11.9). In contrast, floodwaters following large storm events flush the algal filter and nutrient-rich, low-salinity waters into Pamlico Sound and adjacent coastal waters (Paerl *et al.*, 2006a,c). From a eutrophication perspective, the productivity and algal bloom response takes place in the Sound and coastal waters during storm-prone periods, while during storm-free periods, the productivity response is more confined to the upstream estuarine regions (Paerl *et al.*, 2001; Peierls *et al.*, 2003, Valdes-Weaver *et al.*, 2006). Where and how this largely-anthropogenically generated N load manifests itself is a product of climatic forcing features such as storms and the resultant freshwater discharge patterns (see also Chapter 9 by Seitzinger and Harrison, this volume).

A single large summer–fall hurricane like Fran (1996) or Floyd (1999) can deliver about as much "new" N as the more predictable winter–spring wet period (Fig. 11.10). Thus, during a year supporting "normal" winter–spring runoff, accompanied by one or several summer–fall hurricanes, approximately twice the expected annual N load is delivered to downstream estuarine and sound waters. The eutrophication response to these large N loads can be seen in the form of above-average phytoplankton biomass production in the downstream waters of Pamlico Sound (Fig. 11.9) (Paerl *et al.*, 2006a,c). This demonstrates that the eutrophication gradient can be displaced in response to hydrologic discharge.

The manner and extent to which climatic conditions affect coastal N loading and eutrophication are, to some extent, dependent on land-based N sources and discharge characteristics. In rural agricultural watersheds, a large proportion (as much as 80% in coastal North Carolina) of anthropogenic N is discharged as diffuse, non-point source (NPS) loading. In contrast, in mixed urban and agricultural watersheds such as those in the Chesapeake Bay region, NPS loads account for about half the N discharge, while in largely urban watersheds such as those discharging to the Long Island Sound, point sources (PS) tend to dominate N discharge (80% PS, 20% NPS). NPS-dominated watersheds tend to be far more "leaky" in response to storm-driven N discharge events than PS dominated watersheds. On the other hand, point sources tend to dominate N discharge to estuarine and coastal waters during relatively dry periods (Howarth, 1998). The ecological and management ramifications of these contrasting scenarios are considerable. For example, if receiving waters have a tendency to develop blooms during high flow early spring-summer or fall periods, NPS controls are likely to be more effective at stemming eutrophication. On the other hand, PS controls may prove critical in controlling blooms under mid-summer, low flow conditions. In most instances, combined NPS and PS N input reduction is the most prudent and effective N management strategy for controlling eutrophication on a year-round and longer-term basis (see section VII) (Paerl *et al.*, 2006b).
Figure 11.10 Annual patterns of dissolved inorganic nitrogen (DIN: nitrate/nitrite plus ammonium) loading to the Neuse River Estuary, NC. Years were chosen that represented different hydrologic conditions, including a drought year (1994), a year with relatively high rainfall during the typically rainy winter–spring periods, followed by low rainfall summer conditions (1998), years in which large summer–fall hurricanes affected the watershed (Fran in 1996, Dennis and Floyd, in 1999) and relatively wet years that were impacted by a coastal hurricane that delivered relatively little rainfall (Bonnie in 1998, Isabel in 2003). In years where hurricanes delivered large amounts of rainfall to the watershed (1996, 1999), hurricane-based N loads were on the same order of magnitude as spring runoff based N inputs. It is evident that rainfall amounts and periodicity have very large impacts on the delivery of land-based N to the lower estuary, receiving sound and coastal waters.

4. Is Nitrogen Nitrogen? Roles of Different Nitrogen Sources in Marine Eutrophication

Externally-supplied N comes in a various forms, including inorganic and organic, reduced (ammonium) and oxidized (nitrate, nitrite) inorganic N, all of which are potentially available to support new production and eutrophication. Laboratory experiments on phytoplankton isolates and bioassays with natural phytoplankton communities have indicated that these contrasting forms may be differentially and preferentially utilized, indicating that, depending on composition of the affected phytoplankton community, some forms are more reactive than others (Collos, 1989; Riegman, 1998; Stolte et al., 1994; see also Chapter 7 by Mulholland and Lomas, this volume). Phytoplankton community composition can also be altered by varying proportions and supply rates of different forms of N (Dortch, 1990; Harrington, 1999; Piehler et al., 2002; Pinckney et al., 1999; Stolte et al., 1994). In addition, specific N compounds may interact with light availability, hydrodynamics and other nutrients, most notably P, Si, Fe, and trace metals, to influence phytoplankton community growth rates and composition (Dortch and Whitledge, 1992; Harrison and Turpin, 1982; Smith, 1990; see also Chapter 38 by Hutchins and Fu, this volume and Chapter 37 by Kudela, this volume). These findings raise important questions about the quantitative and qualitative linkages between new N inputs and marine eutrophication:

- How does the composition of the new N pool influence new production and biogeochemical cycling in N-sensitive waters?
- To what extent does enrichment with certain N forms affect algal bloom potentials, specifically dominance by harmful algal bloom taxa (dinoflagellates, cyanobacteria, etc.)?
- Are some forms of N more potent catalysts of eutrophication than others?
- How are projected changes in human activities in coastal water- and air-sheds related to shifts in the composition of new N inputs, and can we link these shifts to predictable changes in the composition and ecological roles of primary producers catalyzing marine eutrophication?

One example of shifting N inputs is the proliferation of intensive livestock operations in coastal watersheds, which has led to large increases and changes in chemical composition of nitrogenous compounds discharged to estuarine and coastal waters via runoff, groundwater and atmospheric deposition (Galloway and Cowling, 2002; Howarth, 1998; Paerl, 1997). In general, coastal waters under the influence of these operations are experiencing increases in total N loading as well as a shift toward more reduced N (ammonium, organic N) relative to oxidized N (nitrate, nitrite) (Galloway and Cowling, 2002; Howarth et al., 2002). These increases, combined with increases in hypoxia and anoxia in receiving waters, are leading to more ammonium-rich conditions, which will favor algal species able to best exploit this N form. Alternatively, conversion of agricultural to urban lands tends to lead to more nitrate-enriched conditions, potentially favoring plant taxa best able to exploit this N form. Lastly, disruption or destruction of wetlands adversely affects their important N filtering capabilities, resulting in changes in both the amount and composition of N compounds that are processed by these ecosystems.

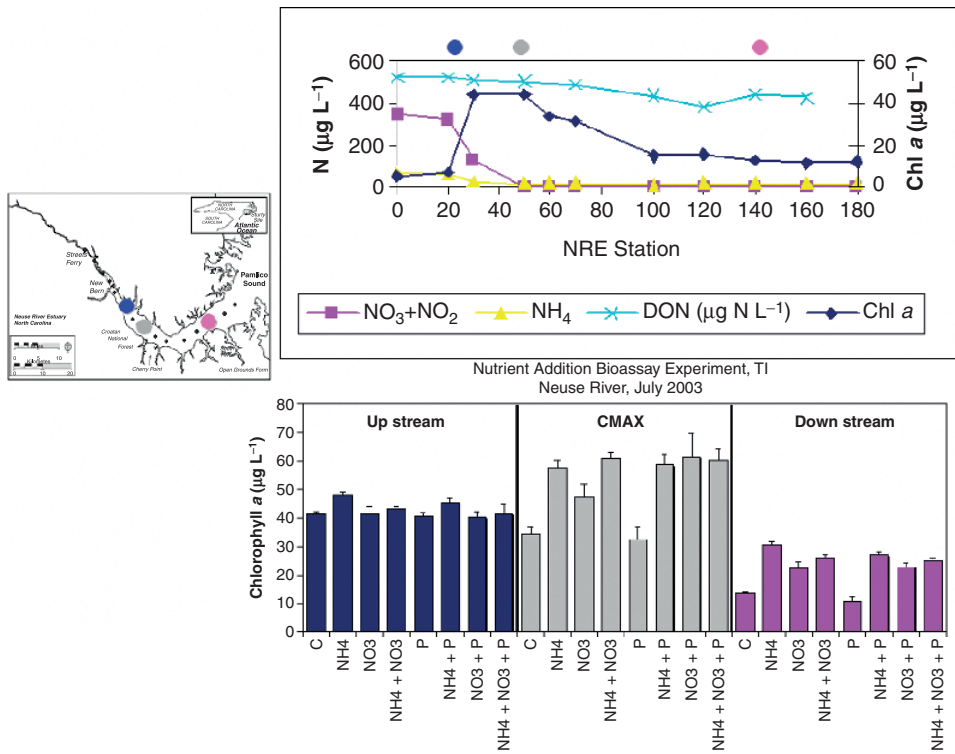
To improve our understanding of the biogeochemical and trophic roles "new" N composition plays in marine eutrophication, we must combine observational and experimental approaches focused on microalgal and higher plant communities responsible for eutrophication. Approaches include linking loading characteristics of specific N compounds and groups of compounds (e.g., dissolved organic matter) to microalgal growth responses in space and time. This approach relies on: (1) intensive monitoring of N inputs, their distributions and uptake characteristics in relation to microalgal community dynamics (Fig. 11.11), (2) nutrient manipulations (additions or reductions) where the community growth and compositional responses are assessed using various groups of species–specific growth/composition parameters, including microscopic observations, biochemical, molecular and automated identification and enumeration techniques (e.g., image analysis, diagnostic photopigment analyses, flow cytometry, genetic screening using probes, fluorescence *in situ*


Figure 11.11 Results from a set of *in situ* nutrient addition bioassays conducted at three locations along the axis of the Neuse River Estuary that was routinely monitored for ambient nutrient (ammonium, nitrate, phosphate) concentrations and chlorophyll *a* as an indicator phytoplankton biomass. All nitrogen forms were added at 20 μM-N, while phosphate was added at 5 μM-P. The locations of bioassays are shown (symbols) on the map: (A) just upstream of the chlorophyll *a* maximum (C$_{max}$); (B) at the C$_{max}$ and (C) downstream of the C$_{max}$. Strong N limitation was encountered at the C$_{max}$ location. Downstream of the C$_{max}$, N limitation dominated and there was a strong preference for ammonium over nitrate as a DIN source.

hyridization, microautoradiography, microarrays), (3) a combination of the above, in which observational and experimental results are coupled to predictive modeling over a range of complexities, from species to communities to habitat and ecosystem levels.

The ability of some algal groups to utilize organic N, which often is the most plentiful new N source (Cornell *et al.*, 1995; Peierls and Paerl, 1997; Seitzinger and Sanders, 1999; see also Chapter 7 by Mulholland and Lomas, this volume), can also provide a competitive advantage (Antia *et al.*, 1991). For example, some heterotrophic dinoflagellates, cyanobacteria, diatoms, and brown algae (e.g., the brown tide species, *Aureococcus anophagefferens*) can assimilate diverse organic compounds over a range of naturally-occurring concentrations (Antia *et al.*, 1991; Gobler *et al.*, 2002; Kana *et al.*, 2004). In addition, members of these groups are capable of photoheterotrophy, which could be advantageous in illuminated surface waters where bloom species often thrive (Paerl, 1991). Lastly, it is well known that bloom-forming phytoplankton exchange a variety of organic and inorganic N compounds with bacterial and other algal epiphytes in consortial relationships (Paerl and Pinckney, 1996). Such exchanges can benefit the growth of both host and epiphyte, and may be particularly effective in the development and persistence of blooms in low-nutrient oligotrophic waters experiencing incipient eutrophication. Essential to these consortial associations is metabolic flexibility, particularly the ability to utilize and exchange a variety of N-containing compounds if and when they become available for supporting growth and bloom formation. This is relevant for planktonic and benthic marine cyanobacterial nuisance bloom genera (e.g., *Nodularia*, *Aphanizomenon*, *Lyngbya*), which can utilize inorganic and organic new N inputs and can also resort to N_2 fixation as an N source when external N sources are depleted. Using this "switch hitting" capability, these taxa are able to take advantage of intermittent or pulse nutrient loading events such as periods of riverine runoff following storm events, periodic upwelling and deepening of the mixed layer, atmospheric deposition (rainfall and dryfall) and groundwater loading events. This metabolic flexibility may help initiate and sustain massive blooms of these diazotrophic cyanbacteria in the eutrophied Baltic Sea, nutrient enriched coastal lagoons, and some estuaries (Paerl, 1988) as well as shallow water benthic environments (tropical reefs and intertidal flats) experiencing nutrient enrichment (La Pointe *et al.*, 1997).

Some allochthonous organic N compounds may also have chemotactic and allelopathic functions (Gallucci and Paerl, 1983; Keating, 1977; Legrand *et al.*, 2003). In these capacities, specific compounds that are excreted by some phytoplankton taxa may attract or repel other phytoplankton or bacterial taxa, and serve as cues for establishing specific associations between consortial and symbiotic partners. In this manner, organic N compounds (e.g., amino acids, peptides) may play a central and crucial role in determining microbial community composition, including establishment and proliferation of bloom species (Suikkanen *et al.*, 2004).

These results provide insight into the potential biogeochemical and trophic impacts of shifting compositions and quantities of new N compounds implicated in marine eutrophication. Both the amount and makeup of new N play critical roles in determining the magnitude and composition of primary producers. Structural and functional modifications of the primary producer community strongly influence

biogeochemical cycling and trophic (heterotrophs, grazers, herbivores and carni-
vores) responses to nutrient over-enrichment and eutrophication of estuarine, coastal
and open ocean waters.

5. THE ROLE OF NITROGEN IN RELATION TO OTHER NUTRIENTS

While excessive N loading has been implicated in marine eutrophication, it
also plays a role in the balance, availability and ecological manifestations of other
potentially-limiting nutrients, most notably P, Si and Fe (Hecky and Kilham, 1988;
see also Chapter 37 by Kudela, this volume and Chapter 38 by Hutchins and Fu, this
volume). N loading from anthropogenic sources has dramatically increased over the
past 50 years (National Research Council, 2000), to the extent that in some
receiving waters N over-enrichment has led to shortages in other nutrients required
for metabolic activity and growth. Under these conditions, N may be supplied in
excess of the stoichiometric nutrient ratios needed to support phytoplankton and
higher plant growth (i.e., Redfield ratio, Redfield, 1958). If N over-enrichment
persists for days to weeks, other nutrient limitations may, at times, dominate.
Examples can be found in the Northern Gulf of Mexico and the Northern Adriatic
Sea, regions receiving very high N loads discharged via the Mississippi and Po Rivers
respectively. Here, P limitation, N and P co-limitation and Si limitation (of diatom
growth) have been observed in the fresh and brackish water components of riverine
plumes that can extend well over 100 km into the receiving waters (Lohrenz *et al.*,
1999; Sylvan *et al.*, 2006). In these instances chronic increases in N loading from the
vast amount of agricultural land in the Mississippi and Po river basins appear to have
induced P and other nutrient limitations (Ferber, 2004, Justić *et al.*, 1995a,b). A
similar scenario is evident in the Chesapeake Bay, where elevated N loading
accompanying the spring maximal freshwater runoff period increases the potential
for P limitation (Fisher and Gustafson, 2004) (Fig. 11.12).

These shifts in nutrient limitation can lead to alterations in phytoplankton commu-
nity composition, such as a shift from diatoms towards flagellates and dinoflagellates
(Justić *et al.*, 1995b; Rabalais *et al.*, 2001; Turner *et al.*, 1998). Planktonic invertebrates,
shellfish and finfish consumers whose diets are highly dependent on the composition
and abundance of specific phytoplankton food species and groups may then be affected
(Turner *et al.*, 1998). In the Baltic and Black Sea basins, the combined effects of
enhanced watershed N loading and increased Si retention due to damming of rivers
has led to dramatic decreases in Si:N ratios in freshwater discharge to these seas. These
changes may affect nutrient cycling and food web dynamics (Humborg *et al.*, 2000).

Biogeochemical and trophic responses to altered nutrient loading stoichiometry
are intimately linked (Conley, 2000). For example, if phytoplankton composition
and biomass are altered in response to relatively high N:P and N:Si loads, the trophic
fate of this new production may change. In the case of diatoms, which are readily
grazed and packaged as fecal pellets by zooplankton, changes in their availability and
abundance may affect the downward flux and accumulation of such nutrient-rich
pellets. Furthermore, Si sedimentation via such pellets may be altered, resulting in
Figure 11.12 Seasonal variations in light, P, and N as limiting resources for phytoplankton at mesohaline Chesapeake Bay station CB4.3C during 1990–2003. Responses to nutrient addition bioassays were transformed to indices as described in Fisher *et al.* (1999). Values of the index >0.5 indicate the primary limiting resource. Upper panel is the average monthly Susquehanna River discharge during 1968–2001 (long term mean) and the monthly average discharge during the study period (Aug. 1990–Dec. 2003), with the 30 year mean discharge shown as the horizontal line (Figure adapted from Fisher and Gustafson, 2004).

changes in biogenic Si cycling in sediments and availability to future diatom populations. The composition of other phytoplankton groups may also be affected by anthropogenically-altered inputs and fluxes of growth-limiting nutrients. For example, taxa that are favored by increased levels of N supply relative to P and Si are likely to benefit (Dortch and Whitledge, 1992). These would include flagellates and dinoflagellates (Elmgren and Larsson., 2001; Humborg et al., 2000), and groups that include toxic and other bloom-forming nuisance species (Anderson and Garrison, 1997; Hodgkiss and Ho, 1997). Toxic, ungrazed nuisance species are likely to increase the downward flux of carbon and other nutrients, since they will be less effectively cycled in the water column. This, in turn may exacerbate hypoxia and anoxia potentials in vertically stratified waters. The ecosystem-level ramifications are multifold, including altered cycling of oxygen and nutrients, which would impact nutrient supply and availability to primary and secondary producers and trophic relations between them (including the microbial loop).

At nearshore and offshore oceanic locations, nitrogen enrichment can also affect primary production, nutrient cycling, and nutrient limitation. Nutrient addition experiments conducted on natural phytoplankton communities over a range of scales (microcosms to large-scale surface water fertilization experiments) have shown that N additions that mimic upwelling, atmospheric and riverine inputs are capable of stimulating primary production and may help initiate blooms (Paerl, 1997; Paerl et al., 1999; Zhang, 1994) (Fig. 11.13). These studies have also shown the potential for N-driven eutrophication to exist in open ocean waters. However, aside from some coastal seas such as the North Sea, Baltic, N. Adriatic, Northwest Pacific coastal regions, Sea of Japan and W. Mediterranean, the rates of N loading appear to still be too low to elicit the most obvious signs of eutrophication, such as noticeable ''greening'' of these oligotrophic waters and persistent algal blooms. The slow delivery of N and other potentially-limiting nutrients (e.g., Fe) to these waters most likely prevents such events from occurring. In contrast, acute N loading events, such as fertilizer spills from ships, riverine floodwaters extending over continental shelves (e.g., Gulf of Mexico, Amazon, Yangtze and Yellow Rivers), and experimental large-scale fertilization experiments (Kolber et al., 2002) are capable of eliciting significant increases in primary and potentially secondary production. Therefore, the potential for open ocean eutrophication exists and should be carefully monitored.

Fortunately, remote-sensing platforms specifically designed for detecting and quantifying phytoplankton biomass (as chlorophyll and other photopigments) are routinely collecting data over a range of temporal and spatial scales. In particular, NASA's satellite-based SeaWiFS ocean color sensing system can examine long-term, large-scale trends in estuarine, near-shore and oceanic primary production and producer biomass (http://seawifs.gsfc.nasa.gov/SEAWIFS.html) (Harding and Perry, 1997). This system, as well as aircraft and satellite-based multispectral (e.g., MERIS, MODIS) and hyperspectral (e.g., AVIRIS) remote sensing platforms offer an excellent opportunity to document coastal and open ocean phytoplankton (and higher plant) production baselines, against which change can be gauged over appropriate spatial and temporal scales.

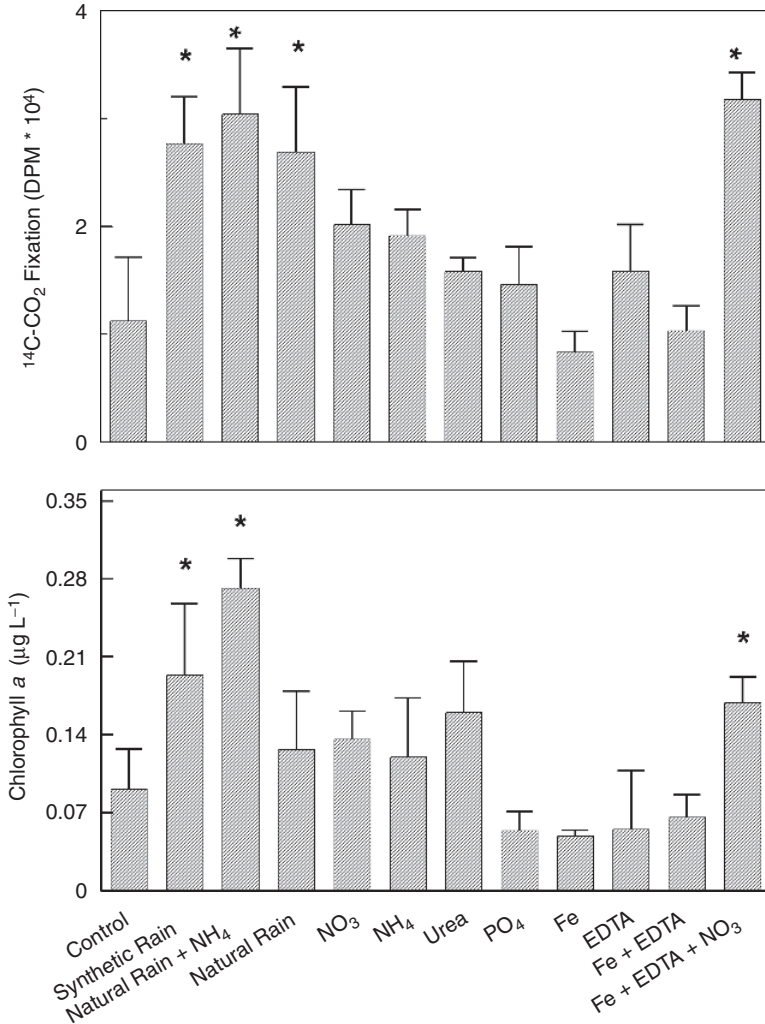
An interesting result of open ocean nutrient limitation/enrichment research is the discovery that primary production in certain oligotrophic ocean gyres (Northern and


Figure 11.13 Effects of the addition of dissolved inorganic N (NH_4^+ and NO_3^-, 5 μM each), N-containing rainfall (collected at Morehead City, NC), iron (as EDTA-chelated and non-chelated $FeCl_3$; 0.2 μM each; EDTA, and the combination of NO_3^- and EDTA-chelated $FeCl_3$) on coastal Atlantic Ocean phytoplankton communities. *In situ* bioassays were conducted for 5 days on seawater collected approximately 25 km SE of Beaufort, NC in the summer of 1994. Phytoplankton growth responses are reported as photosynthetic CO_2 fixation and chlorophyll *a* accumulation. *Indicates treatments were significantly ($p < 0.05$) from controls, using Bonferroni *a posteriori* comparisons of the means. See Paerl *et al.* (1999) for details of the experimental procedures.

Central Pacific, Southern Ocean) can be Fe rather than N or P limited (Behrenfeld and Kolber, 1999; Martin *et al.*, 1994). These regions have dissolved inorganic N and P concentrations in excess of phytoplankton requirements, indicating that N enrichment is not likely to impact eutrophication potentials of these waters and that any eutrophication effect of N enrichment is reliant on parallel new Fe inputs (Kolber *et al.*, 2002).

New Fe inputs to these regions are largely atmospheric, originating from continental dust, volcanic sources, fossil fuel combustion and industrial sources (Duce *et al.*, 1996; GESAMP, 1989). For subtropical N. Atlantic oceanic waters, African Saharan dust storms appear to be a major Fe input source supporting algal bloom formation, including red tides (Walsh and Steidinger, 2001). New Fe inputs from this and other aeolian sources may in part control the assimilation of externally-supplied N as well internally-supplied N via N_2 fixation and upwelled regenerated N. A similar scenario has been proposed for a region of the Indian Ocean (Takeda *et al.*, 1995).

In more coastal/shelf regions, such as the W. Atlantic Gulf Stream off the US East Coast and off western Florida, the potential for iron limitation has also been demonstrated (Paerl *et al.*, 1999; Walsh and Steidinger, 2001). However, in these regions, Fe and N limitations appear to be closely linked and interdependent. For example, while dissolved inorganic nitrogen (DIN) additions, as either ammonium or nitrate, stimulated primary production and phytoplankton productivity (as CO_2 fixation) and biomass (as chlorophyll *a*) in oligotrophic Gulf Stream and Sargasso Sea waters off the North Carolina coast, per amount of N, ammonium often proved to be more stimulatory than nitrate (Paerl *et al.*, 1999) (Fig. 11.13). This differential response was attributed to the Fe required by phytoplankton to reduce nitrate (nitrate reductase) prior to its use as an N source to support growth. This requirement does not exist for ammonium assimilation. These results suggest that, in the case of nitrate enrichment, there may be a parallel Fe requirement, indicating that for eutrophication to proceed additions both nutrients are required. This synergistic enrichment may be provided by certain anthropogenic pollution sources, such as industrial and urban atmospheric emissions or riverine inputs enriched in both N and Fe (Church *et al.*, 1984; Duce *et al.*, 1986). Thus, the connection between human activities and marine eutrophication may need to include consideration of simultaneous multiple nutrient enrichment processes, which are influenced by agricultural, urban, and industrial activities.

6. HUMAN ACTIVITIES IN THE COASTAL ZONE AND EUTROPHICATION

Human activities in and modifications of coastal watersheds significantly affect estuarine and coastal N–driven eutrophication (Boesch *et al.*, 2001a,b; Vitousek *et al.*, 1997; see also Chapter 36 by Boyer and Howarth, this volume and Chapter 9 by Seitzinger and Harrison, this volume). Most prominent are coastal urbanization, human wastewater discharges, the destruction and modification of coastal wetlands, and large-scale agricultural and aquacultural operations (Fig. 11.1). As population density continues to grow in the coastal zone, these activities and associated pollution are becoming increasingly significant sources of N and other nutrients to coastal waters.

6.1. Human development of the coastal landscape

With increases in coastal population, and the accompanying shifts in land use (Vitousek and Mooney, 1997), come several changes that have significant impacts on the delivery of nitrogen to coastal waters. Sources of N change, and generally

increase, as human use of a coastal region intensifies. Wastewater, agricultural discharge, stormwater and industrial sources of N are among the major contributors. Another change that accompanies human development of the coastal landscape is an alteration of the transport mechanisms of N to coastal waters. Imperviousness, ditching, channelization of streams and rivers and removal of native vegetation all contribute to increased rates and quantities of N transport from the land to the adjacent water bodies. Finally, human activities in the coastal region often lead to significant loss of the natural landscapes that either retain or remove N. Wetland loss and watershed-scale landscape alterations are well documented, and contribute to the increased transport of N from human affected coastal regions. There is a cumulative impact on N transport to coastal waters from human development of the coastal landscape that includes the effects of increased sources, modified transport and altered biological processing of N (Fig. 11.1).

Sources of N that increase with human activity include sewage treatment plant discharges, fertilizers associated with agriculture and other activities (e.g., lawns, gardens, golf courses), increased atmospheric N deposition and increased stormwater carrying myriad non–point source pollutants associated with urbanization (Boesch et al., 2001a; Paerl, 1997). In the first stages of human development of coastal regions, the shifts in land use are generally from forest to agriculture and residential. Once an area is populated, the shifts in land use are then away from open space (forest and agriculture) toward residential and industrial (Beach, 2002). Through this sequence of land use alteration the N sources change and the trend is generally towards more and more N transported to coastal waters (Line et al., 2002).

Human modifications in the transport of water from land to coastal waters occur throughout coastal watersheds (Schueler and Holland, 2000). If sources of N are present, transport of water from the landscape to the aquatic system usually translates into enhanced N mobilization and loading. Urbanization leads to increased imperviousness through the presence of roads and rooftops, and imperviousness leads to accelerated transport of water from the landscape. However, imperviousness alone is not responsible for the changes in transport of stormwater and entrained pollutants (Beach, 2002). Poorly planned urban areas often exacerbate the problems associated with imperviousness through sprawling development. Development characterized by sprawl tends to have more and wider roads that have the added effect of more driving, and thus larger sources of N and other potential pollutants (Trobulak and Frissell, 2000). Improving the quality of planning during development can significantly reduce the negative impacts on water quality. A three phased approach that includes strategies to reduce the area covered by streets and parking lots, improved site design and conserve natural areas is required to address the impacts of urbanization on stormwater transport to adjacent waters (Schueler and Holland, 2000).

The retention and removal (i.e., attenuation) of N during transport through the watershed can be significantly affected by human activities. Ditching, channelization and increased imperviousness all facilitate movement of water, and thus N, to coastal waters. Reduced residence time often equates to reduced biological attenuation of the N load from a watershed. Larger quantities of faster moving waters are less likely to be effectively filtered in small headwater streams, wetlands and riparian areas. Human activities also lead to direct negative effects on natural systems that attenuate the N load from the landscape. Destruction and degradation of headwater streams

that often occurs in areas with intensive human use is likely to significantly reduce N removal and retention (Peterson *et al.*, 2001). In the US, wetland loss is on the order of 50% since the pre-settlement era and despite legal protections, this loss is likely to continue to increase (Mitsch and Gosselink, 2000). Even with laws in place to protect wetland loss, management of wetland resources presents a significant challenge (La Peyre *et al.*, 2001).

Wetlands are known sinks for N transported to them from watersheds (Reddy and Gale, 1994). The loss of wetland transformations of N (as opposed to removal of N) are also potential contributors to water quality by transforming N from highly biologically available inorganic forms to possibly less labile organic forms (Craft *et al.*, 1989). Riparian areas are also sites of significant biological removal of N via denitrification (Jacobs and Gilliam, 1985; Spruill, 2004). Their function is frequently either lost or significantly compromised by human activities, diminishing the ability of the landscape to remove N (Groffman *et al.*, 2003). Urbanization is common enough in coastal regions that nitrogen cycling research in the urban landscapes is required to understand the transport and transformation of N in these areas (Groffman *et al.*, 2002)

6.2. Agricultural activities

World-wide, coastal regions are experiencing unprecedented agricultural growth, in the form of conversion of forests, swamps and wetlands to row-crop farmland and the conversion of small family farms to intensive livestock (poultry, hogs, cattle) operations (see also Chapter 9 by Seitzinger and Harrison, this volume and Chapter 36 by Boyer and Howarth, this volume). The rapid rise in commercial fertilizer use accompanying agricultural expansion in coastal watersheds has accelerated N loading from these lands. This trend has been evident in developed regions of Europe, North America, and Australia for at least half a century (i.e., post World War II; Chambers *et al.*, 2001; Howarth, 1998; Nixon, 1995; Vitousek *et al.*, 1997). However, currently the most rapid rise in N loading from agricultural lands is occurring in developing nations in Asia, Africa, South and Central America. In addition, countries that have had traditional agricultural sectors (e.g., China, India) are using ever-increasing amounts of synthetic N fertilizers to bolster production. Not surprisingly, these countries are experiencing some of the largest increases in N discharge to N limited estuarine and coastal waters (Vitousek *et al.*, 1997). There is substantial evidence that symptoms of advanced eutrophication are proliferating in these waters, including a troublesome rise in harmful (toxic, hypoxia-inducing) algal bloom events (Hallegraeff, 1993; Richardson, 1997), hypoxia and anoxia (Rabalais, 2002).

In many watersheds along the US East and Gulf Coasts, as well as throughout Canada, agriculture is responsible for at least half the estuarine and coastal new N (and P) inputs (Table 11.1, Fig. 11.14) (Castro *et al.*, 2003; Driscoll *et al.*, 2003). This percentage is growing in regions that have yet to experience forest and wetland conversion to intensive agriculture. Clearly, this sector of human activity is a prime target for N input reductions. A variety of best management strategies aimed at reducing N losses from agricultural operations is either in place or being formulated for coastal watersheds in North America and Europe. In most mandated N reduction

Table 11.1 Comparison of P and N loading to Canadian surface and ground waters from various sources, 1996

Nutrient Source	Nitrogen (10^3/year)	Phosphorus (10^3t/year)
Municipality	80.3	5.6
Municipal wastewater treatment plants	11.8	2.3
Sewers		
Septic systems	15.4	1.9
Industry[a]	1.8	2.0
Agriculture[b] (residual in the field after crop harvest)	293	55
Aquaculture	2.3	0.5
Atmospheric deposition to water	182 (NO_3^- and NH_4^+ only)	N/A

[a] Industrial N loads are based on NO_3^- NH_4^+ and are thus DIN not TN; industrial loads do not include New Brunswick, Prince Edward Island or Nova Scotia. Quebec data are only for industries discharging to the St. Lawrence River.
[b] Agricultural residual is the difference between the amount of N or P available to the growing crop and the amount removed in the harvested crop; data are not available as to the portion of this residual that moves to surface or ground waters.
Source: Environment Canada.
Figure 11.14 Relative contributions of atmospheric deposition, human sewage, forests, urban non-point sources and agriculture to "new" N loading in a set of representative US Atlantic (East Coast) and Gulf of Mexico estuaries. Figure adapted from Castro *et al.* (2003).

strategies that have be formulated for watersheds where agriculture constitutes a significant fraction of new N input, a 30–50% reduction of N discharge from agricultural lands can be expected. There are numerous efforts in place to meet such mandated reductions. They include; construction of riparian vegetative buffers, no-till farming practices, restrictions on timing and amount of N fertilizer application, use of organic fertilizer and the use of natural sources of new N, such as soybeans and other leguminous plants that are rotated with N demanding crops such as cereals (corn, wheat, rice), fiber crops (cotton, flax) and vegetables.

While nitrate is a dominant new N source from agriculture, ammonium and organic N can also be significant waste products, especially from animal operations where reduced N tends to accumulate in waste stored in "lagoons" or sprayed as fertilizer on surrounding fields. Discharge from agriculture is dominated by surface runoff (Boesch *et al.*, 2001a,b). Subsurface and atmospheric N inputs can also be large from intensive animal operations and feedlots (Paerl, 1997; Walker *et al.*, 2004; Whitall and Paerl, 2001). Each of these sources is significant enough to warrant their inclusion in basin-wide and regional N reductions aimed at improving water quality (e.g., EPA's Total Maximum Daily Loads or TMDLs; US EPA, 1999b).

6.3. Aquaculture/mariculture

As a means of sustaining coastal fisheries-based economies and as a source of animal-based protein, coastal aquaculture and mariculture (jointly termed aquaculture) have grown rapidly. In part, the need for and success of aquaculture can be attributed to the depletion of traditional estuarine and coastal fisheries in many regions of the world, including Asia, Europe, North and South America. Aquaculture has also proven more profitable and attractive than many sustenance fisheries because highly-desired, high-income specialty fisheries are often amenable to aquaculture. These include shellfish (oysters, clams, mussels), crustacean (shrimp, lobster, crab, crayfish), and finfish (salmon, trout, catfish, striped bass, tilapia) operations that are expanding worldwide. A vast majority of these operations depend on fertilization and/or input of food supplies to sustain productivity. As with intensive agricultural operations, ensuring adequate N supply is critical to maximizing aquacultural production. Invariably, this translates into administering high doses of fixed N, of which a significant fraction, ranging from a few percent to well over 50% is released to the surrounding waters (Leung *et al.*, 1999; Tovar *et al.*, 2000; Wu, 1995). While overall, aquaculture represents a much smaller N input source than agriculture, from an N retention perspective, aquaculture operations can constitute localized intensive sources of N fertilization and potential drivers of eutrophication in nearby N-limited waters. The unintentional eutrophicating effects of aquaculture have already become evident in coastal net-pen fish (salmon in particular) operations in semi-enclosed (i.e., poorly-flushed) lagoons and embayments (fjords) in Northern Europe (Denmark, Norway, Sweden, Scotland), North and South America (Western Canada, New England and the Canadian Maritime provinces, Colombia, Brazil and Chile. In particular, the Scandinavian fjords have experienced symptoms of advanced eutrophication in response to excessive fertilization associated with these as well as agricultural operations (Christensen *et al.*, 2000). Additionally, the

eutrophication related impacts that result from these operations are complicated by the use of antibiotics in feed formulations. Antibiotic introduction could affect microbial antibiotic resistance, and hence alter microbial community composition and activities in response to nutrient enrichment. In Asia and South America, brackish to full-salinity coastal lagoonal ecosystems are being used to produce shrimp, shellfish and a variety of finfish species. These systems represent concentrated nutrient sources adjacent to low-nutrient-adapted estuarine and coastal habitats, including mangroves, mudflats, marshes, coral reefs, and oligotrophic near-shore surface waters (Wu, 1995). Although little work has been done to detect and characterize ecological responses to the nutrient enriched effluent from these operations, previous experimental work indicates that both increases in benthic and planktonic microalgal production, epiphytization of seagrasses and corals, shifts in plant in producer and grazer community composition are among the responses accompanying eutrophication of receiving waters (D'Elia et al., 1981; Johannes, 1975; LaPointe et al., 1997; Laws and Redalje, 1979). The global expansion of aquaculture represents a potential threat to both water quality and habitat integrity of ambient waters, many of which support flora and fauna adapted to oligotrophic conditions.

7. The Future and Nitrogen Management

It is clear that N over-enrichment due to human population growth in coastal water- and air-sheds will remain a key driver of marine eutrophication (Peierls et al., 1991; Vitousek et al., 1997) well into the foreseeable future, especially in the rapidly-developing regions of Asia, Africa, and South America. The growing N "glut" that accompanies anthropogenic encroachment on the coastal zone will continue to enhance primary production and accelerate eutrophication. Because few receiving waters show any indication of becoming N saturated, the potential exists for coastal and oceanic waters to exhibit further N-enhanced eutrophication. While some upstream segments of estuarine ecosystems that have experienced a lengthy history of excessive N enrichment at times experience N saturation and show spring N & P co-limitation or even P or Si limitation (Fisher and Gustafson, 2004, Fisher et al., 1999; Justić et al., 1995a,b; Sylvan et al., 2006), they continue to show an overall high degree of sensitivity to N enrichment. This is especially true for the broader downstream mesohaline and euhaline portions of estuaries, where the combined effects of denitrification and relatively abundant and readily recycled marine P and Si supplies preclude limitation by these elements.

Therefore, preservation of acceptable water quality and reversal of eutrophication in these systems will invariably include reductions of current loads and setting limits on new N input, either alone or in combination with other nutrient (e.g., P) input reductions. Freshwater nutrient management has, in many instances, successfully arrested and reversed eutrophication by reducing P loadings (Edmondson, 1970; Likens, 1972; Vollenweider, 1982). Indeed, the upstream freshwater portions of many estuaries are also P-limited (Boynton and Kemp, 2000; Fisher et al., 1999), and P input constraints in these waters have been quite successful in reducing the unwanted symptoms of eutrophication (nuisance algal blooms, toxicity, hypoxia,

etc.) (Elmgren and Larsson, 2001; Paerl *et al.*, 2004, 2006b; Vollenweider *et al.*, 1992). As estuaries drain to the seas, both salinity and N limitation increase (Ryther and Dunstan, 1971; Nixon, 1986, 1995). However, reducing N alone can create favorable conditions for N_2 fixing phytoplankton and present the possibility of the return of N to the system through N_2 fixation (Horne, 1977; Piehler *et al.*, 2002). Therefore, along the freshwater-estuarine-coastal transitional zone, both N and P input constraints are likely to be needed if we are to control and manage marine eutrophication (Cloern, 2001; Conley, 2000; Paerl *et al.*, 2004, Sylvan *et al.*, 2006). This calls for addressing nutrient management along the integrative watershed-to coastal ocean (and beyond) scale; a scale that is no doubt challenging, but essential if we are to consider effective, long-term nutrient management aimed at preserving the entire suite of biotic resources involved in and affected by marine eutrophication.

Coastal waters are sensitive to both human and natural perturbations. For example, accelerating nutrient, sediment, and toxics inputs, may be accompanied by climatic, geochemical (i.e., volcanism, subsidence) and other forms of natural change. There is evidence that certain manifestations of climate change, including tropical storm and hurricane frequency, may also be increasing (Goldenberg *et al.*, 2001, Webster *et al.*, 2005). It is therefore useful to develop management approaches and indicators of ecosystem response that could help distinguish human from natural perturbations.

Determining and evaluating the ecological response of marine ecosystems to N enrichment and interacting physical-chemical perturbations is highly dependent on the indicators used and sampling sites selected. Benthic indicators may tell quite a different story from planktonic ones in ephemerally-stratified system (e.g., Chesapeake Bay, Pamlico Sound, Mobile Bay, Florida Bay). In well-flushed (short water residence time) systems, phytoplankton growth responses to nutrient enrichment may not be nearly as profound as those for benthic microalgae. Here, benthic microalgae and associated infauna may be more sensitive and meaningful indicators of ecosystem response to nutrient enrichment. In addition, indicators of community structure (i.e., diversity indices, keystone species) may gauge ecosystem conditions quite differently than indicators of function (primary and secondary production, respiration, nutrient cycling). Indices of biotic integrity (IBI) and habitat suitability indicators (HBI) are specific examples of indicators that in combination can assess structure, physical-chemical quality and biological measures.

To link N and other nutrient inputs to eutrophication dynamics across diverse coastal and oceanic systems, specific, broadly-applicable and integrative indicators that can couple biotic community structure to function in the context of ecological condition and change are needed (*cf.* Bartone, 2005; Committee on Environment and Natural Resources, 1997). Using case studies representing a range of impacted habitats, we need to develop and assess indicators of water quality, food web and habitat condition in response to a range of physical, chemical and biotic perturbations in marine ecosystems varying in water residence time, climatic regime and trophic state. Emphasis should be placed on microbial, plant and animal taxa and assemblages capable of providing qualitative and quantitative responses to nutrient and other stressors. These indicators should have sufficient detail to help clarify mechanisms underlying ecological change in response to external perturbations, with the ultimate goal of identifying indicators that will help researchers and

managers quantify roles of key organisms mediating production, energy flow, nutrient and oxygen cycling aspects of eutrophication. Combining these specific indicators with modeling efforts will help clarify and distinguish anthropogenic from natural stressors in diverse marine environments.

NITROGEN UPTAKE IN THE SOUTHERN OCEAN

William P. Cochlan

Contents

1. INTRODUCTION

Nitrogen (N) is generally considered to be the most important macro-nutrient limiting primary production in neritic and oceanic regions of the ocean. This is not the case in the Southern Ocean, where elevated concentrations of nitrate (NO_3^-) persist throughout the growth season, and phytoplankton biomass remains modest—the so-called ''Antarctic Paradox'' (e.g., El-Sayed, 1987; Priddle *et al.,* 1998). In this respect, the Southern Ocean can be classified as a High Nutrient, Low Chlorophyll region (HNLC; Minas *et al.,* 1986). The exact mechanisms responsible for the relatively low biomass and lack of NO_3^- depletion common to HNLC areas are still unknown, but explanations have generally been divided into either ''top-down'' (ecological) or ''bottom-up'' (physiological) controls; in other words those controlling ''yield'' versus ''rate.'' However, the Southern Ocean should not be considered as a single marine ecosystem, and this vast polar ocean is much more heterogeneous than originally thought. Seasonal and spatial dynamics of nutrients and primary productivity are strongly influenced by the presence of complex frontal features associated with the major current systems and bottom topography, and the annual advance and retreat of sea ice, resulting in considerable variability in phytoplankton production and the relative use of N substrates.

The Southern Ocean encompasses a region that is 10–20% of the world ocean (Laws, 1985; Boyd, 2002), and comprises two major current systems: the strong,

eastward flowing Antarctic Circumpolar Current (ACC) and the more southerly, but westward flowing Antarctic Coastal Current. The pelagic ecosystem can be divided into a series of distinct environments (or biomes) using a number of different criteria, including the distribution of the essential micronutrient iron (Fe) regulating phytoplankton growth (cf. Longhurst, 1998). Due to the complexity of the region, there is often duplication of Southern Ocean terminology resulting in some confusion. I refer the reader to a comprehensive review of the Southern Ocean and its biomes by Longhurst (1998) for a more complete description of the physical and biological characteristics of Southern Ocean oceanography.

The biogeochemical provinces of the Southern Ocean, as defined by Tréguer and Jacques (1992), are the Polar Front Zone, the Permanently Open Ocean Zone, the Marginal and Seasonal Ice Zones, and the Coastal and Continental Shelf Zone (Fig. 12.1). Note that the Marginal Ice Zone is a seaward subzone of the Seasonal Ice Zone delimited by the recent melting of ice, a seasonally migrating band of recently exposed surface waters within the Seasonal Ice Zone (Moore *et al.,* 2000). The
Figure 12.1 The sectors of the Southern Ocean and the four biogeochemical provinces: the Polar Front Zone, the Permanently Open Ocean Zone, the Marginal and Seasonal Ice Zones, and the Coastal and Continental Shelf Zones.

terminology of Tréguer and Jacques (1992) is commonly used in the polar N literature, and will be employed throughout this chapter.

The concept of new and regenerated production has been used for over three decades as a basis to link surface N dynamics with biogenic particle flux (Dugdale and Goering, 1967; Eppley and Peterson, 1979). Under steady-state conditions and averaged over appropriate time scales, new production is the proportion of total production that can be exported from the euphotic zone, mainly through the sinking of particles, without depleting the system; this proportion is also known as the f-ratio, the ratio of new to total production (Eppley and Peterson, 1979). Traditionally, new production has been equated with the uptake of ^{15}N-labeled NO_3^-, which is allochthonous (from outside of the system) in open water systems, and regenerated production with the uptake of ^{15}N-labeled ammonium (NH_4^+)and more recently ^{15}N-labeled urea, which are both autochthonous in that their presence relies on metabolic recycling in the upper water column. Recent evidence, including substantially higher N_2 fixation rates, aeolian inputs of organic and inorganic N, nitrification within the euphotic zone, and $DO^{15}N$ release may require the original model to be reevaluated for some regions (e.g., Bronk $et\ al.,$ 1994). In practice, f-ratios are generally estimated as the proportion of NO_3^- uptake to the total N (NO_3^- plus NH_4^+ and sometimes urea) uptake.

In the Southern Ocean, the f-ratio has been estimated for surface waters using ^{15}N uptake techniques in a number of investigations since 1977. Studies include those conducted in the Indian Ocean Sector (Collos and Slawyk, 1986; Lucas $et\ al.,$ 2007; Mengesha $et\ al.,$ 1998; Probyn and Painting, 1985; Semeneh $et\ al.,$ 1998; Slawyk, 1979), the Ross Sea (Cochlan and Bronk, 2001, 2003; Cochlan $et\ al.,$ 2002a; Goeyens $et\ al.,$ 2000; Hu and Smith, 1998; Lipizer $et\ al.,$ 2000; Nelson and Smith, 1986; Olson, 1980), the Scotia Sea (Cota $et\ al.,$ 1992; Glibert $et\ al.,$ 1982; Goeyens $et\ al.,$ 1991a,b; Koike $et\ al.,$ 1986; Olson, 1980; Owens $et\ al.,$ 1991; Rönner $et\ al.,$ 1983) the Weddell Sea (Cota $et\ al.,$ 1992; Goeyens $et\ al.,$ 1995; Kristiansen $et\ al.,$ 1992; Rönner $et\ al.,$ 1983; Smith and Nelson, 1990), the Antarctic Peninsula (Cochlan $et\ al.,$ 1993; Probyn and Painting, 1985); the Bellingshausen Sea (Waldron $et\ al.,$ 1995; Bury $et\ al.,$ 1995), the Australian Sector (Savoye $et\ al.,$ 2004; Elskens $et\ al.,$ 2002), and the Pacific Ocean Sector (Cochlan $et\ al.,$ 2002b; Coale $et\ al.,$ 2004; Sambrotto and Mace, 2000).

While this list is not exhaustive, a few notable trends have emerged. First, despite the abundance of NO_3^-, the Permanently Open Ocean Zone generally supports low rates of N uptake (except in proximity to islands), and the rates are dominated by regenerated N, resulting in low f-ratios (averaging ~0.2–0.5) and no measurable declines in surface NO_3^- concentration. Second, in the Coastal and Continental Shelf Zone and the Seasonal Ice Zone, N uptake patterns are more similar to those found in temperate upwelling zones, but with much lower uptake rates. Here, water column stabilization and cell seeding from retreating sea ice allow for considerable bloom development and substantial declines in surface NO_3^- with initial N-nutrition dominated by new N, resulting in high f-ratios (averaging ~0.7–0.9). Third, the seasonal increase in regenerated production in both regions is generally accompanied by an increase in surface concentrations of NH_4^+, and a transition from a predominately diatom- to a flagellate-dominated community, although not always. Others

have previously reviewed the dynamics of N nutrition in the Southern Ocean for both open ocean and marginal ice zones (e.g., Bury *et al.,* 1995; Goeyens *et al.,* 1995; Jacques, 1991; Tréguer and Jacques, 1992), including their relationship to ambient concentrations of silicic acid ($Si(OH)_4$, abbreviated Si; Goeyens *et al.,* 1998), and thus will not be repeated here. In this chapter, I will instead attempt to summarize the basic environmental factors regulating N uptake in the Southern Ocean, rather than concentrate on regional and/or seasonal differences. These environmental factors include: iron and light availability, NH_4^+ concentration and its inhibitory effects on NO_3^- uptake, the low ambient seawater temperature, and the role of heterotrophic bacteria as competitors for N in the Southern Ocean.

2. Environmental Factors Regulating Nitrogen Uptake

2.1. Micro-nutrient iron

Iron (Fe) is now recognized as an important factor regulating the productivity of many areas of the ocean, specifically those regions characterized as HNLC areas where rates of primary productivity and concentrations of biomass are lower than expected based on the availability of NO_3^-, phosphate, and Si. The key aspect of the nitrogenous nutrition of phytoplankton in these HNLC regions is the failure of primary production to fully utilize the abundant NO_3^- reserves during the growing season. In the open ocean regions of the Southern Ocean, the apparent "Antarctic Paradox" has been observed for decades, and Fe's possible role as a bio-limiting factor in the underutilization of surface macro-nutrients and production of modest biomass has been long suggested (Gran, 1931; Hart, 1934 as cited by de Baar *et al.,* 1990). Indirect evidence for the role of Fe in the Southern Ocean was first provided by de Baar *et al.* (1995) who demonstrated a positive relationship between the magnitude of *in situ* phytoplankton biomass and ambient Fe concentrations in the vicinity of the Antarctic Polar Front in the South Atlantic sector during a natural Fe fertilization event during austral spring 1992. However, the first studies to provide direct evidence of Fe-stimulated phytoplankton growth were conducted in the Southern Ocean in 1988 in the Weddell/Scotia Seas (de Baar *et al.,* 1990; Buma *et al.,* 1991), and later in 1990 in the Ross Sea (Martin *et al.,* 1990; 1991) and the Drake Passage in 1991 (Helbling *et al.,* 1991) using shipboard Fe-enrichment experiments.

   The early, multi-day, shipboard incubation experiments exhibited Fe-enhanced phytoplankton biomass (relative to un-enriched controls) over time, but generally long lag periods were observed. Both Fe-enriched and control treatments showed significant increases in chlorophyll *a*, reaching levels not normally observed *in situ*, presumably due to reduced grazing pressure and a more favorable light environment within the bottles (e.g., de Baar, 1994). These and more recent deck–board experiments (e.g., Sedwick and DiTullio 1997; Sedwick *et al.,* 1999) report Fe-enhanced draw-down rates of NO_3^- over time, with NO_3^- often declining to levels below detection (e.g., 0.03 μM) after many days of incubation, a situation rarely observed

in the Southern Ocean except at intense ice-edge (e.g., Nelson and Smith, 1986) and coastal blooms (e.g., Holm-Hansen *et al.,* 1989; Kocmur *et al.,* 1990), or in strongly stratified fjords (e.g., McMinn *et al.,* 2000). However, it has been suggested that due to the concomitant increase in biomass following Fe enrichment, such enhanced rates of NO_3^- utilization are not necessarily due to any actual increase in the NO_3^- uptake capability of the resident phytoplankton. In a re-analysis of the NO_3^- depletion data from the Ross Sea Fe-experiments of Martin *et al.* (1990), Dugdale and Wilkerson (1990) contend that Fe had no effect on specific NO_3^- uptake rates, despite the enhancement in NO_3^- depletion rates, and when absolute rates were normalized to an appropriate biomass parameter (particulate N) the resultant specific uptake rates of NO_3^- in the Fe-treatments did not differ from those of the controls.

Since then, a number of similar deck-board experiments have been conducted using ^{15}N isotopes to estimate specific N uptake rates from short-term incubations (3–24 h) determined at either the beginning (Timmermans *et al.,* 1998), the end (Franck *et al.,* 2000), both (van Leeuwe *et al.,* 1997), or throughout (Cochlan *et al.,* 2002a) multi-day, experimental bioassays. In each of these studies, specific NO_3^- uptake rates were enhanced following the addition of Fe. In the HNLC waters just north of the sub-Antarctic Front and south of the Antarctic Polar Front in the Pacific region of the Southern Ocean, Timmermans *et al.* (1998) report significant (1.25–1.45-fold) increases in specific $^{15}NO_3^-$ uptake rates even after the first day (27 and 29 h), whereas specific $^{15}NH_4^+$ uptake rates (only done south of the Antarctic Polar Front), remained unaltered by Fe additions. In the ACC/Polar Front Zone/Weddell Sea regions, modest (0–1.3-fold) increases are reported by van Leeuwe *et al.* (1997) for specific $^{15}NO_3^-$ uptake rates conducted at the beginning of their experiments, with (1.4–1.7-fold) increases found at the end (9–12 d) of their bioassays. In the Pacific sector of the Southern Ocean, similar increases (1.6–1.8 and 1.1–2.5-fold) are reported for specific $^{15}NO_3^-$ uptake rates determined 10–16 d after Fe enrichment in the high Si (also HNLC) waters south of the Antarctic Polar Front during austral spring and summer, respectively, whereas greater (2.9–4.4-fold) increases were found in the low Si waters north of the Antarctic Polar Front (Franck *et al.,* 2000). In the Ross Sea, Fe-enrichment experiments were conducted close to the Ross Ice Shelf and further north in HNLC waters (near the original Martin experiments) during austral summer 1997 (Cochlan *et al.,* 2002a). During this study, specific NO_3^- uptake rates were also enhanced by Fe additions, although as found by van Leeuwe *et al.* (1997) uptake rates for the Fe-treatments did not differ substantially from the uptake rates observed in the controls during initial sampling periods. It is not until the later sampling periods (i.e., after 3 d), that the specific NO_3^- uptake rates were >1.9-fold and >2.6-fold higher than rates measured in the controls for the continental shelf and HNLC sites, respectively. Specific uptake rates of NH_4^+ were not enhanced by Fe at their HNLC site (actually they were negatively correlated with increasing Fe concentration), but the 30–40% increase in NH_4^+ uptake in the higher Fe enrichments during the later sampling periods for the continental shelf station was explained as a concentration-dependent function of the increasing NH_4^+ concentration found during that time. In the Ross Sea study, specific NO_3^- uptake rates also were reported to be significantly correlated to the

Fe concentrations measured at the start of the bioassays, and based on the estimated half-saturation constant (K_s) of 0.09 nM Fe (by employing Michaelis–Menten type kinetics), the availability of Fe during that time (ambient dissolved Fe concentration of 0.03–0.04 nM) would appear to limit NO_3^- uptake by phytoplankton. These studies all demonstrate a clear enhancement of specific and absolute NO_3^- uptake rates by Fe during short-term incubations, and are supported by similar results conducted in other HNLC regions including the equatorial Pacific Ocean (Coale et al., 1996; Cochlan, 2001; Price et al., 1991, 1994) and the eastern (Boyd et al., 1996, 1998; Marchetti et al., 2006) and western (Kudo et al., 2005, in review) subarctic Pacific Ocean.

The short-term N uptake studies, together with the overall enhancement in biomass accumulation and macro-nutrient (NO_3^- and phosphate) decline seen during multi-day, Fe-enrichment shipboard incubation experiments, provide strong support for Fe-limitation in HNLC areas of the Southern Ocean. However, even though such long-term incubation experiments reflect many of the in-situ chemical and biological processes occurring in the natural ecosystem, loss terms such as grazing by larger zooplankton, and sinking/sedimentation of diatoms, are altered within bottles and may have a significant effect in natural ecosystems. Consequently, extrapolation of these experiments as accurate representations of the in situ response have been strongly criticized (e.g., Banse, 1991; Dugdale and Wilkerson, 1990, 1991; Frost, 1991). In contrast, in situ experiments provide a cohesive link between the addition of a potentially limiting resource and the biological response, without uncertainties such as light field alteration, reduced turbulence, and exclusion of grazers (Carpenter et al., 1995; Hecky and Kilham, 1988; Watson et al., 1991).

Twelve such in situ Fe-enrichment experiments have now been conducted in HNLC regions of the ocean (see comparative reviews by de Baar et al., 2005, and Boyd et al., 2007), including six in the Southern Ocean with varying degrees of enhanced phytoplankton biomass and draw-down of NO_3^- following Fe enrich-ment. The first in situ Fe experiment in the Southern Ocean—Southern Ocean Iron Release Experiment (SOIREE; Boyd et al., 2000) was conducted at the end of the austral summer in February 1999 south of the Antarctic Polar Front in the Australian sector in a region of relatively low Si (10 µM), but high NO_3^- (25 µM). By the final day (day 13) of this mesoscale open ocean experiment, chlorophyll a concentration had increased 5-fold and both NO_3^- and Si had decreased by 3 µM (Frew et al., 2001); no rates of N uptake are available. The Carbon Dioxide Uptake Southern Ocean (CARUSO)/Eisen Experiment (EisenEx) followed in austral spring 2000 in the core of a cold Antarctic eddy which had spun off the Polar Frontal jet into the Atlantic sector of the sub-Antarctic region. Twenty days since the first Fe infusion, the draw-down in NO_3^- and Si concentrations was 1.61 µM and 4 µM, respectively (Bozec et al., 2005). In 2004, two in situ Fe experiments were performed in the Southern Ocean. The European Iron Fertilization Experiment (EIFEX) was con-ducted within a mesoscale eddy at the Antarctic Polar Front in the Atlantic sector of the Southern Ocean for five weeks starting in during January (Hoffmann et al., 2006; Jacquet et al., 2008), and the SOLAS Air–Sea Gas Experiment (SAGE; Hall et al., 2005) was conducted east of New Zealand in sub-Antarctic waters around an eddy during March–April. Although chlorophyll biomass increased by 2-fold (SAGE)

and > 5-fold (EIFEX) during these experiments, estimates of NO_3^- depletion during the Fe-enriched blooms are not yet published. The only currently available $^{15}NO_3^-$ uptake rates, as opposed to net draw-down estimates, determined during polar, open ocean Fe enrichment experiments are those from the Southern Ocean Fe Experiment (SOFeX; Coale et al., 2004, Cochlan et al., 2002b, 2004) conducted in late January–February 2002.

During SOFeX, two separate patches north and south of the Antarctic Polar Front were enriched with Fe; the northern patch had low ambient Si concentrations (<3 μM) and high ambient NO_3^- concentrations (20 μM), and the southern patch had elevated ambient concentrations of both Si (~60 μM) and NO_3^- (28 μM). In both the northern and southern patches, there were clear decreases in the ambient NO_3^- concentration (1.4 and 4.1 μM; Hiscock and Millero, 2005) and 10–20-fold increases in phytoplankton chlorophyll a (Coale et al., 2004) following Fe enrichment. Although it is not surprising that both NO_3^- and NH_4^+ absolute uptake rates also increased as a result of the biomass increase, the dramatic enhancement of the specific uptake rates of NO_3^- relative to outside control waters (average increase was ~6–7-fold), and only a modest increase (average increase was ~2-fold) in specific rates of NH_4^+ or urea (Cochlan et al., 2002b, 2004; Cochlan and Kudela, 2006), is clearly indicative of faster rates of NO_3^- consumption per unit phytoplankton biomass, a result similar to those reported for Fe-amended bottle experiments discussed above. During SOFeX, the proportion of NO_3^- uptake to the total N (NO_3^-, NO_2^-, NH_4^+ and urea) uptake was measured throughout the experiment, and the resulting f-ratio increased in the southern patch from 0.1–0.2 to ~0.5–0.6, and from ~0.2 to ~0.3–0.4 in the northern patch (Fig. 12.2). The increased f-ratio in both regions clearly indicates that alleviation of Fe-limitation allows for the greater relative utilization of NO_3^- reserves that would otherwise be underutilized for growth in the surface waters south and north of the Antarctic Polar Front zone, and confirms the role for Fe-limitation in the creation of HNLC waters in the Southern Ocean.

Recent experiments in the Southern Ocean also have implicated zinc as a co-limiting nutrient, primarily through the regulation of Si uptake by diatoms (Franck et al., 2000, 2003), but not NO_3^- (see also Kudela, this volume). Iron and zinc-limitation have also been linked to increased Si:NO_3^- depletion ratios and increased silicification of diatoms (Hutchins and Bruland, 1998; Takeda, 1998), which are disproportionately represented in previous Fe-enriched blooms in both in vitro (e.g., Martin et al., 1989) and in situ experiments (e.g., Boyd et al., 2000; Coale et al., 1996). Although phytoplankton do not have an absolute zinc requirement during the uptake and assimilation of NO_3^- and NH_4^+, zinc is required for Si uptake (e.g., De La Rocha et al., 2000; Rueter and Morel, 1981), and for the activities of the metallo-enzymes, carbonic anhydrase, and alkaline phosphatase (e.g., Anderson et al., 1978). However, under zinc limitation, other elements may substitute for zinc in these enzymes both in vivo and in vitro (e.g., Lee and Morel, 1995; Morel et al., 1994; Price and Morel, 1990). During the shipboard incubations conducted just north and south of the Antarctic Polar Front, zinc alone had no effect on NO_3^- uptake (Franck et al., 2000), and in the offshore HNLC region of the Ross Sea, Cochlan et al. (2002a) found that the N uptake response to zinc was relatively
Figure 12.2 SOFeX depth profiles of biomass (PN)-specific NO_3^- uptake rates, determined during 24-h incubations in Plexiglas® acrylic incubators under simulated *in-situ* light and temperature conditions. Ultra-clean trace-metal techniques were used for sample collection within and outside (control waters) of the Fe-enriched patch north and south of the Antarctic Polar Front zone. The f-values [$f = V_{NO_3}/(V_{NO_3} + V_{NH_4} + V_{NO_2} + V_{Urea})$] were determined at the isolume depths of 47 and 16% surface irradiance, using tracer-level isotopic enrichments, and are not corrected for the effects of isotopic dilution. Error bars represent the range of duplicate samples ($n = 2$). Corrected from Coale *et al.* (2004).

modest, presumably due in part to the relatively high dissolved concentrations of zinc present ($\sim$2 nM). However, during the later sampling periods, zinc addition at the HNLC site resulted in a 40% increase in the specific uptake rates of NO_3^- but not NH_4^+, whereas the specific uptake rates of NO_3^- and NH_4^+ increased by 4–16% and 18–49%, respectively, at a continental shelf site close to the Ross Ice Shelf.

In contrast to zinc, the crucial role of Fe in the bioenergetics of carbon (C) and N metabolism is well recognized (e.g., Morel *et al.,* 1991; Sunda, 1989). Substantial amounts of Fe are required in both photosynthetic and respiratory electron transport chains (e.g., Raven, 1988), the synthesis of chlorophyll (Chereskin and Castelfranco, 1982), and the assimilation of NO_3^-. Theoretical calculations based on Fe utilization efficiencies and cellular metabolic Fe demands, predict that phytoplankton growing on NO_3^- require 60% more Fe than those growing on NH_4^+ (Raven, 1988, 1990), and greater cellular Fe requirements for NO_3^- growth have indeed been demonstrated for laboratory cultures of diatoms (Maldonado and Price, 1996). The extra Fe is needed to reduce NO_3^- to NH_4^+ before it can be incorporated into amino acids. This process requires the assimilatory enzymes nitrate reductase (requires one

atom of Fe) and nitrite reductase (requires five atoms of Fe), and either ferredoxin (an Fe-containing e^- donor) or flavodoxin (a non-ferrous e^- donor; Doucette $et\ al.,$ 1996; La Roche $et\ al.,$ 1993), plus the need for greater quantities of reducing power (8 mol e^-/mol N) derived from Fe-dependent photosynthetic redox reactions. Thus, the utilization of NH_4^+ over NO_3^- observed in HNLC regions such as the Southern Ocean can be assumed to be a more energetically efficient strategy for obtaining N in response to Fe-limitation.

2.2. Nitrogen concentration effects

For nearly 40 years, the kinetics of N uptake of both cultured and natural assemblages have been determined using the Michaelis–Menten formulation for enzyme kinetics:

$$V = \frac{V_{max}\ S}{K_s + S}$$

where V is the particulate N (PN) specific uptake rate, V_{max} is the maximal specific uptake rate, S is the substrate concentration, and K_s is the half-saturation constant at which V is equal to half the maximum uptake rate (i.e., $V = V_{max}/2$) (Dugdale, 1967). The substrate affinity at low concentrations (i.e., $S < K_s$) can be determined from the initial slope (α) of the Michaelis–Menten plot, and is generally calculated as $\alpha = V_{max}/K_s$; the derivative of the equation, with respect to S, as S approaches zero (Button, 1978; Healey, 1980). Only a few kinetics studies have been conducted in the Southern Ocean, and although some results are suggestive of a rectangular hyperbolic relationship between N concentration and uptake (e.g., Collos and Slawyk, 1986; Glibert $et\ al.,$ 1982; Mengesha $et\ al.,$ 1998), not enough concentrations were employed in these studies to estimate statistically, meaningful kinetic parameters. Kinetic parameters are not available for NO_3^- uptake because of the elevated NO_3^- concentrations (>20 μM) routinely present in the surface waters of open ocean regions, and in marginal ice and continental shelf zones at the beginning of the growth season (e.g., Tréguer and Jacques, 1992).

Kinetic parameters for NH_4^+ and urea uptake in the Southern Ocean have only been estimated for phytoplankton assemblages in the western Ross Sea during a 1996–1997 seasonal study covering austral spring and summer (Cochlan and Bronk, 2001). Their results demonstrate that, with the exception of a pack ice station with high ambient NH_4^+ concentrations, the affinity estimates of Ross Sea phytoplankton for NH_4^+ are greater than those found in other marine systems, as demonstrated by K_s values <0.40 μM and isotope-corrected α values that range from 12.1 to 36.8×10^{-3} h^{-1}/μM. In the pelagic waters of the Arctic, K_s values for NH_4^+ are generally greater and range from <0.1 to 2.2 μM (Table 12.1), similar to those values reported for temperate neritic diatoms and flagellates (1.82 ± 0.09 μM; Eppley $et\ al.,$ 1969) and natural assemblages of coastal phytoplankton ($\sim$ 0.5–2.0 μM; Kudela and Cochlan, 2000). However, the lower K_s values measured in the open Ross Sea (0.04 to <0.4 μM) are more similar to those reported for oceanic

Table 12.1 Summary of half-saturation constants (K_s), determined for natural phytoplankton assemblages from polar regions

Region	K_s-NH_4^+	K_s-NO_3^-	K_s-Urea	Source
Barents Sea				
$[NO_3^-] \geq 1\ \mu M$	1.3	1.8	0.2	Kristiansen et al. (1994)
$[NO_3^-] \leq 1\ \mu M$	0.1–0.2	0–2.2	0.0–0.1	Kristiansen and Farbrot (1991) Kristiansen and Lund (1989)
Greenland Sea[a]	2.2	0.29–2.7	–	Muggli and Smith (1993)
Barrow Strait, NWT (ice algae)	1.6	<4.0	0.9	Harrison et al. (1990)
Eastern Canadian Arctic				
$[NO_3^-] < 1\ \mu M$	0.17	0.87	0.30	Smith and Harrison (1991)
Toolik Lake, Alaska				
$[NO_3^-] < 1\ \mu M$	0.05–0.49	0.05–0.30	–	Whalen and Alexander (1986)
Western Ross Sea				
$[NO_3^-] > 10\ \mu M$	0.04–0.33[b] 0.12–1.60[c]	★	0.12	Cochlan and Bronk (2001)

Isotope-dilution corrected NH_4^+ uptake rates were used in the Ross Sea study to determine K_s; all other sources report uncorrected rates. Half-saturation constants reported in units of μM-N (Note: 1 μM urea = 2 μM urea-N).
[a] *Phaeocystis pouchetii* bloom.
[b] Estimates determined from isotopic-dilution corrected rates.
[c] Estimates determined from uncorrected rates.
★ Ambient NO_3^- concentrations were too high to determine K_s.

phytoplankton species (0.1–0.5 μM; Eppley *et al.,* 1969) and oligotrophic oceanic regions (0.03–0.6 μM; Kudela and Cochlan, 2000; MacIsaac and Dugdale, 1969).

The half-saturation constant for urea (K_s = 0.12 μM-N) was only estimated for one station, composed primarily of diatoms and nanoflagellates, and is similar to those determined for the Barents Sea in the Arctic (0–0.120 μM-N; Kristiansen and Farbrot, 1991; Kristiansen *et al.,* 1994). Note that the urea concentrations reported here (and in Table 12.1) are in terms of N (i.e., 2 μM urea-N is equivalent to 2.0 μg-at N L^{-1} which equals 1 μM urea). The K_s values from both polar regions are lower than the few values reported for cultures of neritic marine diatoms (0.4–2.0 μM-N; McCarthy, 1972; Rees and Syrett, 1979), pico- and raphidophycean flagellates (0.4 μM-N; Cochlan and Harrison, 1991a; Herndon and Cochlan, 2007), and dinoflagellates (0.9–6.6 μM-N; Fan *et al.,* 2003; Kudela *et al.,* 2008), but very similar to the range reported for natural assemblages in non-polar, oceanic areas (0.02–0.27 μM-N; cf. Kudela and Cochlan, 2000). Based on these kinetic parameters,

although the Ross Sea is a NO_3^-–rich region populated by relatively large phytoplankton, the half-saturation constants are more characteristic of oligotrophic waters dominated by picoplankton assemblages. In this respect, the Ross Sea phytoplankton communities are similar to oceanic phytoplankton in that they possess a relatively efficient means of acquiring these reduced N forms, even though they are normally available in very low concentrations in the euphotic zone of the open waters of the Southern Ocean.

Elevated surface concentrations of NH_4^+ in the Southern Ocean are only generally observed in the vicinity of land masses and ice-edge zones, and range from >1 to ∼4 μM (e.g., Koike *et al.,* 1986; Owens *et al.* 1991); concentrations that would easily saturate the uptake capability of the Ross Sea phytoplankton. Ambient concentrations of urea, although not as frequently measured, can reach 1 μM-N in the open surface waters of the Pacific sector (Sambrotto and Mace, 2000) and the Marginal Ice Zone of Bellingshausen Sea (Bury *et al.,* 1995) with much greater concentrations beneath (1.6–2.8 μM-N) and within (6–18 μM-N) the sea ice. However, surface concentrations of urea in the Ross Sea are very low, year-round (≤0.1 μM-N) and only reach 0.3–0.4 μM-N during the austral fall (Cochlan and Bronk, 2003; US JGOFS database—current URL: http://usjgofs.whoi.edu/index.html) still far below the concentrations necessary to saturate urea uptake.

2.3. Nitrogen substrate interactions

An important factor to consider when examining the nitrogenous nutrition of phytoplankton is the availability of different N substrates for growth and the uptake interactions between them. A commonly held belief in phytoplankton ecology is that phytoplankton prefer to use NH_4^+ over NO_3^-, presumably as an adaptation in terms of energetic savings (e.g., Thompson *et al.,* 1989), and that little or no NO_3^- uptake occurs when ambient NH_4^+ exceeds a certain threshold value. Classically, this concentration has been reported as *ca.* 1 μM (McCarthy, 1981), although in an extensive review of field studies Dortch (1990) found that NH_4^+ inhibition of NO_3^- uptake is rarely so severe, and that it is a highly variable phenomenon dependent on a number of factors including nutrient history, light, and the taxonomic composition of the phytoplankton assemblage. For example, whereas NH_4^+ concentrations as low as 0.1–0.3 μM completely inhibit NO_3^- uptake in subarctic Pacific assemblages dominated by autotrophic flagellates (Booth, 1987; Wheeler and Kokkinakis, 1990), NH_4^+ concentrations as high as 0.6 μM have little effect on NO_3^- uptake by diatom–dominated assemblages of recently upwelled waters off Oregon (*f*-ratios averaged 0.83; Kokkinakis and Wheeler, 1987).

In the Southern Ocean, a number of temporal and spatial correlation studies have shown lower *f*-ratios with elevated NH_4^+ concentrations where the reduction in the *f*-ratio may be due to increased NH_4^+ uptake rates and/or reduced NO_3^- uptake rates (e.g., Goeyens *et al.,* 1995; 1998; Lucas *et al.,* 2007; Owens *et al.,* 1991). However, there have been few inhibition (suppression) studies in the Southern Ocean where either single or multiple NH_4^+ concentrations are experimentally increased to evaluate the effects on NO_3^- uptake rates. The first such study was conducted at two stations in the Scotia Sea by Glibert *et al.* (1982), and an inhibitory effect was

only seen at one station; an $\sim$30% inhibition of $^{15}NO_3^-$ daily uptake rates was observed with a 5 μM addition of NH_4^+. However, Reay et al. (2001) reported significant inhibition of daily $^{15}NO_3^-$ uptake rates both north and south of the Antarctic Polar Front in the northern Scotia Sea (near South Georgia Island) at all seven stations where they enriched samples with 1 μM of NH_4^+. Three other studies in the Southern Ocean have demonstrated that NO_3^- uptake can be strongly suppressed by experimentally elevating NH_4^+ using a series of concentrations. Both linear and non-linear (convex) responses have been observed; non-linear responses have been described by either a three-parameter exponential function (Varela and Harrison, 1999) and/or an inverse Michaelis–Menten hyperbola (Harrison et al., 1996) characterized by the kinetic parameters I_{max} (potential maximal inhibition) and K_I (half-saturation constant of inhibition). The first of these studies was conducted in the Indian sector by Mengesha et al. (1998) at an ice-edge station (conducted twice) dominated by diatoms and a picoflagellate-dominated assemblage further north in the permanently open ocean zone. Their pooled data of both ambient and added NH_4^+ effects on NO_3^- uptake demonstrate an 88% maximum reduction in NO_3^- uptake in the spring, and that an NH_4^+ concentration of 0.21 μM (K_I) would reduce NO_3^- uptake by 50%. However, since the ambient NH_4^+ concentrations during spring were low relative to the K_I, inhibition at that time was considered minimal. With the seasonal increase in ambient NH_4^+ concentrations in this region, their derived parameters would suggest increased inhibition of NO_3^- uptake rates further on in the growing season, a suggestion supported by lower specific rates of NO_3^- observed during the summer, although inhibition results were not reported.

In the western Ross Sea, a similar study was conducted in 1996–1997 during three cruises spanning pre-bloom, bloom, and bloom decline conditions (Cochlan and Bronk, 2003). At all but two of the seven stations, one being in the NH_4^+-rich waters under the pack ice, the maximal realized inhibitions (mean I_{max} = 0.63, range from 0.40 to 0.83) and half-inhibition concentrations (mean K_I = 0.10 μM, range from 0.04 to 0.22 μM) suggest that NO_3^- uptake could be reduced by an average of 63%, and that an ambient concentration of only 0.10 μM would reduce the NO_3^- uptake rate by 50%. However, even with their highest NH_4^+ additions (5–10 μM) there was never complete inhibition of NO_3^- uptake. Their analysis also suggests a seasonal progression in NH_4^+ inhibition of NO_3^- uptake, with the greatest inhibition occurring during the summer period despite the low ambient NH_4^+ concentrations present, in contrast to the Indian sector study. Using the derived NH_4^+ inhibition constants and kinetic uptake parameters determined during concurrent NH_4^+ uptake experiments (Cochlan and Bronk, 2001), they also estimated the proportion of new to total production (the f-ratio) at in situ and elevated NH_4^+ concentrations during the year for the western Ross Sea. In this simple modeling effort, they were able to differentiate between the two well-known effects of NH_4^+ on phytoplankton nitrogenous nutrition: substrate-dependent NH_4^+ uptake and inhibition of NO_3^- uptake, and suggest that the most important factor influencing the proportion of new and regenerated production in the Ross Sea is the concentration-dependent NH_4^+ uptake rate, not the inhibition of NO_3^- uptake rates by increasing ambient NH_4^+ concentration that has been suggested for other coastal and open ocean regions of the Southern Ocean. Similar inhibitory experiments were

conducted in the Australian sector (sub-Antarctic and Antarctic Polar Front zones) during 1998 by Elskens *et al.,* (2002), who found that the maximum apparent inhibition of NO_3^- uptake ranged from 33 to 81%; again even at the highest NH_4^+ concentration (1 μM), NO_3^- uptake was never totally suppressed.

The inhibitory effect of NH_4^+ on the uptake of NO_3^- has been suggested by Jacques (1991) to invalidate the applicability of the new and regenerated production paradigm to the Southern Ocean. However, to what extent elevated NH_4^+ concentrations repress the utilization of NO_3^- is still a poorly understood question in the Southern Ocean, and our knowledge is based primarily on a compilation of correlative studies of NO_3^- uptake and ambient NH_4^+ concentration with little regard to the phytoplankton species composition of the assemblage. The role of Fe in this interaction also is unclear, but given the greater Fe demand for phytoplankton growth on NO_3^- versus NH_4^+ (e.g., Maldonado and Price, 1996), modeling efforts have suggested a close interaction between Fe and NH_4^+ in regulating new (NO_3^-–based) production (Armstrong, 1999; Elskens *et al.,* 2002). These studies predict that in conditions of abundant ambient NO_3^- and Fe-limitation, the effect of experimentally increasing NH_4^+ on NO_3^- uptake rates will be minimal, whereas in conditions of enhanced Fe availability, abundant NO_3^- and low ambient NH_4^+, spiking with NH_4^+ will significantly reduce the *f*-ratio, mainly as a result of the inhibition of NO_3^- uptake. This interaction was studied in 2002 during the SOFeX mesoscale open ocean Fe experiment (Cochlan *et al.,* 2004; Cochlan and Kudela, 2006). Ammonium inhibition experiments were conducted with phytoplankton assemblages collected 13 and 22 days after the initial Fe infusion, and compared with samples collected on day 22 from the outside (control) waters of the southern Fe patch. Greater half-inhibition (K_I) concentrations (1.1 and 1.5 μM) estimated for the Fe-patch relative to the K_I of 0.26 μM in the control waters indicate that higher concentrations of NH_4^+ would be needed to reduce the NO_3^- uptake rate by 50% in the Fe–replete assemblages. Despite the increase in ambient NH_4^+ concentrations observed within the blooming Fe patch, the realized NO_3^- uptake rates ranged from 84 to 96% of the potential NO_3^- uptake rates (theoretical maximum rate at zero NH_4^+ concentration) in contrast to the NO_3^- uptake rate in the outside waters, which was only 63% of the potential rate. These results, together with the enhancement in specific NO_3^- rates (up to 10-fold) following Fe enrichment strongly suggest that the alleviation of Fe deficiency resulted in decreased sensitivity to NH_4^+ inhibition, not increased sensitivity as predicted by the models. A similar reduction in the inhibitory effects of NH_4^+ on NO_3^- uptake rate was determined during the second Subarctic Pacific Iron Experiment for Ecosystem Dynamics Study (SEEDS-II) conducted in July–August 2004 in the western subarctic Pacific Ocean (Cochlan *et al.,* 2005), despite a relatively modest increase in phytoplankton biomass following Fe enrichment.

Interactions between urea and other N-forms have been studied even less, and primarily with cultured, non–polar phytoplankton; however, it is generally assumed that urea suppresses the uptake of NO_3^- to a lesser extent than NH_4^+ (Cochlan and Harrison, 1991b; Molloy and Syrett, 1988) or not at all (Lund, 1987). No actual perturbation or correlative studies of the effects of urea on NO_3^- or NH_4^+ uptake have been published to date for the Southern Ocean, although conversely, Elskens

et al., (2002) found that NH_4^+ additions had no significant effect on urea uptake in natural assemblages. However, urea appears to be particularly important in communities under the ice, where elevated ambient concentrations are present, and urea is the dominant N source (Bury *et al.,* 1995).

In most open ocean regions of the Southern Ocean, ambient NH_4^+ concentrations are generally low (<0.5 µM), but exceptions exist (e.g., Glibert *et al.,* 1982; Sambrotto and Mace, 2000), whereas elevated concentrations are routinely found in association with the productive waters of receding ice-edges (e.g., Goeyens *et al.,* 1995; Tréguer and Jacques, 1992), pack ice (Ross Ice Shelf: Biggs *et al.,* 1985), continental ice (Jacobs *et al.,* 1979), and in the vicinity of land masses (e.g., Bransfield Strait; Owens *et al.,* 1991). Near the islands of South Georgia, it has been shown that mesozooplankton (including krill) are important contributors to the elevated (>1 µM) mixed layer concentrations of NH_4^+ (Atkinson and Whitehouse, 2000, 2001), are responsible for diurnal changes in the mixed layer NH_4^+ concentrations (Priddle *et al.,* 1997), and high NH_4^+ concentrations within and adjacent to intense aggregations of these populations (Johnson *et al.,* 1984). Based on these observations, one might expect ephemeral micropatches of concentrated NH_4^+ (e.g., McCarthy and Goldman, 1979), not measurable by traditional analytical methods, although the existence of such micropatches has been criticized on theoretical grounds (Jackson, 1980). However, as the above studies suggest, ambient NH_4^+ concentrations need not be elevated to have a crippling inhibitory effect on NO_3^- uptake by phytoplankton in the Southern Ocean, particularly where dissolved Fe concentrations are considered limiting to phytoplankton growth.

2.4. Temperature effects

Given the known influence of temperature on phytoplankton growth (e.g., Eppley, 1972; Raven and Geider, 1988) and photosynthesis (e.g., review by Davidson, 1991) it is not surprising that temperature affects cell N composition (e.g., Thompson *et al.,* 1992a, b), maximum N uptake rates (e.g., Lomas and Glibert, 1999a; Underhill, 1977), NO_3^- assimilatory enzymes (e.g., Berges *et al.,* 2002; Lomas and Glibert, 1999b), NH_4^+ inhibition of NO_3^- uptake (Lomas and Glibert, 1999a; Reay *et al.,* 2001), and even short-term NH_4^+ uptake (Raimbault, 1984) in cultured phytoplankton and field assemblages. While these effects may be subtler than those on growth and photosynthesis, it is likely that they all contribute somewhat to species succession and dominance, and thus should be considered when examining the phytoplankton and N dynamics of the Southern Ocean. The water temperature of the Southern Ocean (south of the Antarctic Polar Front) ranges from $-1.8°C$ (the freezing point of seawater) to ~5°C in the summer (e.g., Neori and Holm-Hansen, 1982), but most of our knowledge on the effects of temperature on phytoplankton N uptake have been conducted at temperatures far in excess of this range and may not be directly applicable to polar assemblages; few studies on temperature effects have been conducted using natural assemblages in the Southern Ocean.

During the first ^{15}N uptake study in the Southern Ocean, specific NO_3^- uptake rates were positively related to temperature over large temporal (2–16°C) and spatial

scales (40–62°S latitude) during a north–south transect (Slawyk, 1979). However, during this study, not only were there gradients in temperature, but also in ambient NH_4^+ concentrations, and likely species composition, which renders the interpretation of N uptake solely as a function of temperature difficult; see also Harrison *et al.* (1996) and Kanda *et al.* (1985) for examples of similar relationships in non-polar environments. During short-term (6 h) $^{15}NH_4^+$ and $^{15}NO_3^-$ uptake experiments conducted in the Scotia Sea at three different temperatures, Olson (1980) found that phytoplankton from two stations were not adapted for optimal N uptake at their *in situ* temperature (0°C), and that they increased uptake rates with 5–10°C increases in temperature. More recently, phytoplankton from the southwest Atlantic sector of the Southern Ocean were incubated at ambient and elevated temperatures (ambient plus 3°C and ambient plus 6°C), and both long-term (72 h) N-depletion and short-term (24 h) NH_4^+ and NO_3^- uptake rates were determined (Reay *et al.*, 2001). Although the relationship between temperature elevation and the specific depletion rates of NH_4^+ and NO_3^- was highly variable, they observed a positive relationship between temperature and specific $^{15}NO_3^-$ uptake rates at 8 of 9 stations, even when NH_4^+ concentrations were experimentally elevated by 1 μM; there was no clear temperature dependence of specific NH_4^+ uptake observed. These NO_3^- uptake results support the temperature dependence seen previously in Antarctic sea-ice microalgae for NO_3^- uptake and nitrate reductase activity, but differ in that the sea-ice microalgae NH_4^+ uptake rates were also temperature dependent (Priscu *et al.*, 1989). The microalgae study also suggests that at *in situ* temperatures (−1.9°C), utilization of N would be limited by transport into the cell, not intracellular assimilation because of the differential temperature characteristics between N transport and assimilation. Overall, the results of Southern Ocean studies are similar to those conducted in the Arctic Ocean where Q_{10} values for NH_4^+ and NO_3^- uptake of ~2–3 have been determined (Smith and Harrison, 1991); the Q_{10} values are very similar to the photosynthesis–temperature responses of Arctic (Li *et al.*, 1984) and Antarctic (Neori and Holm-Hansen, 1982; Tilzer *et al.*, 1986) assemblages. It appears that natural assemblages of polar phytoplankton do not have any special adaptive strategies to cope with the cold water temperatures of their environment, but high rates of primary productivity and NO_3^--based new production are observed frequently in the Arctic, including areas such as the western Bering Strait (e.g., Sambrotto *et al.*, 1984) and during *Phaeocystis* blooms in the Greenland Sea (Codispoti *et al.* 1991; Smith *et al.*, 1991).

Temperature effects on N utilization have also been examined in unialgal cultures isolated from the Southern Ocean (Reay *et al.*, 1999). During growth kinetic experiments for a *Chaetoceros* sp., the maximum growth rate (μ_{max}) decreased for both NO_3^- and NH_4^+-chemostat grown cultures with reduced temperature, whereas slightly greater reduction in affinity indices (K_s, half-saturation constant and α, initial slope of the Michaelis–Menten hyperbola) were seen for NO_3^- with lower temperatures. The reduction in affinity for NO_3^- observed for this Antarctic isolate was shared by a series of six bacterial isolates and two other phytoplankton isolates and interpreted by the authors as evidence of a bias away from NO_3^- in low-temperature planktonic systems; note that they were generally

grown at temperatures not seen in polar systems. However, such an interpretation ignores the fact that the ambient concentrations of NO_3^- in the Southern Ocean would be considered generally saturating for uptake, and affinity measures are of little value in assessing the potential NO_3^- uptake capabilities in high NO_3^- systems.

2.5. Irradiance effects

The irradiance experienced by phytoplankton in the Southern Ocean is controlled primarily by three factors: (1) the degree of ice cover (including both thickness and overlying snow cover), (2) the depth of vertical mixing, and (3) the time of year (and hence photoperiod and solar angle); factors that are discussed in detail by Smith and Sakshaug (1990). Phytoplankton in both the Arctic and the Antarctic adapt to their *in situ* irradiances by modifying their maximal light-saturated photosynthetic rates (P_{max}^B), and their photosynthetic efficiency (the light-limited rate or initial slope, α) such that low light assemblages generally have similar or slightly lower values of P_{max}^B and α than assemblages adapted to higher irradiances (Harrison and Platt, 1986). However, the N uptake response to irradiance is unclear since numerous factors can affect the relationship between light and the substrate being utilized, and the exact mechanism(s) by which light regulates N metabolism is unresolved (e.g., see review by Syrett, 1981). The dependence of N uptake by phytoplankton upon irradiance has been described by a rectangular hyperbola parallel to that of the Michaelis–Menten equation for N uptake as a function of concentration (MacIsaac and Dugdale, 1972), modified to account for dark uptake (e.g., Cochlan *et al.,* 1991) or characterized by a 3-parameter, exponential (*P* vs. *E*) model to account for photoinhibition (Kudela and Cochlan, 2000; Priscu, 1989). Culture and field studies have demonstrated that N-deprived phytoplankton have greater dark N uptake rates than N-replete phytoplankton (see review by Cochlan *et al.,* 1991); however, given the N-rich environment of the Southern Ocean it is highly unlikely that dark uptake is attributable to this stress response, and instead has been suggested as indicative of heterotrophic N uptake (see below).

The relationship between irradiance and N uptake in the Southern Ocean is unclear and often contradictory, and most of our earlier understanding is based on comparison of specific N uptake rates measured at various depths throughout the euphotic zone using either *in situ* or simulated *in situ* irradiance fields. Although maximal rates for both NO_3^- and NH_4^+ (and during a few studies—urea) are routinely observed at either the 100 or 50% isolumes, maximal specific N uptake rates are also found as low as the 0.1–1.0% isolume (e.g., Collos and Slawyk, 1986; Glibert *et al.,* 1982). Only a few N uptake versus irradiance experiments actually have been conducted in the Southern Ocean.

In the Indian sector, Slawyk (1979) demonstrated that both NH_4^+ and NO_3^- uptake could be described by a hyperbolic relationship, NH_4^+ uptake required less light than NO_3^- to support the maximal uptake rates realized (the K_{LT} for NH_4^+ was less than the K_{LT} for NO_3^-), and irradiances in excess of 25% of the surface irradiance did not enhance specific rates of NH_4^+ and NO_3^- uptake. During a series of NO_3^- uptake versus irradiance experiments conducted in the Ross Sea during austral spring and summer, Hu and Smith (1998) also showed that relatively low irradiances

were needed to saturate uptake during the spring and summer cruises (means of 37% and 32% of surface irradiance, respectively), and that dark uptake (defined as uptake of NO_3^- at the 0.1% isolume) averaged 9.4% and 16.9% that of the surface rate. Previously, Nelson and Smith (1986) observed a similar saturation response of NO_3^- uptake to irradiance, but found that dark uptake was a much greater proportion (~40%) of the uptake rate realized at the surface. Hu and Smith (1998) explain these differences as a consequence of a difference in either the sampling time during the season, the species composition of the assemblages (diatom versus haptophyte blooms), or the stage of bloom development.

Such differences may indeed limit the comparison of N uptake response to irradiance, and may partially explain the negative relation observed between integrated NO_3^- uptake rates (normalized to chlorophyll) and irradiance along a 66.5°E transect in the Indian sector (Collos and Slawyk, 1986). In contrast, Sambrotto and Mace (2000) demonstrated that using the ratio of critical depth (Z_c; Sverdrup, 1953) to the mixed layer depth (Z_m), the integrated rates of NO_3^- uptake are positively related to the average light conditions experienced in the euphotic zone, and that this index explains over 50% of the variance in the measured rates of NO_3^- uptake along a 170°W transect spanning the Antarctic Polar Front in the Pacific sector.

2.6. Bacterial uptake of nitrogen

Distinguishing bacterial N uptake from phytoplankton N uptake is difficult in field studies. Both size fractionation techniques and metabolic inhibitors have been used, but with limited success due to a lack of specificity between autotrophic and heterotrophic processes, and the overlap in size range between the two groups of marine microorganisms. Despite these methodological limitations, it is widely regarded that heterotrophic bacteria are responsible for a significant, but highly variable (<5 to >90%) fraction of the total dissolved N utilized in estuarine and marine systems (e.g., review by Hoch and Kirchman, 1995; Kirchman *et al.,* 1994; Kirchman, 1994; Middelburg and Nieuwenhuize, 2000). In general, heterotrophic bacteria preferentially utilize NH_4^+ before NO_3^- or urea, but likely gain most of their N requirement from dissolved free amino acids in coastal environments (e.g., Billen and Fontigny, 1987; Hoch and Kirchman, 1995; Kirchman, 1994), although Middelburg and Nieuwenhuize (2000) found that bacteria have a strong preference for NH_4^+ and NO_3^- in the turbid estuaries of western Europe.

In the Southern Ocean, bacterial uptake of NO_3^- was first hypothesized by Glibert *et al.* (1982) based on observations of anomalously high rates of specific NO_3^- uptake at low light levels in the Marginal Ice Zone of the Scotia Sea, and 24-h dark NO_3^- uptake rates, which approximated rates determined under normal light/dark cycles. The importance of heterotrophic N uptake in the Scotia Sea was also suggested by Rönner *et al.* (1983) based on similar 24-h experiments where the percentage of total uptake independent of light increased with depth such that dark NO_3^- uptake equaled light uptake at the 1% isolume. More recently, during 3-day incubation experiments of samples collected near South Georgia Island, Reay *et al.* (2001) interpreted the minimal depletion of NH_4^+ and NO_3^- within dark controls as

indicative of insignificant heterotrophic inorganic N utilization. Others, however, have reported that nighttime NO_3^- uptake either ceased (Olson, 1980) or was very low (10–30%) compared to daytime uptake rates (Koike $et\ al.$, 1986), or argue that phytoplankton are adapted to utilize NO_3^- at low light depths (Nelson and Smith, 1986).

Direct measurements of N uptake by heterotrophic bacteria in the Southern Ocean have only been conducted in the coastal waters of the northern Gerlache Strait region of the Antarctic Peninsula (Tupas $et\ al.$, 1990, 1994). They determined that during a rich phytoplankton bloom, bacteria (<0.80 μm filtrates incubated in the dark) were responsible for 8–25% (mean = 17%) of the total community $^{15}NH_4^+$ uptake. They also found that heterotrophic bacteria were taking up and regenerating NH_4^+ simultaneously, in contrast to the concept presented earlier by Goldman $et\ al.$ (1987) where active heterotrophic NH_4^+ utilization implies an insufficiency of suitable organic substrates in the environment, and consequently no regeneration of NH_4^+.

Bacterial N demand for a region can also be estimated from bacterial C production rates (determined using ^{3}H-thymidine or –leucine incorporation rates), assuming a constant bacterial C:N ratio, and correcting for the efficiency of the filters used in standard ^{15}N uptake experiments (generally combusted glass-fiber filters) to retain bacteria (e.g., Fuhrman $et\ al.$, 1988). Using these assumptions in the western Ross Sea, the potential bacterial contribution to ''tracer-level'' community NH_4^+ uptake rates averaged 13%, (range: <1–26%), and was only high (35%) when bacterial abundance and biomass were maximal during a bloom of $Phaeocystis\ antarctica$ (Cochlan and Bronk, 2001). Similarly, if we assume that all bacterial N demands are met by NO_3^-, rather than NH_4^+, the average bacterial portion of total NO_3^- uptake is 10% (range: <1–36%), substantially lower than the 5–60% (mean = 32%) reported for the HNLC waters of the subarctic Pacific Ocean (Kirchman and Wheeler, 1998).

The extent to which bacteria compete with phytoplankton for inorganic and organic N in the Southern Ocean is still uncertain, but if results from temperate coastal environments (Long Island Sound, New York, USA) are applicable, ambient N concentration may influence the partitioning of N into bacteria and phytoplankton. Using ^{13}N, Suttle $et\ al.$ (1990) showed that by increasing the NH_4^+ concentration from undetectable (<0.08 μM) to just 0.5 μM, relatively more of the NH_4^+ goes into the larger plankton; uptake into the >1 μm assemblage increased from 50 to almost 80%. In the only study that has actually quantified the N uptake kinetics of a natural heterotrophic bacterial assemblage, Fuhrman $et\ al.$ (1988) report that in Long Island Sound, the maximum specific uptake rate of $^{13}NH_4^+$ by bacteria is less than for most marine phytoplankton, but the half-saturation constant (K_s) for uptake is extremely low (50 nM) resulting in an NH_4^+ affinity (estimated as α, the initial slope of the uptake vs. concentration hyperbola) that is 6-fold greater than the estimate for similarly-sized, eukaryotic picoplankton ($Micromonas\ pusilla$, Cochlan and Harrison, 1991a), and 1–2 orders of magnitude greater than N affinity estimates derived from natural assemblages and cultured phytoplankton (e.g., Goldman and Glibert, 1983; Riegman $et\ al.$, 2000), including those from the Southern Ocean (Cochlan and Bronk, 2001). These results suggest that at the low NH_4^+ concentrations normally experienced in the open waters of the Southern

Ocean, the high surface area to volume ratio of bacteria may provide them with a competitive advantage over phytoplankton. Superior competitive ability of bacteria to remove NH_4^+ from the water would force phytoplankton to utilize NO_3^- to satisfy their N demands, resulting in higher f-ratios, while factors which suppress bacterial uptake of NH_4^+ could have a negative feedback on autotrophic uptake, resulting in decreased f-ratios (Probyn, 1992). Thus, the relationship between the availability of N and the uptake capacities of bacteria and phytoplankton may be important in controlling their relative biomass levels in natural systems, including the Southern Ocean (Azam and Smith, 1991).

3. SUMMARY

A number of environmental factors exert a strong influence on the nitrogenous nutrition of Antarctic phytoplankton, and the evidence to date cannot demonstrate the dominance of one factor over another for the whole of the Southern Ocean. Observational and experimental studies conducted over the past three decades demonstrate that NO_3^- is not limiting primary production since surface concentrations of NO_3^- are in excess of those generally assumed saturating for its uptake. Other limiting factors must be considered in order to develop a mechanistic understanding of phytoplankton N utilization, and ultimately primary productivity, in the waters surrounding Antarctica. Von Liebig's Law of the Minimum (see review by de Baar, 1994) states that co-limitation, where phytoplankton growth and/or nutrient uptake are simultaneously limited by more than one factor, does not occur in natural phytoplankton populations. However, in the Southern Ocean, the largest of the HNLC regions, co-limitation by a micro-nutrient (Fe) and a macro-nutrient (NO_3^-) appears to occur, in that Fe regulates the capability of phytoplankton to utilize NO_3^- that is normally found in excess. Others have suggested similar co-limitation (or simultaneous limitation) of phytoplankton processes in the Southern Ocean by Fe and Si, or Fe and irradiance (e.g., Boyd, 2002 and references therein).

With the development of trace metal clean techniques, it has become apparent that the availability of Fe is a major factor limiting phytoplankton growth in the deep, open ocean regions of the Southern Ocean; regions minimally affected by potential sources of Fe from upwelled waters associated with shallow sea bottoms, or adjacent to land and/or glacial masses. Based on the Fe requirements for N assimilation it also would be expected that Fe would be more important in the regulation of NO_3^- uptake, and have a lesser effect on the uptake of reduced N substrates (urea and NH_4^+), although only a few studies have concurrently measured all three major substrates as a function of Fe. Given the greater Fe requirements for phytoplankton growth at low light, the regulatory role of Fe is likely accentuated in open ocean areas dominated by deep, wind–mixed layers, and less so in marginal ice zones where low density meltwater stabilizes the water column. The effect(s) of one N source on the utilization of another, namely NH_4^+ inhibition of NO_3^- uptake, cannot be ignored, particularly in regions of elevated surface concentrations

of NH_4^+. However, the few studies of concentration-dependent experiments demonstrate that even the relatively low concentrations of NH_4^+ (0.1–0.2 μM) present throughout the Southern Ocean can potentially reduce NO_3^- uptake by 50% or more. Of particular interest is the possibility of a common source of both Fe and NH_4^+ in melting sea-ice, and their opposing effects on NO_3^- uptake rates. Finally, although the regulatory role of temperature has not been investigated in detail, low ambient temperature undoubtedly factors into the subdued rates of nitrogenous nutrient uptake and primary productivity realized by most pelagic phytoplankton assemblages in the Southern Ocean.

Although much progress has been made toward solving the Antarctic Paradox in the last 25–30 years, temperature may ultimately prove to be the limiting environmental factor controlling the absolute magnitude of both new and regenerated productivity, whereas the availability of trace metals (notably, Fe), regenerated N sources, and light, appear crucial in dictating their relative importance in the open ocean and seasonal ice zones of the Southern Ocean.

Nitrogen in the Atlantic Ocean

Dennis A. Hansell *and* Michael J. Follows

Contents

1. Introduction

The location of the North Atlantic (between Europe and North America) has made it the focus of considerable study; some of the most important advances in marine nitrogen dynamics have been developed in the region (Lipschultz *et al*, 2002). The South Atlantic, in contrast, has undergone expeditionary surveys, but fewer process studies have been specific to that basin.

The Atlantic is fed by the northward flow of upper ocean waters that are depleted in nitrate and phosphate, while North Atlantic deep waters, formed in the northern high latitudes, move southwards through the basin gathering remineralized nutrients. The proximity of the vigorous source of iron from Saharan dust suggests that productivity in the basin is limited by the availability of these macro-nutrients. The North Atlantic is unique among ocean basins with a nitrate:phosphate ratio (N:P) in thermocline waters in excess of the requirements of "average" Redfieldian organisms (Fanning, 1992), a situation commonly interpreted as a signature of N input by nitrogen fixation.
Figure 13.1 Map of the Atlantic Ocean depicting locations of hydrographic sections contoured for this chapter, as well as the locations of the time series study sites referenced. Map (as well as several figures in this chapter) prepared using Ocean DataView (Schlitzer, 2005).

This feature suggests that the Atlantic Ocean may be a source of fixed nitrogen to the global ocean, thus balancing the nitrogen removal due to denitrification occurring elsewhere.

In this chapter we focus on the factors regulating the nitrogen cycle of the Atlantic Ocean, with special attention on the North Atlantic, where data are plentiful. We begin the chapter with a description of the distributions of the major forms of N. A map of the Atlantic depicting locations of data collection for ocean sections and time-series discussed here is given in Fig. 13.1. We then consider the processes that regulate the nitrogen budget in the region, including physical transports, N_2 fixation, atmospheric deposition, and denitrification. We close with a quantitative evaluation of the major reservoirs and fluxes of nitrate in the North Atlantic.

2. DISTRIBUTION OF NITROGEN IN THE ATLANTIC

2.1. Nitrate

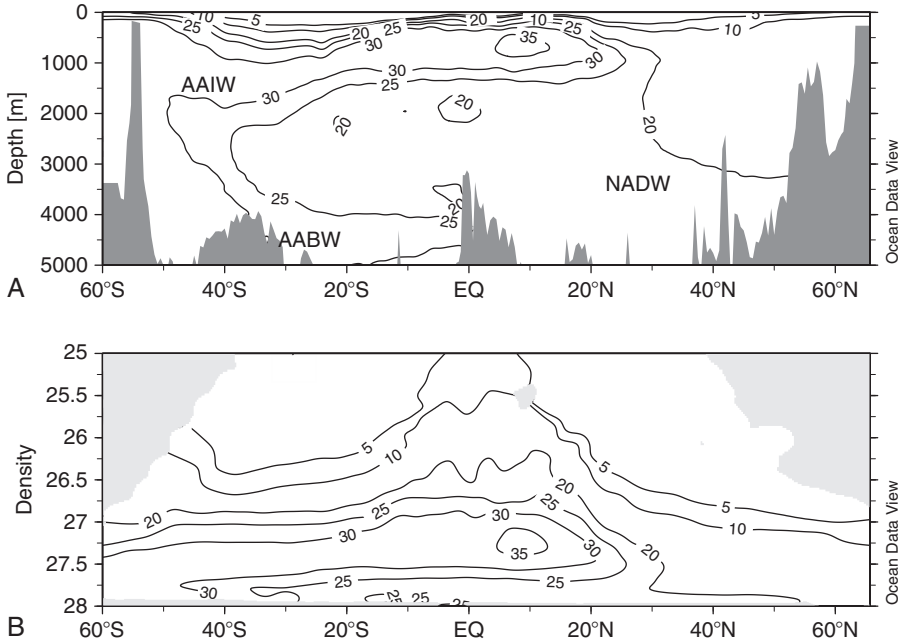
The meridional distribution of nitrate in the Atlantic generally follows the major water masses, with a clear and dominant signature of North Atlantic Deep Water (NADW) formed from northern high latitude, nutrient depleted waters (Fig. 13.2A).


Figure 13.2 Section of (A) nitrate versus depth and (B) nitrate versus potential density (sigma theta) using combined data from the 2003 (North Atlantic) and 2005 (South Atlantic) occupations of the A16 line. North Atlantic Deep Water (NADW), Antarctic Bottom Water (AABW) and Antarctic Intermediate Water (AAIW) are indicated. Units μmol kg^{-1}.

Nitrate-rich signatures of Antarctic Bottom Water (AABW) and Antarctic Intermediate Water (AAIW) extend northward, reflecting the high surface concentrations where these water masses are formed. These water masses are also evident in the zonal structure of the North and South Atlantic, and nitrate-rich (>30 μM) AAIW is evident in the South Atlantic (Fig. 13.3) at mid-depth, along with a hint of AABW with elevated nitrate concentrations in the deep western part of the basin. There is
Figure 13.3 Section of nitrate versus depth at 30°S (WOCE A10) in 1993. AAIW present in the waters with nitrate >30 μmol kg^{-1}. Units μmol kg^{-1}.

only weak horizontal variation in the east–west direction; nonetheless, the gradient can be significant when coupled with the east–west variations in volume transport (Rintoul and Wunsch, 1991; see Section 3.1).

The large scale pattern of wind stress over the oceans drives the Ekman suction (upwelling) over the cyclonic subpolar gyres and in the tropics, advecting nitrate upwards in those regions and providing a source of nutrients to the euphotic zone. Strong seasonality in mixed-layer depths at northern mid- and high-latitudes is reflected in the nutrient supply (Glover and Brewer, 1988), which fuels the subsequent spring bloom following stratification (Sverdrup, 1953) in the North Atlantic, where the aeolian iron supply is strong.

The high southern latitudes are dominated by zonal features associated with the Antarctic Circumpolar Current. To the south of the Polar Front, surface nitrate concentrations are high year-round, owing to the upwelling of nitrate-rich, iron-starved circumpolar deep waters (e.g., Boyd *et al.*, 2000) by the residual mean overturning circulation (e.g., Marshall, 1997). During northward transit across the circumpolar current region, nitrate is stripped from the surface waters, aided by the aeolian iron source, though surface concentrations are still elevated in the regions of Antarctic Intermediate Water (AAIW) and Sub-Antarctic Mode Water (SAMW) formation, providing these water masses with pre-formed nitrate (Fig. 13.2A).

In the subtropical gyres, Ekman pumping (downwelling) drives nitrate-rich waters away from the surface. In the oligotrophic surface waters, nitrate concentrations are generally at low nanomolar levels (Cavender-Bares *et al.*, 2001; Eppley *et al.*, 1990; Garside, 1985; Lipschultz, 2001). In the ventilated thermocline, spatial gradients of nitrate along isopycnal surfaces (Fig. 13.2B) are determined by the balance between transport and remineralization of organic matter: On the σ_θ 26 surface, for example, nitrate increases from 5 to 10 μM towards the equator, reflecting the accumulation of regenerated nutrients as the waters of the ventilated thermocline transit away from the subduction region. While the nitrate distribution on σ_θ 26 (Fig. 13.2B) reflects the somewhat symmetrical subtropical overturning cells (Zhang *et al.*, 2003), deeper isopycnals also exhibit an asymmetry due to the northward transit of relatively nitrate-rich AAIW and SAMW.

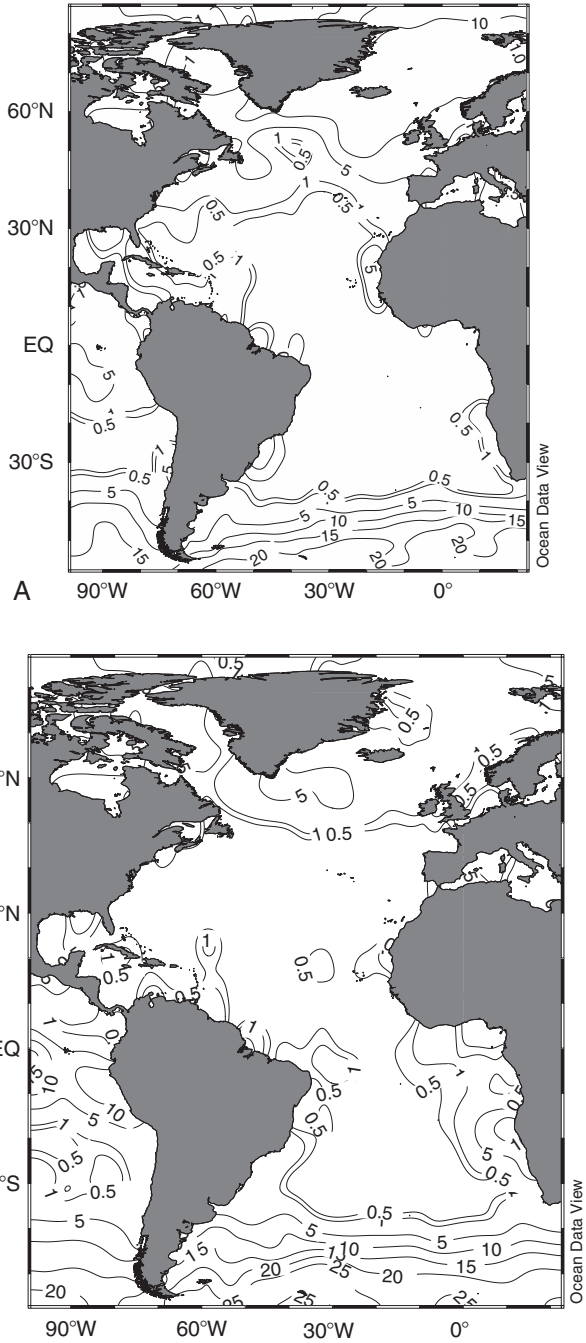
There is anomalously high nitrate (>35 μM) at low latitudes in the density class of AAIW and SAMW (Oudot *et al.*, 1998), with elevated tongues north and south of the equator (Fig. 13.2A; centered near 8–10°N and 8–10°S, at 400–900 m). These persistent features were present during the earlier GEOSECS occupations (see Fig. 4 in Sharp, 1983) and appear to be transported from regions of strong coastal upwelling off Africa (Fig. 13.4C; see also model study of Williams *et al.*, 2006). Particulate organic nitrogen (PON), formed during primary production in systems enriched by upwelled nutrients, sinks out of the euphotic zone before eventual remineralization to nitrate in the water column or sediments. In coastal upwelling zones this occurs over the shelf and at relatively shallow depths (<200 m in the NW Iberian shelf system of Alvarez-Salgado *et al.*, 1997). Regenerated nutrients are "trapped" on the shelf by the combination of upwelling and biological export. Several studies of upwelling off Africa have reported relatively shallow (<200 m) length scales for regeneration (see Codispoti, 1983; Calvert and Price, 1971; Dittmar and Birkicht, 2001; Minas *et al.*, 1982; Rowe *et al.*, 1977; Treguer and LeCoore,


Figure 13.4 Climatological distributions of nitrate at the surface during (A) the January–March period and the (B) July–September period, and

(Continued)

1979) though the high concentrations of nitrate emanating from the coastal zone of West Africa occur at depths of 500 m or more (Fig. 13.4C). The presence of enhanced nitrate at these depths suggests either a significant contribution from deeper remineralization, or significant physical interaction with the shelf waters at these depths. The spreading of this nitrate at intermediate depths eventually feeds into the source waters for the North Atlantic (Williams *et al.*, 2006; see Section 3.1), suggesting a significant role for the African upwelling regions in maintaining macro-nutrient abundance in the northern basin.

2.2. Dissolved organic nitrogen

A significant fraction of dissolved nitrogen is in the form of dissolved organic nitrogen (DON; recently reviewed by Bronk, 2002), the prevalent form in oligo-trophic surface waters (Bode *et al.*, 2001; Cavender-Bares *et al.*, 2001; Hansell and Carlson, 2001; Vidal *et al.*, 1999). Measurements of DON concentrations are imprecise because the value is calculated as the difference between total dissolved nitrogen and nitrate, both of which can be relatively large values compared to DON. The propagation of errors causes low precision in DON estimates, particularly in deep waters. Because the DON data are often inadequately precise for resolving small concentration differences or minor changes with time, the DON field can
Figure 13.5 Upper 500 m distributions of (A) nitrate (μmol kg^{-1}) and (B) DON (μmol kg^{-1}) along section A16 (North and South Atlantic basins occupied in January 2003 and June 2005, respectively, with data combined from those cruises). Dots indicate sample depths.

appear relatively invariant (e.g., Hansell and Carlson, 2001). In nutrient-replete systems such as the English Channel, however, DON has a strong seasonality and large concentration changes that are anti-correlated with nitrate (Butler *et al.*, 1979).

There is a paucity of information on the large scale spatial distribution of DON in the Atlantic, but DON has been determined on a few sections. Mahaffey *et al.* (2004) presented data from the Atlantic Meridional Transect, evaluating the dynamics of nitrogen and phosphorus, with special consideration for the role of DON. Vidal *et al.* (1999) presented a quasi-meridional section from 22°N to 31°S in the central Atlantic, while Doval *et al.* (2001) reported DON in the temperate, transitional and subtropical waters of the Azores Front region east of Azores. A survey of DON in the upper 500 along Climate Variability and Predictability (CLIVAR) section A16 (a meridional section from 60°S to 60°N) is shown in Fig. 13.5. DON is measured with highest precision where nitrate concentrations are minimal (Hansell, 1993), and thus the most informative DON assessments are in oligotrophic surface waters. On A16, in the North Atlantic, surface waters with <5 μmol kg^{-1}NO$_3^-$ had DON concentrations >5 μmol kg^{-1} in the subtropical and subpolar regions and >7 μmol kg^{-1} in the more stratified tropical waters (<20°N) (Fig. 13.5). This tropical enhancement may be due to the abundance of diazotrophs in tropical waters

(Capone *et al.*, 1994; Glibert and Bronk, 1994), as has been suggested to explain elevated DON in the western equatorial Pacific (Hansell and Feely, 2000) and the central Atlantic (Vidal *et al.*, 1999). But Mahaffey *et al.* (2004) reported that the particulate organic N fraction in the tropics are enriched in ^{15}N, suggesting nitrate as a likely source. Similarly, the ^{15}N content of total organic N in the Sargasso Sea suggests that N$_2$ fixation is a minor contributor to DON (Knapp *et al.*, 2005; Meador *et al.*, 2007). Upwelling of nitrate (whether coastal or equatorial), subsequent enhanced productivity, and horizontal transport likely supports the DON accumulation observed. It is puzzling, though, that the nitracline is similarly shallow in the subpolar region (e.g., 50°N), thus making nitrate available by vertical mixing there, but DON remains less abundant than in the tropics (Fig. 13.5). This finding suggests differing controls on DON concentrations for the various zonal sectors.

In the South Atlantic, with similarly low surface nitrate concentrations, DON is consistently <5 µmol kg^{-1}, or 2 µmol kg^{-1} lower than the North Atlantic. In fact, the western Sargasso Sea (near Bermuda) also has relatively low surface DON values (Hansell and Carlson, 2001), similar to values found in the South Atlantic. The relatively elevated DON concentrations in the low latitude North Atlantic are suggestive of unique inputs there (such as atmospheric deposition, N$_2$ fixation, or upwelled nitrate with horizontal transport) compared to the South and western North Atlantic.

DON concentrations are also elevated in the Atlantic coastal and shelf regions (Bode *et al.*, 2001; Doval *et al.*, 1997) where freshwater inputs are significant (Bates and Hansell, 1999; Lopez-Veneroni and Cifuentes, 1994). This material may be transported off-shelf and photo-oxidized, releasing ammonium to the phytoplankton community (Morell and Corredor, 2001).

2.3. Seasonal variations of surface nitrate

The broad pattern of surface nitrate concentrations is related to the patterns of wind-driven upwelling and downwelling in the upper ocean. The subpolar and tropical surface waters have seasonally elevated nitrate concentrations in contrast to the continuously oligotrophic subtropical gyres (Figs. 13.4A and B). The North Atlantic undergoes a basin-wide seasonal and meridional advance and retreat in the nitrate front, related to a springtime advance of the phytoplankton community (Siegel *et al.*, 1990), while the South Atlantic apparently undergoes greater seasonal nitrate enrichment along the continental margins than in the interior (Figs. 13.4A and B).

Seasonal and longer term variability of upper ocean nitrate has been observed at several sites in the North Atlantic (Table 13.1). These time-series studies span a range of latitudes (Fig. 13.1) and physical forcing regimes. The Bermuda Atlantic Time-series Study (BATS) site is located within the subtropical gyre of the North Atlantic (31.66°N, 64.16°W), remote from continental land masses and coastal influences. There, winter cooling results in vertical mixing that, if strong enough, introduces nitrate to the surface layer (Fig. 13.6). Since insolation is relatively high year-round, this nutrient injection stimulates a late winter bloom (Michaels *et al.*, 1994b; Steinberg *et al.*, 2001).

Corredor *et al.* (1999)	A review of mechanisms leading to nutrient limitation in tropical marine systems, emphasizing N cycling in Caribbean ecosystems

There exist time-series observations at two locations in the Caribbean: South of Puerto Rico at the Caribbean Time-series Study site (CaTS; 17.6°N, 67°W), and north of Venezuela at the CARIACO site (Carbon Retention in a Colored Ocean Project; 10.5°N, 64.67°W). At the former, the Caribbean Surface Water (upper 75 m) experiences a yearlong influence of continental river input, as evidenced by lowered
Figure 13.6 Temporal variability of (A) temperature ($^\circ$C) and (B) nitrate (μmol kg^{-1}) at the BATS site. Sampling was conducted at approximately monthly intervals.

salinity and elevated silica (Corredor and Morell, 2001). Marine nutrients, elevated at depths greater than 100 m, do not break through to the surface due to the stratification imposed by the low density surface layer (Fig. 13.7). At the CARIACO site, elevated nitrate waters are close to the surface layer year-round, with water of >1 μmol kg^{-1}NO$_3^-$ mixing to the surface on occasion (Fig. 13.8). Upwelling of Subtropical Underwater (SUW) starts around October and lasts through May each year, fuelling a winter maximum in chlorophyll *a* (Muller-Karger *et al.*, 2001).

The European Station for Time-Series in the Ocean, Canary Islands (ESTOC), located north of the Canary Islands at 29.16°N, 15.5°W, was established in 1994 in the eastern boundary system of the subtropical North Atlantic Gyre. The seasonality of phytoplankton biomass and productivity is very similar to that found at BATS (Neuer *et al.*, 2002a). Nitrate is usually below detection in the surface layer (<0.1 μmol kg^{-1}) but convective overturning in late fall and winter introduces nitrate into the euphotic zone, initiating a phytoplankton maximum coincident with the period of deepest mixing (Neuer *et al.*, 2007). In contrast to BATS, N:P is near the Redfield ratio (Neuer *et al.*, 2002a). Intermittent increases in mixed layer nitrate in summer might be related to the passage of mesoscale features or the mixing of the water column due to the onset of the strong trade winds.

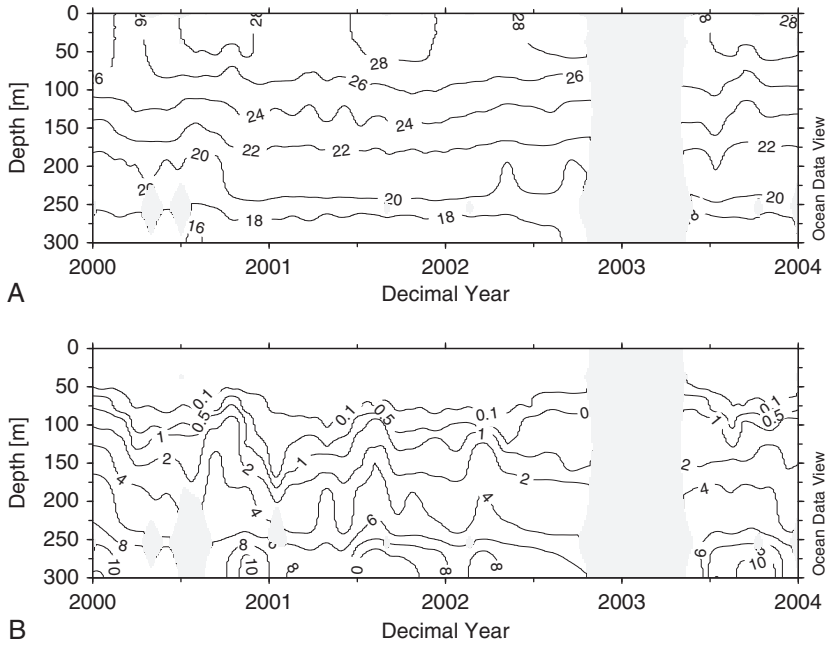
No dedicated biogeochemical observation sites currently exist in the subpolar North Atlantic, but studies such as the North Atlantic Bloom Experiment (Ducklow and Harris, 1993) and weather ship observations (Stramska *et al.*, 1995) provide


Figure 13.7 Temporal variability of (A) temperature (°C) and (B) nitrate (μmol kg^{-1}) at the CaTS site. Sampling was conducted at approximately monthly intervals. Note gap in data at end of 2002 and early 2003.
Figure 13.8 Temporal variability of (A) temperature (°C) and (B) nitrate (μmol kg^{-1}) at the CARIACO site. Sampling was conducted at approximately monthly intervals.

insights into the seasonal cycle at higher latitudes. There is a strong seasonal amplitude both in winter deepening of the mixed-layer and insolation, leading to elevated surface nutrient concentrations in the winter that are drawn down by the onset of the spring bloom as insolation increases and the water column stratifies again (Sverdrup, 1953).

In the equatorial Atlantic, surface nitrate concentrations vary seasonally with the rate of upwelling. Measurable nitrate is present in the east during the boreal summer but apparently absent year-round in the west (Oudot and Morin, 1987).

3. Sources of Nitrogen to the Euphotic Zone

The availability of nitrogen in the euphotic zone is an important, potentially limiting factor for productivity and the biological sequestration of carbon in the ocean. There are three principal routes by which new nitrogen makes its way into the euphotic zone of the Atlantic Ocean: Physical transport of nitrate, nitrogen fixation by diazotrophic organisms, and aeolian transport and deposition.

3.1. Physical supply of nitrate

The subpolar North Atlantic is a site of significant deepwater formation and export (Fig. 13.2) balanced by the northward flow of warm, nutrient depleted surface waters into the basin. Biological activity further strips the macro-nutrients from the surface waters, while newly formed deep waters make their way southward, accumulating regenerated nutrients. This contrasts with the deep Indo-Pacific basins where the deep inflow brings nutrient-rich bottom waters into the basin where they are upwelled. This simple, two-dimensional view of the Atlantic, with inflow of low nutrient surface waters and outflow of high nutrient deep waters, suggests a significant net transport of macro-nutrients out of the basin. However, the horizontal circulation in the thermocline provides a compensatory northward transport of nitrate (Rintoul and Wunsch, 1991; Williams and Follows, 2003; Williams *et al.*, 2006). The northward flowing Gulf Stream swiftly transports nutrient rich waters in the thermocline, termed the ''nutrient stream'' (Pelegri and Csanady, 1991; Pelegri *et al.*, 1996). The nutrient stream in the North Atlantic includes contributions from the Southern Hemisphere (Fig. 13.9B) associated with the basin scale meridional overturning circulation, but also from waters recirculating within the subtropical gyre. The stream is strongest on isopycnals associated with the northward transport of SAMW (Fig. 13.9A). The relative distributions of nitrate and silica in the global ocean suggest that this water mass is the major source of macro-nutrients to the surface of the Atlantic basin north of the Antarctic Circumpolar Current (Sarmiento *et al.*, 2004). Nutrient trapping in the Equatorial Upwelling region may increase the nitrate concentration on this density surface and further enhance the nutrient stream (Williams *et al.*, 2006).

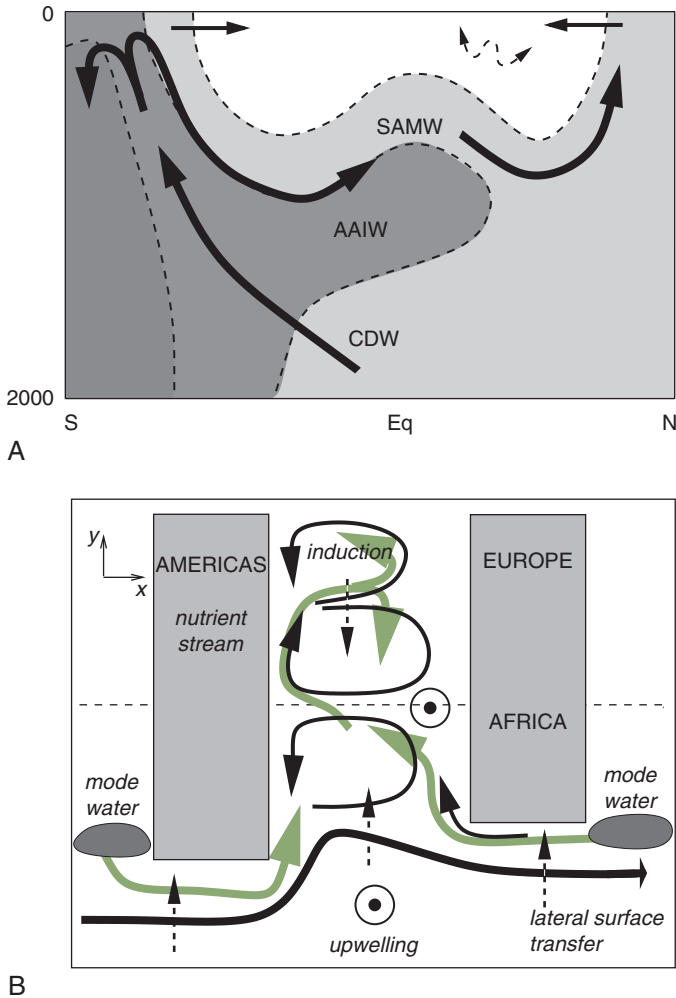
In the subpolar gyre and in the northern sector of the subtropical gyre, the nutrient stream encounters the deep winter mixed-layers and outcrops (Fig. 13.9A), thus sustaining the annual convective supply of nitrate to the surface (Williams and


Figure 13.9 Schematic views of (A) meridional and vertical transport of nitrate in the upper Atlantic basin and (B) associated horizontal transport pathways. Nitrate-rich Circumpolar Deep Water (CDW) upwells in the Southern Hemisphere and the residual mean flow transports some of this upwelled water across the polar front into the regions of intermediate and mode water formation. Nitrate-rich Sub-Antarctic Mode Water (SAMW) and Antarctic Intermediate Water move northward in the thermocline, ultimately outcropping in the subpolar North Atlantic. Ekman transfer provides a source of nitrate to the subtropical gyre along with lateral and vertical eddy transport processes.

Follows, 2003). There, seasonal variations of surface ocean mixing drive a wintertime supply of nitrate to the euphotic zone (Glover and Brewer, 1988), fuelling most of the annual export production.

While the North Atlantic subtropical gyre shows the classical signatures of oligotrophy, with low surface nutrient concentrations and little surface chlorophyll,

there is a significant rate of export production (Jenkins, 1982; Jenkins and Doney, 2003) and there has been considerable effort to understand the source of nitrogen (and phosphorus) to support this biological activity. Interpretations of oxygen and tritium–helium data (Jenkins, 1982; Jenkins and Goldman, 1985) suggest regional export production to be as much as 0.5 mol N m^{-2} year^{-1} in the North Atlantic subtropical gyre; greater than could be sustained by the upwards diapycnal flux assuming mixing rates observed in the interior thermocline (Ledwell et al., 1993). Recent estimates for the flux of nitrate into the euphotic zone near Bermuda are higher yet, at 0.8 mol N m^{-2} year^{-1} (Jenkins and Doney, 2003).

Wintertime convection supports a significant fraction of annual productivity in the subtropics (Michaels et al., 1994b) but it cannot sustain production over longer time-scales (Williams and Follows, 1998), though other physical transport processes may be important. The heaving of nutrient-rich isopycnals into the euphotic zone associated with ocean eddies ("eddy pumping") is suggested to be a significant, adiabatic source of nitrate to the euphotic zone of the subtropical oceans (Falkowski et al., 1991; McGillicuddy and Robinson, 1997; McGillicuddy et al., 2007; Oschlies and Garcon, 1998) though some studies suggest it is not a major contributor (Martin and Pondaven, 2003). In fact, particle export within a cyclonic eddy occupied in the Sargasso Sea near Bermuda was indistinguishable from export outside the eddy (McGillicuddy et al., 2007; Pointer et al., 2006). The biogeochemical imprint of export was evident in the eddy core (McGillicuddy et al., 2007), suggesting that the export event (and upward pumping of nitrate to the euphotic zone) had occurred and was indeed strong, but the process may have occurred nearer the time of eddy formation, and less so during transit in the Sargasso Sea. Numerical models suggest that smaller, frontal-scale features may be more significant sources of nitrate (Levy et al., 2001; Mahadevan and Archer, 2000).

These vertical motions can locally transfer nitrate to the surface from modest depths, but the three-dimensional circulation of the gyre must be invoked to maintain supply from the main thermocline and below. The nitrate-rich nutrient stream feeds nitrate to the deep winter mixed layers of the subpolar gyre and northern subtropical gyre (Fig. 13.9). The high surface concentrations of nitrate in the subpolar latitudes can be transferred into the subtropical gyre at the surface, along with dissolved organic nitrogen, by the ageostrophic Ekman flow and lateral eddy transfers (Abell et al., 2000; Lee et al., 1997; Mahaffey et al., 2004; Rintoul and Wunsch, 1991; Williams and Follows, 1998). Using climatological observations, Williams and Follows (1998) estimated that the Ekman transport of nitrate provides a modest contribution to the maintenance of new production locally in the North Atlantic subtropical gyre (equivalent to $\sim$0.2 mol C m^{-2} year^{-1}). However, this "trickle" of nutrients into the subtropics may be significant in maintaining the integrated nutrient load of the bowl of the gyre, balancing the continual flux of sinking organic matter to depths below the thermocline (Williams et al., 2006). Likewise, a substantial lateral transfer of surface properties from one side of the current to the other might occur in association with baroclinic eddies and their subsequent interactions with the Gulf Stream (Dutkiewicz and Paldor, 1994; Dutkiewicz et al., 2001). Such diapycnal, inter-gyre transports can be supported in the surface ocean by significant buoyancy forcing due to air-sea heat fluxes in combination with the strong inter-gyre surface nutrient gradients.

While some of the nutrient stream nitrate originates in the southern hemisphere with SAMW, a fraction has recirculated within the subtropical gyre (Fig. 13.9B). Jenkins and Doney (2003) hypothesize a "nutrient spiral" in which enhanced diapycnal mixing associated with the eddy-rich, western boundary current also leads to a significant vertical transfer of nutrients (and other properties including helium) into the mixed-layer of the subtropical gyre.

3.2. Geochemical investigations of nitrogen fixation

An alternative source of nitrogen to the euphotic zone is the fixation of N_2 by diazotrophic organisms (Karl *et al.*, 2002; Mahaffey *et al.*, 2005). This process has received considerable attention using direct biological observations (Capone *et al.*, 2005; Voss *et al.*, 2004), modeling (most recently for the Atlantic; Coles *et al.*, 2004a and Hood *et al.*, 2004), remote sensing (Coles *et al.*, 2004b; Hood *et al.*, 2002) and indirect geochemical approaches. Fanning (1987, 1992) first invoked nitrogen fixation to explain high N:P ratios (or excess nitrate) in the thermocline of the Sargasso Sea. Michaels *et al.* (1994a) noted decreases in carbon stocks from the spring to autumn in the upper 150 m of the Sargasso Sea near Bermuda not attributable to nitrate consumption, thus suggesting a role for N_2 fixation (see also the models of Anderson and Pondaven, 2003; Bissett *et al.*, 1999; Marchal *et al.*, 1996).

The relative abundances of nitrate and phosphate are typically discussed in terms of the diagnostic parameters $N\star$ ($N\star = NO_3^- - 16PO_4^{3-} + 2.90$) (Deutsch *et al.*, 2001; Gruber and Sarmiento, 1997; Michaels *et al.*, 1996) or DIN_{xs} ($DIN_{xs} = NO_3^- - 16PO_4^{3-}$) (Bates and Hansell, 2004; Hansell *et al.*, 2004). These indices measure the departure from classical Redfield ratios of the dissolved inorganic forms of nitrogen and phosphorus (the $N\star$ and DIN_{xs} indices differ only in the offset of 2.90 μM, a value that was intended to fix the global mean $N\star$ to zero). Negative values of DIN_{xs} (or $N\star$ values < 2.9 μmol kg^{-1}) indicate a deficit in N relative to P with respect to the requirements for Redfieldian production of organic matter; positive values of DIN_{xs} (or $N\star$ values >2.9 μmol kg^{-1}) indicate excess N relative to P. In the Atlantic (Fig. 13.10), there is negative DIN_{xs} throughout the upper layer ($\sigma_\theta < 26$), in the deep subpolar waters (>40°N), and in the South Atlantic (south of 10°N). The region of positive values is largely confined to the North Atlantic subtropical thermocline, between σ_θ surfaces 26 and 27.5 (to depths of ≈1100 m). This distribution implies net addition of excess nitrate (or the removal of P relative to N) in that region.

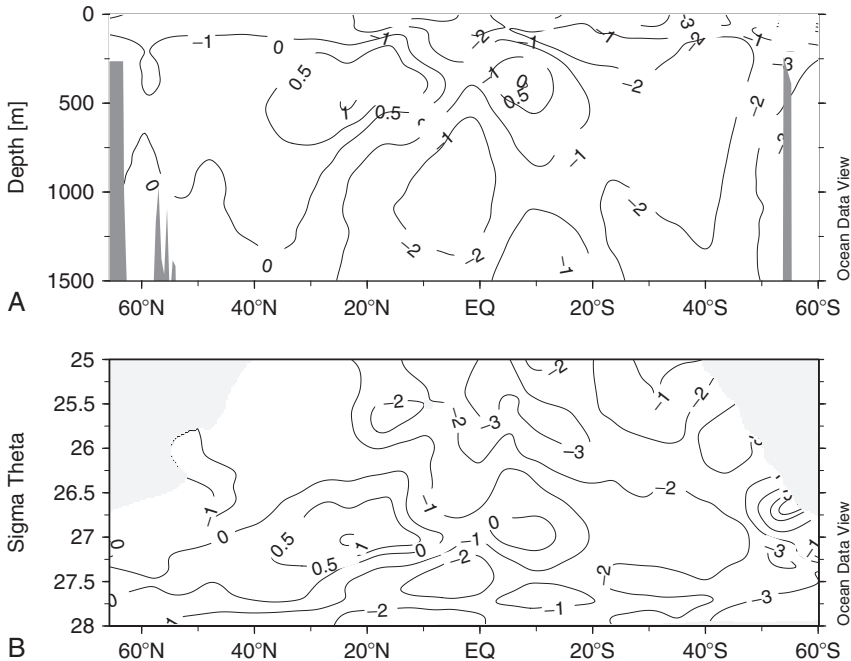
A number of recent studies have used the observed nitrate and phosphate distributions to infer local and basin scale rates of allochthonous nitrogen inputs to the North Atlantic (presumably due to nitrogen fixation, but other processes likely contribute; Hansell *et al.*, 2007). Due to the relative scarcity of appropriate data (required to provide high resolution spatial coverage), unresolved temporal variability, and uncertainties in estimated ventilation timescales, the inferred N_2 fixation rates have a large uncertainty, and the published basin integrals span an order of magnitude (0.15–6.4×10^{12} mol N year^{-1}; Table 13.2). Michaels *et al.* (1996) assessed the $N\star$ gradients on isopycnal surfaces in the upper thermocline between the BATS site and sites of ventilation for those surfaces. Using concurrent age (time since ventilation)


Figure 13.10 Section of (A) DINxs vs depth and (B) DINxs versus density (sigma theta) using data combined from the 2003 (North Atlantic) and 2005 (South Atlantic) occupations of the A16 line. Units $\mu mol\,kg^{-1}$.

estimates from transient tracers they inferred the rate of excess nitrate accumulation that is ascribed to N_2 fixation in the overlying waters. Their inferred N_2 fixation rates are the highest reported (up to 6.4×10^{12} mol N year^{-1} over the North Atlantic), but this was an extrapolation from a small region to the entire northern basin. Gruber and Sarmiento (1997) presented a more complete derivation of N* and an assessment of N* gradients in the global ocean from which they determined a lower, but still substantial, rate of N_2 fixation (2×10^{12} mol N year^{-1}) in the North Atlantic. Lee *et al.* (2002) estimated the net summer-time drawdown of inorganic carbon in nitrate-depleted tropical and subtropical waters and hypothesized that it must be balanced by N_2 fixation, totaling 2.3×10^{12} mol N year^{-1} for the whole basin with most occurring in the North Atlantic.

Ganachaud and Wunsch (2002) evaluated volume fluxes, nutrient transports, and net nutrient sources using a global set of hydrographic sections in the context of an inverse model. Their analysis inferred a significant net source of nitrogen (i.e., a high rate of N_2 fixation) in the South Atlantic (0.4 ± 0.17 mol N m^{-2} year^{-1}) and a net sink of nitrate (i.e., denitrification) in the subtropical North Atlantic, contrary to expectations. Note that their results do not imply that nitrogen fixation is not significant in the North Atlantic, but rather that the total N balance may be dominated by denitrification or the influence of lateral transport of dissolved organic nitrogen (Lee and Williams, 2000; Rintoul and Wunsch, 1991).

Table 13.2 Summary of indirect (geochemical) estimates of N_2 fixation in the Atlantic Ocean

	Fixation rate		Period of data collection	Comments
	$mol\,N\,m^{-2}\,year^{-1}$	$mol\,N\,year^{-1}$		
Michaels *et al.* (1996)	0.13–0.23★	$3.7–6.4 \times 10^{12}$	1989–1992	North Atlantic. Rate determined from N★ gradient between two sites in North Atlantic subtropical gyre, then extrapolated to entire gyre. ★Areal rate calculated using tropical and subtropical area of 27.8×10^{12} m^2
Gruber and Sarmiento (1997)	0.072	2×10^{12}	1977–1982	North Atlantic rate. Basin wide survey of N★
Lee *et al.* (2002)	–	2.3×10^{12}	1981–1998	40°S to 40°N. Estimated from summertime drawdown of inorganic carbon in nitrate depleted waters (data selection criteria: SST >20°C; NO_3^- <0.1 µmol kg^{-1}), converted to N using C:N molar ratio of 7
Ganachaud and Wunsch (2002)	0.4	–	1991–1994	Subtropical South Atlantic only; inverse methods using WOCE data
Hansell *et al.* (2004)	0.045	$0.15–0.46 \times 10^{12}$	1992–1998	North Atlantic rate. Basin wide survey of DIN_{xs} gradients using WOCE data.
Bates and Hansell (2004)	–	$0.22–0.61 \times 10^{12}$	1988–2001	North Atlantic rate; largely BATS and WOCE data.
Hansell *et al.* (2007)		$\sim 0.4 \times 10^{12}$	2003	Calculated by mass balance of total excess N accumulation rates and estimated inputs by atmospheric deposition and DOM export

Hansell *et al.* (2004) followed the analytical approach of Gruber and Sarmiento (1997), but using data collected during the World Ocean Circulation Experiment (WOCE; mostly 1990s) while Gruber and Sarmiento (1997) used data from earlier programs. Both analyses of the North Atlantic resulted in comparable areal rates for N_2 fixation (0.045 and 0.072 mol N m^{-2} year^{-1}, respectively), yet their extrapolated rates for the basin differed by more than 6-fold (Table 13.2). Gruber and Sarmiento (1997) applied their volumetric N accumulation rates for each isopycnal surface to the entire area of 10–50°N and 10–90°W. Hansell *et al.* (2004), deeming this area too large to be representative of the zone of N_2 fixation in the North Atlantic, limited their extrapolation to subtropical waters showing positive spatial gradients in the concentrations of DIN_{xs} (thus indicating regions of net excess nitrate additions to the thermocline waters). Without greater spatial coverage of the distribution of excess N accumulation, the basin integral remains very uncertain.

Besides uncertainty in the spatial extent of excess N, it is possible that significant temporal variability, manifested on large spatial scales, may be reflected in the contrasting estimates. Bates and Hansell (2004), in a study of DIN_{xs} and its variation at the BATS (Bermuda Atlantic Time-Series Station) site, found that local variations in excess nitrate in the Sargasso Sea correlated with the North Atlantic Oscillation Index. Positive states of the index correlated with elevated concentrations (and presumably production rates) of excess nitrate, and it is during such phases that the Michaels *et al.* (1996) and Gruber and Sarmiento (1997) data were collected. Negative phases correlated with lower concentrations of excess nitrate, and it was during such a phase that the data employed by Hansell *et al.* (2004) were collected. It may be that the difference in basin integral estimates of nitrogen fixation partly reflects large-scale, temporal variability.

What might give rise to such temporal variability? Atmospheric dust inputs of iron to the subtropical North Atlantic have been implicated (Gruber and Sarmiento, 1997; Mahaffey *et al.*, 2003; Michaels *et al.*, 1996) since diazotrophs have a high iron requirement relative to other plankton (Berman-Frank *et al.*, 2001; Kustka *et al.*, 2003; Raven, 1988). The magnitude and timing of the atmospheric transport of dust to the region is related to the changes in atmospheric circulation characterized as the North Atlantic Oscillation (NAO), which has also been linked to variability in the excess nitrate signal in the western Sargasso Sea (Bates and Hansell, 2004). Hansell *et al.* (2004) found the strongest signature of excess nitrate in the southeastern North Atlantic where there is an input of North African dust. It is not yet clear, though, the extent to which diazotrophs are iron limited in the North Atlantic (Mills *et al.*, 2004; Sanudo-Wilhelmy *et al.*, 2001; Voss *et al.*, 2004).

Geochemical estimates for N_2 fixation rates can be compared to those determined by direct biological measurements (i.e., bottle incubations of *Trichodesmium*). Based on such direct, though sparse, measures Capone *et al.* (1997) estimated the average N_2 fixation rate for the tropical oceans to be 106 μmol N m^{-2} day^{-1} (0.039 mol N m^{-2} year^{-1}) and tabulated measurements from the Atlantic showing a range of 1.4–278 μmol N m^{-2} day^{-1} (0.050–0.10 mol N m^{-2} year^{-1} if extrapolated), with the highest rate located in the Caribbean Sea. Capone *et al.* (2005) conducted an extensive survey of N_2 fixation by *Trichodesmium* in the North Atlantic and conservatively estimated a basin-wide rate of 1.6×10^{12} mol N; a rate in general

agreement with the Gruber and Sarmiento (1997) estimate but larger than that of Hansell *et al.* (2004, 2007). Estimates of N_2 fixation in the western tropical North Atlantic have also been made after combining remote sensing and modeling techniques (Coles *et al.*, 2004b), resulting in a rate of 220 µmol N m^{-2} day^{-1}.

There are intriguing DIN_{xs} features in the eastern tropical South Atlantic (Fig. 13.11) that suggest N_2 fixation, but that are, as yet, unsubstantiated. Coincident with the enrichment of nitrate on the σ_θ 26.8 surface along the western Africa coast (Fig. 13.11A) is an elevation of DIN_{xs}, (Fig. 13.11B) with values of –1 µM near the coast, though the source waters (SE South Atlantic) typically show $DIN_{xs} \sim -3$ µM. This coastal region is known for its strong upwelling and, therefore, nutrient inputs, so it seems an unlikely candidate for strong N_2 fixation. Hood *et al.* (2004) employed a coupled biological/physical model, with explicit representation of *Trichodesmium*, which consistently suggested possible high and persistent *Trichodesmium* spp. concentrations in the Gulf of Guinea, off the west coast of Africa.
Figure 13.11 South Atlantic distributions of (A) nitrate (µmol kg^{-1}) and (B) DIN_{xs} (µmol kg^{-1}) on σ_θ surface 26.8. Data collected in the South Atlantic Ventilation Experiment (SAVE) project. Dots are station locations.

It is also probable that N and P are not remineralized in Redfield proportion. Some organisms may directly utilize DOP as a source of phosphorus and there may be preferential remineralization by bacteria (Wu *et al.*, 2000). Perhaps processes such as differential remineralization of N and P in sinking particles are significant here and the attribution of DIN_{xs} to N_2 fixation alone should be reconsidered. This highlights the issue that the evaluation of nitrogen fixation rates from geochemical evidence is not simple since a number of processes can affect the DIN_{xs} ($N^\star$) signals (Gruber, 2004) and because of uncertainties in ventilation time scales. Denitrification will also have a direct impact on the N:P ratio (e.g., Deutsch *et al.*, 2001, 2007), though it is expected that denitrification is more significant over the shelves than in the interior of the Atlantic, which is generally well oxygenated.

3.3. Atmospheric deposition and possible contribution to excess nitrate

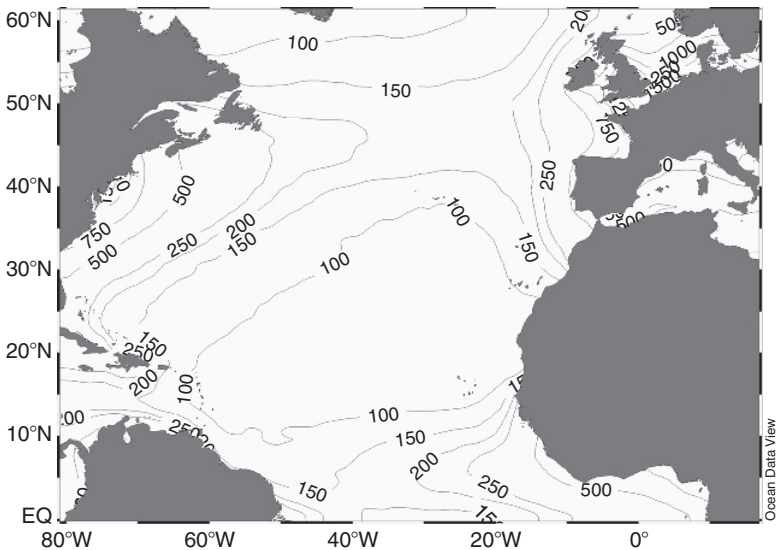
New nitrogen is also introduced to the Atlantic through wet and dry atmospheric deposition (Baker *et al.*, 2003; Spokes *et al.*, 2000). Nitrogen emitted to the atmosphere in the northeastern United States moves downwind for deposition to the mid-latitudes of the North Atlantic, while material emitted from equatorial Africa is transported to the low latitudes of the Atlantic (Fig. 13.12; Galloway *et al.*, 2004). Duce *et al.* (1991) estimated input of 0.6×10^{12} mol N year^{-1} for the total North Atlantic and 0.3×10^{12} mol N year^{-1} for the subtropical and tropical North Atlantic alone. Similarly, Prospero *et al.* (1996) estimated N added by deposition to


Figure 13.12 Modeled nitrogen deposition (sum of NOy and NHx; mg N m^{-2} year^{-1}) to the North Atlantic in the year 1990. These are net rates as they are corrected for the emissions of NH_3 from the oceans. Data adapted from Dentener *et al.* (2006).

the entire North Atlantic of 0.6×10^{12} mol N year^{-1}. Galloway *et al.* (2004) modeled the deposition of N to the North Atlantic, finding a rate of 0.8×10^{12} mol N year^{-1}. These values lie between the rates of excess N accumulation given by Gruber and Sarmiento (1997) and by Hansell *et al.* (2004) (Table 13.2), suggesting that deposition from the atmosphere has to be considered in the geochemical budget for excess N accumulation in the thermocline. Net input by atmospheric deposition to the South Atlantic is smaller at 0.15×10^{12} mol N year^{-1} (Galloway *et al.*, 2004).

Deposition of both inorganic and organic forms of nitrogen is of interest (Cornell *et al.*, 1995), since both are available as nutrients that can increase new and export production, though far fewer data exist for organic N. Wet deposition (during precipitation events) is readily measurable, but the contribution from dry deposition has been more difficult to quantify. Russell *et al.* (2003) reported that 43% of total N deposition on the US coast is dry, while Rendell *et al.* (1993) found a similar fraction in the North Sea. The greatest deposition rates occur in waters adjacent to the continents, particularly where anthropogenic influences are greatest (Paerl *et al.*, 2002), and decreases into the ocean interior. Much of the DON deposited is biologically labile and thus available to phytoplankton (Scudlark *et al.*, 1998; Seitzinger and Sanders, 1999), but the low fluxes have relatively little direct impact on the open ocean biota (Knap *et al.*, 1986; Michaels *et al.*, 1993).

In considering the characteristics of nutrients deposited to the ocean, it becomes clear that N_2 fixation is not the only process that (1) leads to the accumulation of "excess N" in the upper thermocline (that is, the nutrients regenerated there have high N:P ratios), (2) introduces excess N with low δ^{15}N values, (3) has seasonality such that it would cause a summertime drawdown of surface layer CO_2 in extremely oligotrophic conditions, and (4) occurs in regions of high atmospheric inputs of material such as dust. The existence of high N:P signatures in the North Atlantic thermocline has been ascribed to N_2 fixation, yet the deposition of nutrients from the atmosphere also occurs with elevated N:P ratios (ratios of 50–100 are common, with some ratios >1000 in dry deposition; Baker *et al.*, 2003). The low δ^{15}N values found in organic matter in the North Atlantic have been assigned to N_2 fixation (which produces organic matter with δ^{15}N values <0‰; Carpenter *et al.*, 1997), yet N added by deposition has low δ^{15}N values as well (Hastings *et al.*, 2003; Paerl and Fogel, 1994; exceptions have been reported where values >8‰ have been reported for N of an African source, Swap *et al.*, 1996). Drawdown of CO_2 during oligotrophic periods could be due to N_2 fixation (Lee *et al.*, 2002) driven by Fe inputs, but along with the heavy input of iron is a load of macronutrients that need to be considered (e.g., Herut *et al.*, 2002; Krom *et al.*, 2004).

Since the atmospheric deposition of nutrients could result in the same biogeochemical features as presently ascribed to N_2 fixation, dissecting the contribution each makes to the tracers we now ascribe to N_2 fixation should be a priority (Hansell *et al.*, 2007). Interestingly, where DIN_{xs} grow-out in the thermocline is greatest (15–30°N in the eastern Atlantic, according to the analysis of Hansell *et al.*, 2004), deposition of N is relatively low. But *Trichodesmium* biomass is low there as well (Tyrrell *et al.*, 2003). The highest atmospheric inputs in the mid- to low-latitude North Atlantic are in the tropics (Galloway *et al.*, 2004), where N_2 fixation may be high (Capone *et al.*, 1997; Tyrrell *et al.*, 2003), so separating these inputs may prove difficult.

4. DENITRIFICATION

Denitrification in the Atlantic Ocean is not as well studied as N_2 fixation, but it is the most important N sink in the basin. The shelves are important sites for this sink (Christensen *et al.*, 1987; Laursen and Seitzinger, 2002), though denitrification appears to make a very small contribution to total organic matter oxidation on the continental margin of the NW Atlantic (Martin and Sayles, 2004). Denitrification on the shelves exceeds the combined N inputs by rivers and atmospheric deposition, thus requiring that the deficit be balanced by the influx of nitrate from the open ocean (Seitzinger and Giblin, 1996; see N budget for the North Atlantic below).

Seitzinger and Giblin (1996) used data from a wide range of continental shelf regions to establish the relationship between denitrification and sedimentary oxygen consumption rates, and also to establish the relationship between primary production and sediment oxygen consumption. Combining these relationships resulted in a predictive correlation between shelf denitrification and local primary production rates. They suggested that 13% of N consumed by phytoplankton in shelf waters is eventually lost to denitrification in the sediments. The model predicted the average denitrification rate for the North Atlantic shelves to be 0.69 mmol N m^{-2} day^{-1}, for a total shelf N loss in the basin of 143×10^{10} mol N year^{-1} ($\approx 0.7 \times 10^{12}$ mol N year^{-1}, comparable to the estimates of basin-wide nitrogen fixation). Denitrification rates over the shelves were highest at mid-latitudes and lowest at high latitudes. Twice the N removal occurs in the western shelves than in the eastern shelves.

Studies evaluating denitrification in the South Atlantic are few. Dittmar and Birkicht (2001) evaluated nutrient distributions from on- to off-shore of Namibia, and found decreasing N/P and N/Si ratios with distance away from the upwelling zones. They suggested that these changes indicate considerable N losses in the region, with the low oxygen waters present likely favoring denitrification. As for the deep basin, Bender *et al.* (1977) evaluated pore water distributions of nutrients in pelagic sediments in the eastern equatorial Atlantic, suggesting that these sediments should not be dismissed as important sites of denitrification.

5. THE ATLANTIC AS A SOURCE OF NITROGEN TO THE ATMOSPHERE

Some important atmospheric nitrogen compounds have biogenic sources in the ocean; most significantly N_2O and, to a lesser extent, alkyl nitrates. N_2O has 200–300 times the greenhouse warming effect of CO_2, and it is an intermediate in the destruction of stratospheric ozone and a source of tropospheric ozone (Delwiche, 1981). It is supersaturated in the surface waters of the equatorial Atlantic (Oudot *et al.*, 1990, 2002) and the Caribbean (Morell *et al.*, 2001), and thus a source to the atmosphere. In these waters it is most likely a by product of nitrification (Oudot *et al.*, 1990). Nevison *et al.* (2003) estimated a global release of 0.3×10^{12} mol N year^{-1} as N_2O, a small fraction of the Gruber and Sarmiento (1997) estimate

of global pelagic N_2 fixation (8×10^{12} mol N year^{-1}), an important source to balance this atmospheric sink. Water column N_2O production and loss to the atmosphere is thus more important in terms of atmospheric nitrogen cycling than as a sink for oceanic nitrogen.

Methyl and ethyl nitrates play a role in regulating tropospheric ozone levels in remote marine regions. These alkyl nitrates are reservoir species for NO_x ($= NO_2 +$ NO), while photolysis of NO_2 is the mechanism for producing ozone in the troposphere. Sources of alkyl nitrates, including the ocean, are under investigation. Like N_2O, nitrate-enriched equatorial waters are an important site of formation and export (Chuck *et al.*, 2002). Little work has been done on understanding the mechanisms of production or controls in the ocean, though biological processes may be invoked with methyl nitrate being found to depths of 800 m, with surface enhancement (Moore and Blough, 2002).

6. Is the Atlantic a Source of Nitrogen to the Global Ocean?

Is the Atlantic a net source or sink of nitrogen to the global ocean? This question is difficult to answer, especially in light of the scarcity of relevant studies in the South Atlantic and given the difficulties of accurately determining net meridional transports in the basins. Ganachaud and Wunsch (2002), using hydrographic data, estimated a net southward flux in the South Atlantic (30°S) of about 1×10^{12} mol N year^{-1} to indicate a net loss from the basin, though they did not account for transport of dissolved organic nitrogen. The North Atlantic has been more intensively studied, documented and evaluated (Howarth, 1996). Contributions to the North Atlantic nitrogen budget have been estimated for atmospheric deposition (Prospero *et al.*, 1996), riverine fluxes (Howarth *et al.*, 1996), N in the land–sea margin (Nixon *et al.*, 1996), transformations within the open ocean (Michaels *et al.*, 1996), shelf sediment denitrification (Seitzinger and Giblin, 1996), N_2 fixation (Lipschultz and Owens, 1996; Michaels *et al.*, 1996), and air/sea exchange of ammonia (Quinn *et al.*, 1996). These flux estimates were summarized by Galloway *et al.* (1996), and it is a modification of that budget that we discuss here. Significant uncertainties in the sources, sinks and fluxes prevent an accurate nitrogen budget assessment for the North Atlantic. The exercise is informative nonetheless, providing an indication of the relative contributions from each of these processes and an indication of where additional study is required.

Figure 13.13 illustrates the major fluxes across the boundaries of the basin, as well as sinks (denitrification) and new sources (N_2 fixation) of reactive N. The important physical reservoirs included in the budget are estuaries, continental shelves, and the open ocean, each undergoing additions and removals of N by various mechanisms. The estuaries receive N from rivers (540×10^9 mol year^{-1}), about half of which (250×10^9 mol year^{-1}) is lost from the system via denitrification (Seitzinger, 1988). The bulk of the remainder passes through the system to the shelves, with a small amount lost to the estuarine sediments. Major rivers do not have the conditions
Figure 13.13 Nitrogen budget for the North Atlantic, modified from Galloway *et al.* (1996), demonstrating the major fluxes ($\times 10^9$ mol year^{-1}) across the boundaries of the basin as well as sinks (denitrification) and new sources (nitrogen fixation; nitrogen deposition (N dep.)) of reactive N. Fluxes into the major physical realms of the North Atlantic (open ocean, shelf waters, and estuaries) are highlighted by diagonal-line fills; loss terms and exchange fluxes between realms are indicated by open arrows.

(e.g., long residence time, quiescent environments) necessary to lose much N by denitrification in their estuaries or by delta burial, so most of this fluvial N is passed to the shelf systems.

The continental shelves receive N from the open ocean (820×10^9 mol year^{-1}), from estuaries (250×10^9 mol year^{-1}), from major rivers (350×10^9 mol year^{-1}) and from atmospheric deposition (130×10^9 mol year^{-1}). Some is lost to the sediments (120×10^9 mol year^{-1}) and fish catch (32×10^9 mol year^{-1}), but the majority is removed from the system via sedimentary denitrification (1400×10^9 mol year^{-1}). Nitrogen introduced to the shelves from the open ocean appears to contribute the most to shelf denitrification (Seitzinger and Giblin, 1996).

On balance, the shelves are not a net source of N to the open ocean. Instead, the North Atlantic has major exchanges with the Arctic Ocean and with the South Atlantic. Ganachaud and Wunsch (2002) estimate southerly nitrate fluxes of 2200 ($+/-$ 3800) and 6600 ($+/-$ 4700) $\times 10^9$ mol N year^{-1} at 7.5°N and 4.5°S, respectively. We take their mid point value of 4400 ($+/-$ 4000) $\times 10^9$ mol N year^{-1} as the net transport of nitrate from the North Atlantic to the South Atlantic. A significant uncertainty lies in the net meridional transport of DON in the basin-wide N transport budgets in the Atlantic. Rintoul and Wunsch (1991) speculated that the imbalance they quantified in the poleward nitrate flux across subtropical sections may be compensated by unobserved fluxes of organic nitrogen. DON measurements are still too sparse and too imprecise to test this hypothesis.

The nitrate flux from the Arctic to the Atlantic was estimated by Galloway *et al.* (1996) as 1500×10^9 mol year^{-1}, with most of the nitrate due to Pacific water

passing through Bering Strait, and loss to denitrification in Arctic shelf sediments. This value is also highly uncertain. Ganachaud and Wunsch (2002) estimated a net northward nitrate flux of 300 $(+/- 1050) \times 10^9$ mol year^{-1} at 47°N while Martel and Wunsch (1993) reported a net southward flux of 1800×10^9 mol year^{-1} at 60°N. Hence the direction and magnitude of the flux between the Arctic and the Atlantic remain unknown, so we retain the value from Galloway et al. (1996) in the present budget (Fig. 13.13).

The input from N$_2$ fixation in the North Atlantic was taken to be 5000×10^9 mol year^{-1} by Galloway et al. (1996). More recent work now suggests a lesser value, so that input term in Fig. 13.13 has been reduced to the larger range resulting from Gruber and Sarmiento (1997) and Hansell et al. (2004). Addition of nitrogen by atmospheric deposition, taken from Michaels et al. (1996) and Prospero et al. (1996), remains unchanged from Galloway et al. (1996).

The budget for the open North Atlantic, as presented in Fig. 13.13, is out of balance, with export of nitrogen from the open North Atlantic (to the sediments, to the South Atlantic, and to the shelves; totaling $\approx 5300 \times 10^9$ mol N year^{-1}) exceeding the import of $2500–4200 \times 10^9$ mol year^{-1}. However the two net fluxes are likely not distinguishable given the very large uncertainties associated with the flux estimates summarized here. Too few data exist at present to draw up a similar budget for the South Atlantic.

7. Key Unresolved Issues

The Atlantic basin, particularly the North Atlantic, is the most studied of the global oceans, yet there are several important processes and issues remaining to be addressed. Arguably, the most important issue is the paucity of data from the South Atlantic. There have been excellent expeditionary efforts there (i.e., the WOCE sections and the South Atlantic Ventilation Experiment), so the hydrographic system and the nutrient provinces can now be assessed in greater detail. However there has been little focus on processes of the nitrogen cycle in the basin.

Second, nitrogen fixation remains a poorly quantified process: We need to better understand the relationship of the excess nitrate signals in the thermocline to nitrogen sources and sinks, and the role of physical transport, in order to determine if those signals truly (and primarily) represent N$_2$ fixation in the overlying waters. There are large differences in the published estimates of N$_2$ fixation in the North Atlantic.

Third, temporal variability in nitrogen is poorly quantified. The time series stations are helpful but they are too few. Decadal re-occupation of most ocean sections (such as A16) is too infrequent to resolve the processes forcing change.

Finally, precise estimations of meridional transports provide powerful constraints of the basin scale nitrogen budgets. To provide better constraints, we require zonal sections including appropriately dense observations of the organic forms of dissolved nitrogen (measured at higher precision than now possible) to be used in quantification of the meridional transport of nitrogen.

THE INDIAN OCEAN

S. Wajih A. Naqvi

Contents

1. INTRODUCTION AND BACKGROUND

The first major scientific expedition to the Indian Ocean (Arabian Sea)—the John Murray Expedition—was undertaken in 1933–1934 using the Egyptian vessel *Mabahiss*. It was on this expedition that the thickest oxygen (O_2) deficient zone (ODZ) in the open-ocean was first discovered (Sewell and Fage, 1948) and nitrogen cycling investigated in considerable detail (Gilson, 1937). Subsequently, during the International Indian Ocean Expedition (IIOE, 1962–1965) extensive measurements of nutrients including nitrate (NO_3^-), and in some cases nitrite (NO_2^-), were made; these data were utilized mainly to interpret variations in primary productivity (PP) (e.g., Ryther *et al.*, 1966) or to prepare large-scale maps and sections of NO_3^- (Wyrtki, 1971). It was not until the 1970s that systematic efforts were made again by Sen Gupta and coworkers (e.g., Sen Gupta *et al.*, 1976) to investigate nitrogen cycle processes in the region. A number of studies have since been conducted, but the

majority of them have focused on the northwestern Indian Ocean simply because the most significant processes are by and large confined to this region. Results of these investigations have been reviewed from time to time (Bange *et al.*, 2005; Naqvi, 2001; Naqvi *et al.*, 1992; Sen Gupta and Naqvi, 1984). Benefiting from the excellent data sets that have been made available more recently by the Joint Global Ocean Flux Study (JGOFS) and the World Ocean Circulation Experiment (WOCE) from various geographical areas, this chapter takes a broader view of the nitrogen cycle in the Indian Ocean, highlighting the newer findings and outstanding issues.

There are two unique aspects of geography of the Indian Ocean that profoundly influence its climate and circulation: (a) The Indian Ocean's northern expanse is curtailed by the Eurasian landmass around the Tropic of Cancer (making it the only ocean that is cut off from temperate and polar areas of the Northern Hemisphere), and (b) The Indian Ocean is connected to the Pacific through the Indonesian Archipelago (the only low latitude inter-ocean connection on the planet). The resultant surface circulation divides this ocean into three parts (Wyrtki, 1973): (a) the monsoon gyre, (b) the southern subtropical gyre, and (c) the Antarctic waters with the Circumpolar Current. Surface circulation patterns in the two southern parts do not show any major deviation from those observed in other oceans with the exception of a seasonally-variable poleward surface flow (the Leeuwin Current) and the associated equatorward undercurrent off western Australia. What really differentiates the Indian Ocean from the Atlantic and the Pacific is the unique circulation of its monsoon gyre.

A discontinuity in physicochemical characteristics around Lat. 10°S, called the Hydrochemical Front, marks the boundary between the monsoon gyre and the southern subtropical gyre. This discontinuity is maintained by the unidirectional, perennial flow of the South Equatorial Current (SEC) from the east to the west. The zonal flow of the SEC and related restriction of cross-equatorial exchange of thermocline waters to the western region play a key role in determining O_2 distribution and therefore biogeochemical cycling of nitrogen in the North Indian Ocean (Swallow, 1984; Warren, 1994). Embedded in the SEC is the Indonesian Throughflow (ITF) which is derived from the Pacific Ocean and is carried eastward all across the Indian Ocean and then to the south by the western boundary (the Mozambique and the Agulhas) currents to be transferred eventually to the Atlantic Ocean. This inter-ocean exchange forms a part of the global conveyor belt circulation (Gordon, 1985), and it affects regional climate and rainfall, particularly across Indonesia and Australia. The ITF is also believed to be responsible for setting up the anomalous circulation off western Australia referred to above (Schott and McCreary, 2001).

The differential heating and cooling of air over land and sea forces semi-annual reversals of winds and surface currents north of the Hydrochemical Front. Surface currents flow generally clockwise during the summer or southwest monsoon (SWM; June-September) and anticlockwise during the winter or northeast monsoon (NEM; December-March) in both the northwestern (the Arabian Sea including the Laccadive Sea) and the northeastern (the Bay of Bengal including the Andaman Sea) basins. However, the two basins are disparately affected by the monsoons.

The SWM winds are stronger in the Arabian Sea leading to the development of a very strong western boundary flow (the Somali Current) and vigorous upwelling off the coasts of Somalia, Yemen and Oman (Schott and McCreary, 2001). A notable feature of circulation in the region during the SWM is the persistence of several meso-scale eddies that account for the bulk of the kinetic energy (Flagg and Kim, 1998). While moderate upwelling also occurs along the west coast of India during this season (Banse, 1959, 1968), this process is much less intense in the Bay of Bengal (Shetye et al., 1991). On the other hand, the Bay of Bengal receives far greater freshwater inputs through both precipitation and river runoff as compared to the Arabian Sea. In fact, about half of the total runoff in the entire Indian Ocean occurs in the northeastern Indian Ocean (Dai and Trenberth, 2002). Consequently, the water balance (precipitation + runoff − evaporation) is highly negative in the northwestern Arabian Sea and highly positive in the northeastern Bay of Bengal. The latter results in a very strong thermohaline stratification that severely inhibits vertical mixing. This is why the Bay of Bengal does not experience convective mixing in spite of substantial sea surface cooling during winter in contrast with the Arabian Sea where winter convection occurs over a very large area extending as far south as Lat. 10°N off the African coast (Naqvi et al., 2006a).

There is yet another geography-related factor that differentiates the hydrographies of the northwestern and northeastern sectors of the Indian Ocean. The Arabian Sea is connected to two Mediterranean-type marginal seas - the Red Sea and the Persian Gulf. Warm, saline waters produced in these seas flow out and spread into the Arabian Sea with their core layers at ∼250 and 500 m (Wyrtki, 1971). The O_2 supply by these waters is quite modest, but they contribute substantially to water mass structure and facilitate the O_2-depleted North Indian Intermediate water to occupy a larger volume in the Arabian Sea as compared to the Bay of Bengal, which does not receive such outflows. As discussed in Sect. 3.2.1, this has important implications for the O_2 balance and nitrogen cycling.

2. General Distribution of Water Column Properties

2.1. Nitrate and oxygen

In order to investigate basin-scale distributions (north-south and east-west variabilities) of NO_3^-, by far the most abundant combined nitrogen species in seawater, and O_2 (a key variable controlling nitrogen biogeochemistry), vertical sections of these properties along WOCE Lines I09N and I08S (Fig. 14.1) and I03 (Fig. 14.2) are examined here (Schlitzer, 2000; additional sections are available at http://www.awi-bremerhaven.de/GEO/eWOCE/). These are supplemented with NO_3^- data from a few other regions (Figs. 14.3–14.5).

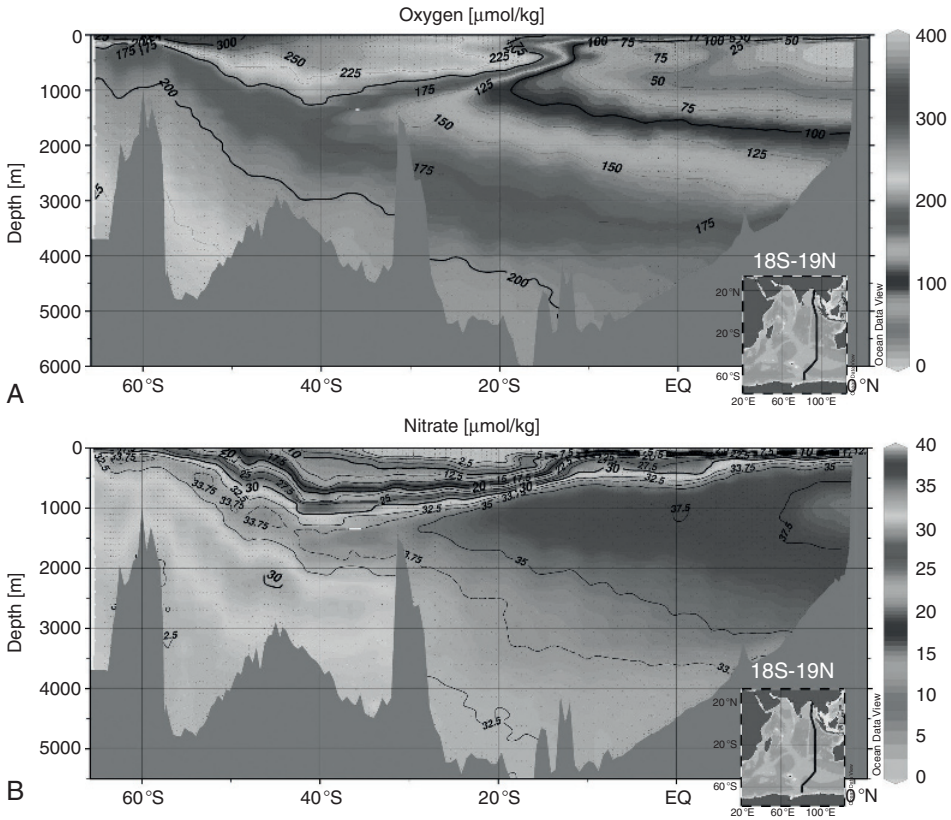
Within the main thermocline, relatively low-NO_3^- waters of the southern subtropical gyre are separated from those rich in NO_3^- in the monsoon gyre to the north and the sub-Antarctic zone to the south by the Hydrochemical Front and the Subtropical Convergence (STC), respectively (Fig. 14.1B). The maximum in NO_3^- generally occurs in the 1–2 km depth range north of the STC, and at


Figure 14.1 Vertical sections of (A) dissolved O_2 (upper panel) and (B) NO_3^- (lower panel), extending from Antarctica to Myanmar, constructed using data from WOCE Legs I08S and I09N. The combined transect is shown in the insets (http://www.awi-bremerhaven.de/GEO/eWOCE/).

progressively shallower depths to the south of this feature. This maximum, which intensifies northward, usually coincides with the maximum in the apparent oxygen utilization (AOU, not shown). South of the Hydrochemical Front, the NO_3^- maximum also coincides with the deep O_2 minimum, but to the north of this discontinuity, as O_2 concentrations fall rapidly and the two O_2 minima merge to form a broad, intense ODZ with its core at $\sim$200–300 m (Fig. 14.1A), the AOU maximum and O_2 minimum are vertically separated. Distributions of O_2 and NO_3^- in the upper few hundred meters in the northwestern Indian Ocean (Fig. 14.3; also see WOCE I07 sections; Schlitzer, 2000) show some important differences from the pattern described above in that in the former region, O_2 deficiency is more severe and widespread, and a pronounced minimum in NO_3^-, dealt with in detail in Sect. 3.2.1, occurs within the core of the ODZ (at $\sim$200–300 m).

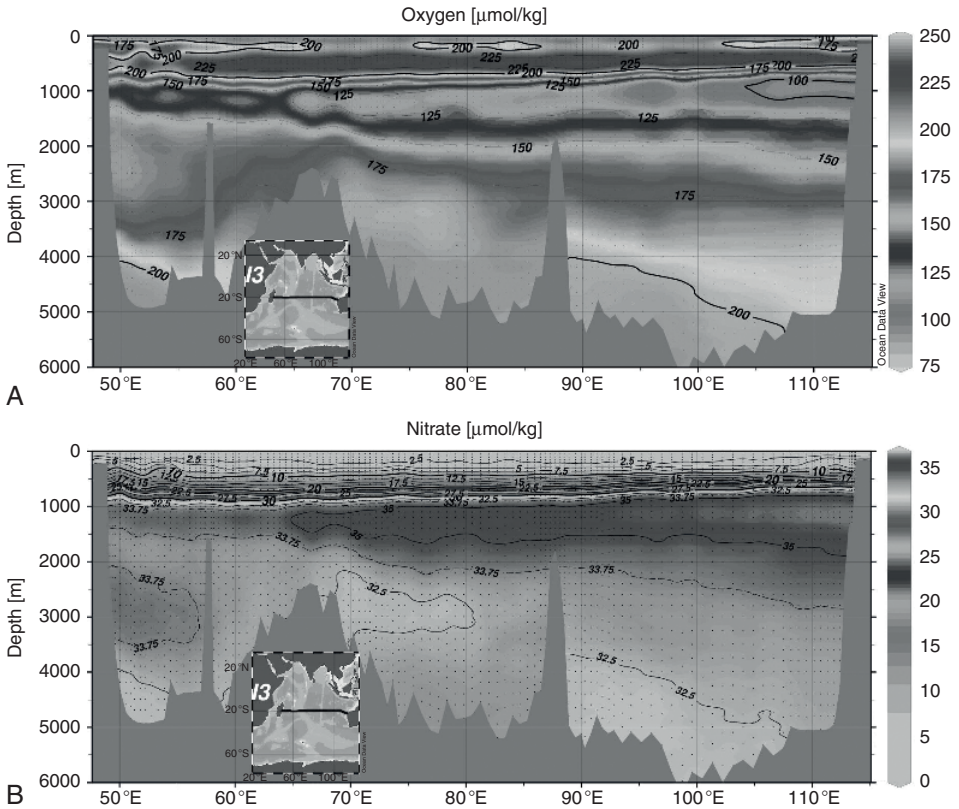
At the sea surface, NO_3^- concentrations are below the limit of detection (<0.1 μM) in most areas including the equatorial Indian Ocean, which does not experience


Figure 14.2 Vertical sections of (A) dissolved O_2 (upper panel) and (B) NO_3^- (lower panel), extending from Madagascar to Australia, along the WOCE Leg I03 (shown in the insets) (http://www.awi-bremerhaven.de/GEO/eWOCE/).

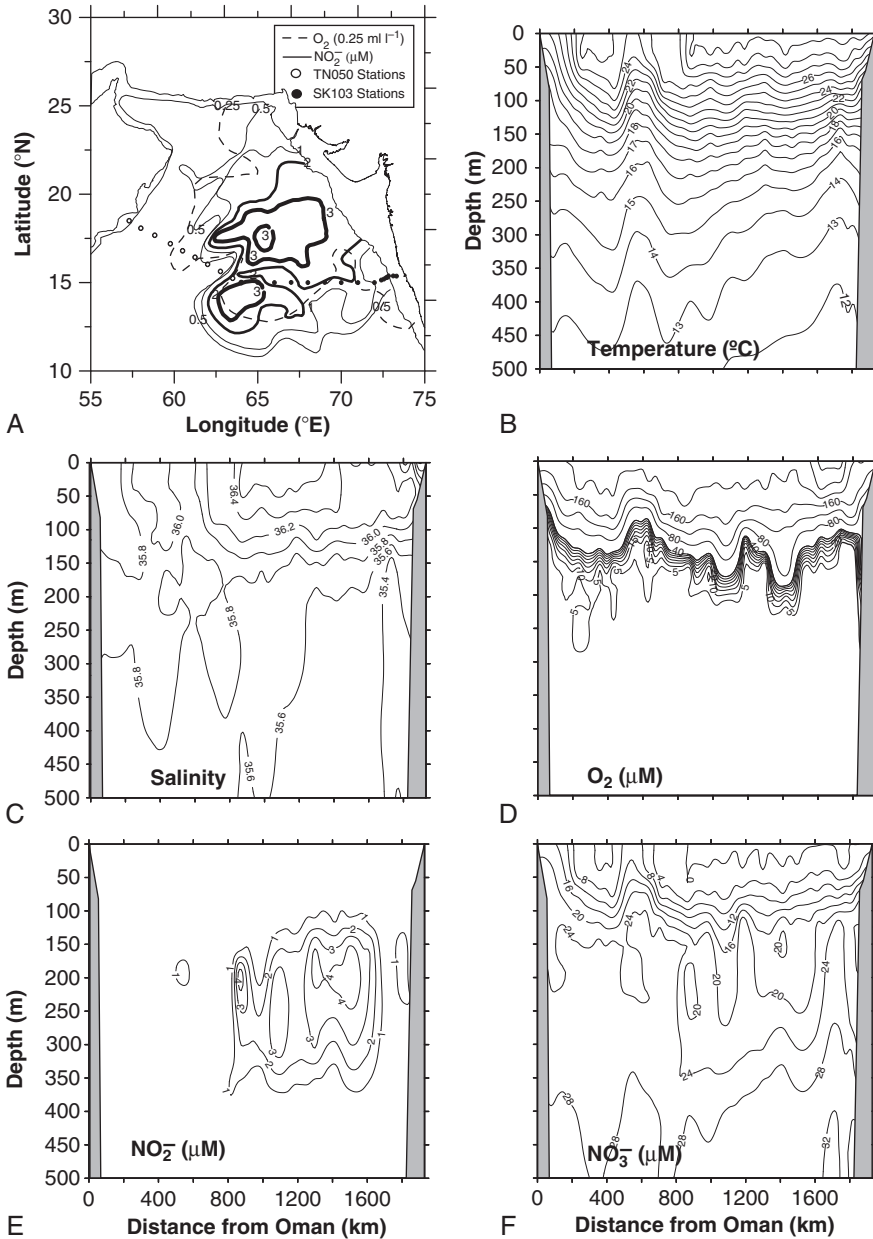
much upwelling. Surface waters are, as usual, NO_3^-–replete south of the STC (Fig. 14.1B), and also in the upwelling zones (e.g. Fig. 14.3F), most of which are found in the Arabian Sea. NO_3^- concentrations in the freshly-upwelled waters frequently exceed 15 μM off Somalia (Smith and Codispoti, 1980), Yemen (van Weering et al., 1997) and Oman (Fig. 14.3f; Morrison et al., 1998; Woodward et al., 1999). After upwelling these waters spread several hundreds of kilometers offshore as filaments and plumes, enriching the euphotic zone with essential nutrients over a very large area (Fig. 14.3F) thereby supporting widespread phytoplankton blooms as revealed by satellite-derived ocean color images (Banse and English, 2000; Wiggert et al., 2005, and references therein). Fertilization of comparable magnitude also occurs along the west coast of India, albeit within a much narrower coastal belt (Fig. 14.3F; Jayakumar et al., 2001; Naqvi et al., 1998a; 2000; 2006a). Moreover, as mentioned earlier, the Arabian Sea experiences convective mixing during winter that raises the surface dissolved inorganic nitrogen (DIN = NO_3^- + NO_2^- + ammonium (NH_4^+)) level to 6 μM (Fig. 14.3; Morrison et al., 1998; Naqvi et al.,


Figure 14.3 Vertical sections of (B) temperature, (C) salinity, (D) O_2, (E) NO_2^- and (F) NO_3^-, extending from Oman to India, constructed using data collected by the Research Vessels *Sagar Kanya* and *Thomas G. Thompson* during June–September, 1995. Locations of stations comprising the section are shown in (A) with reference to the secondary nitrite maximum zone (after Naqvi, 1991) and the zone of minimum (Winkler) O_2 at 300 m as demarcated by the 0.25 ml L^{-1} contour (dotted curve) (Wyrtki, 1971).
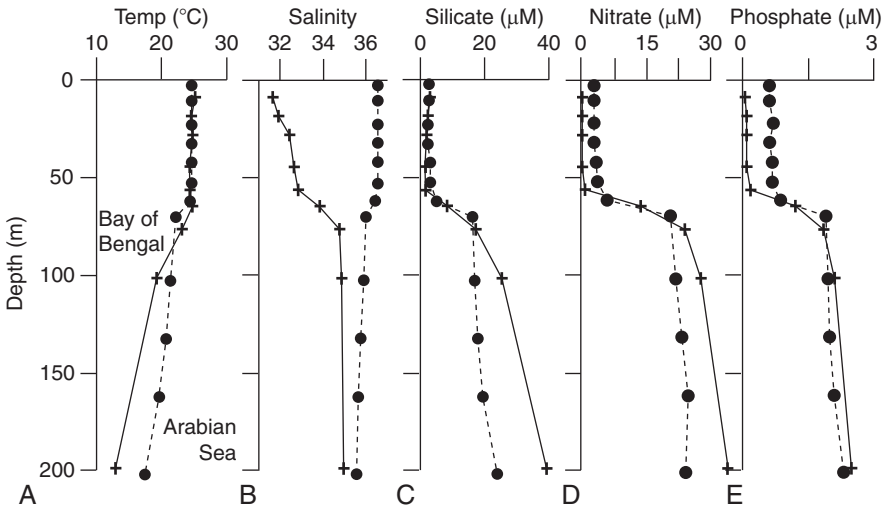

Figure 14.4 Comparison of vertical profiles of (A) temperature, (B) salinity, (C) silicate, (D) nitrate and (E) phosphate in the upper 200 m at one site each in the Arabian Sea (19.17°N, 67.17°E; US JGOFS Cruise TN043; sampling date 13/01/1995) and the Bay of Bengal (19.11°N, 92.65°E; WOCE Leg I09N; sampling date 24/02/1995).

2002). Together these processes maintain high rates of PP over much of the Arabian Sea during a large part of the year (Barber *et al.*, 2001).

Nutrient reflux to surface waters from the thermocline in the Bay of Bengal is limited by the previously mentioned weak upwelling and subdued vertical mixing. Also, the riverine flux of dissolved nutrients (except silicate) into the northeast Indian Ocean is quite modest (Rao *et al.*, 1994; Naqvi *et al.*, in press). This is reflected by an overall nutrient depletion in the surface layer (Fig. 14.4) and accordingly lower biological productivity of the Bay of Bengal relative to the Arabian Sea as revealed by field measurements (Gomes *et al.*, 2000; Qasim, 1977) as well as satellite–based observations (Gomes *et al.*, 2000; Naqvi *et al.*, 2006a). The latter show striking differences in surface chlorophyll concentrations between the two regions including the lack of winter-spring phytoplankton blooms in the Bay of Bengal, except in its southwestern sector (Vinayachandran and Mathew, 2003), unlike the dense blooms occurring in the northern Arabian Sea (Banse and McClain, 1986; Naqvi *et al.*, 2006a; Wiggert *et al.*, 2002; 2005).

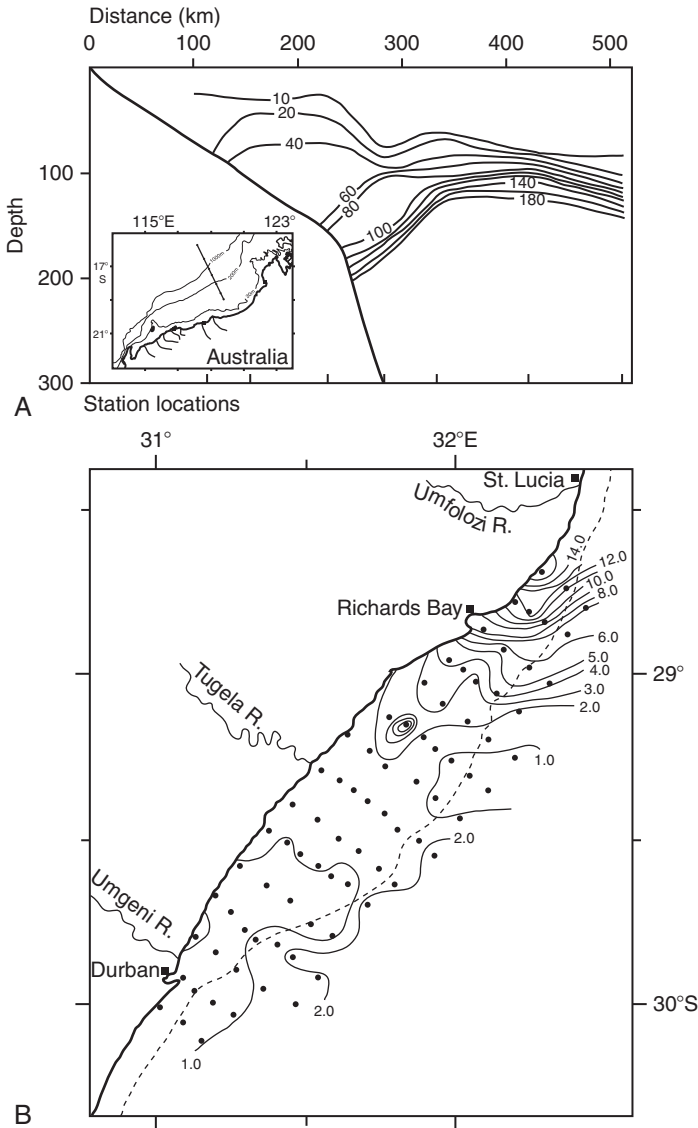
Zonal sections through the southern subtropical gyre at about Lat. 20°S show a trend of eastward intensification of the O_2 minimum and its associated NO_3^- maximum (Fig. 14.2). However, the east-west gradients in both properties are much weaker than the north-south gradients across the Hydrochemical Front; for example, the lowest O_2 concentration along I03 is >90 μM as compared to <5 μM along I07 (not shown; but see Fig. 14.6). Even the modest intensification of the O_2 minimum in the eastern tropical South Indian Ocean is most likely related to relatively poor ventilation rather than an enhanced O_2 demand, a major factor for the acute O_2 depletion in the North Indian Ocean (Sen Gupta and Naqvi, 1984).


Figure 14.5 (A) Vertical section of NO_3^- (in $\mu g\,L^{-1}$; $10\,\mu g\,L^{-1} = 0.714\,\mu M$) off Northwest Australia based on observations in August 1976 (from Holloway *et al.*, 1985). (B) Distribution of NO_3^- (μM) at 10 m over the Natal Bight, east coast of South Africa during July 1989 (from Lutjeharms, 2006).

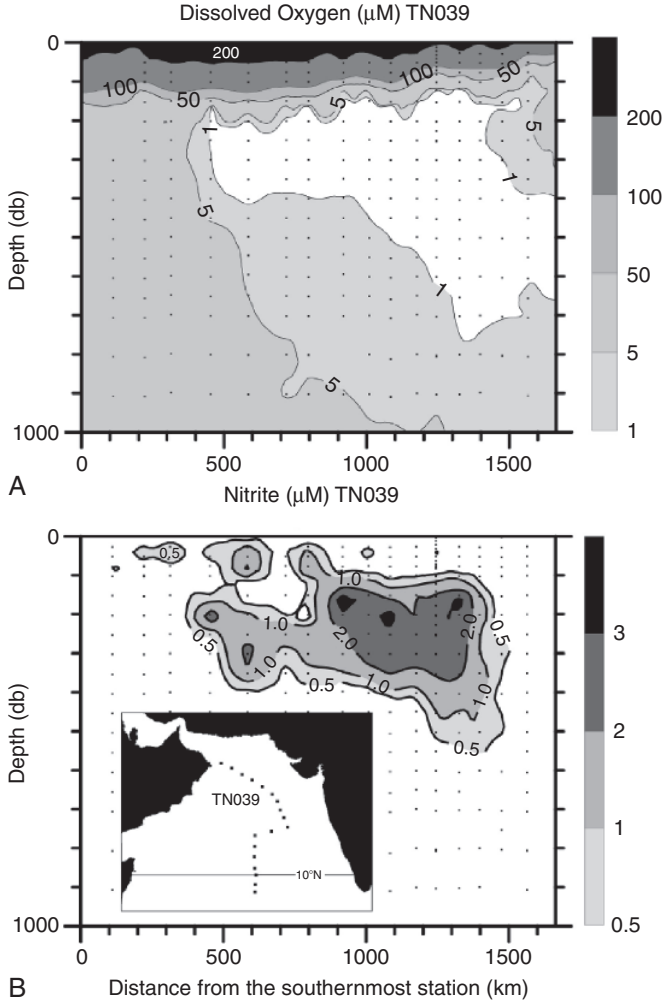
This is because unlike the North Indian Ocean the eastern tropical South Indian Ocean is not very productive due to its atypical, upwelling–unfavorable circulation. If there were no deep passages through the Indonesian islands linking the Pacific and the Indian Oceans, the west coast of Australia would probably host an eastern-boundary upwelling environment with associated severe O_2 deficiency and vigorous nitrogen transformations similar to what one finds in the ocean off Peru–Chile today.


Figure 14.6 Vertical sections of (A) dissolved O_2 (µM) and (B) NO_2^- (µM) in the Arabian Sea based on observations in October, 1994. Station locations are shown in the inset (from Codispoti *et al.*, 2001).

Notwithstanding some localized upwelling during summer due to weakening of the Leeuwin Current, coastal waters off western Australia are among the most oligotrophic found along the oceans' eastern boundaries (Fig. 14.5a; also see Condie and Harris, 2006). Feng and Wild-Allen (in press) proposed a nitrogen budget for the continental shelf off the west coast of Australia according to which DIN inputs from terrestrial sources are quite small ($\sim 9 \times 10^9$ g year^{-1}) as is the annually-integrated rate of N_2-fixation ($\sim 7 \times 10^9$ g). DIN (largely NO_3^-) fluxes from the open ocean through upwelling (1.2×10^{11} g year^{-1}) and advection by the Leeuwin Current (1.4×10^{11} g year^{-1}) are an order of magnitude higher, but still

lower than the estimated supply from the seafloor (6.2×10^{11} g year^{-1}). Thus, the internal cycling seems to dominate nitrogen budget and supports an estimated mean primary production of $\sim$110 gC m^{-2} year^{-1} over this shelf. Episodic events (tropical cyclones) probably play an important role in supplying new nitrogen to the water column largely through entrainment of DIN from the sediments (Feng and Wild-Allen, in press; Holloway et al., 1985).

Farther north, moderate upwelling has been known to occur seasonally (during the southeast monsoon) along the southern coasts of Sumatra and Java (Susanto et al., 2001; Wyrtki, 1962), but still on a far smaller scale than in the Arabian Sea. Unfortunately, little is known about the biogeochemical processes along this coastal segment.

In the southeastern Indian Ocean, containing the only typical boundary environment in the Indian Ocean, topographically-induced upwelling occurs at several places over the continental shelf landward of the Agulhas Current which flows along the shelf break. In two such cells of intense, persistent upwelling found north of the Richards Bay in the Natal Bight (Fig. 14.5B) and off Port Alfred near the northeastern corner of the Agulhas Bank, surface NO$_3^-$ concentrations reach up to 15–18 μM (Baird, in press; Lutjeharms, 2006). In comparison, surface waters are NO$_3^-$ depleted outside these upwelling zones with the exception of the Sofala Bank off Mozambique that receives substantial runoff from the Zambezi River (Lutjeharms, 2006).

2.2. Nitrite

NO$_2^-$, an intermediate of both nitrification and denitrification (see Devol, this volume; Ward, this volume), is found in measurable concentrations either just below the surface mixed layer/euphotic zone or within the ODZ. These features are called the primary nitrite maximum (PNM) and the secondary nitrite maximum (SNM), respectively. While the SNM in the Indian Ocean is restricted only to the Arabian Sea, as will be discussed in Section 3.2.1, the PNM occurs everywhere. The latter is believed to arise from assimilatory reduction of NO$_3^-$ by phytoplankton (Vaccaro and Ryther, 1960; Wada and Hattori, 1971) and/or due to differential photo-inhibition of NH$_4^+$ and NO$_2^-$ oxidation by nitrifying bacteria (Olson, 1981). NO$_2^-$ concentrations at this maximum rarely exceed 0.5 μM, but higher concentrations (up to $\sim$2.5 μM) sometimes extend over the entire euphotic zone in the Arabian Sea following NO$_3^-$ enrichment through upwelling during the SWM and vertical mixing during the NEM, most likely due to incomplete assimilation by phytoplankton (Morrison et al., 1998; Naqvi et al., 2002). Significant amounts (>0.2 μM) of NO$_2^-$ are also found in surface waters of the Southern Ocean where PP is limited by low concentrations of iron (Fe). The assimilatory reduction of NO$_3^-$ by phytoplankton involves the enzymes nitrate reductase (NR) and nitrite reductase (NiR) (see Berges and Mulholland, this volume; Mulholland and Lomas, this volume). Experimental work has demonstrated that due to its much higher requirement of Fe, the activity of NiR is inhibited to a larger extent than that of NR under Fe-limited conditions (Milligan and Harrison, 2000), and this might account for the hitherto unexplained buildup of NO$_2^-$ in the Antarctic surface layer as indeed in all surface waters that contain NO$_3^-$ at micromolar levels.

2.3. Ammonium and organic nitrogen

NH_4^+, like NO_2^-, is also usually undetectable in the water column except within or just below the surface mixed layer. Observations by Woodward *et al.* (1999) in the Arabian Sea during late SWM revealed peak concentrations exceeding 1 μM, a few meters shallower than the PNM. On a subsequent cruise during the following autumn intermonsoon season, when the measurements were made using a more sensitive fluorescence system, maximal concentrations were lower by a factor of three, but the surface waters were found to contain 100–200 nM NH_4^+. The latter observations are perhaps typical of the North Indian Ocean, and even lower levels are expected for the oligotrophic southern gyre. In contrast, coastal waters are often characterized by substantially higher NH_4^+ concentrations. Over the Indian shelf, for example, near-bottom concentrations frequently exceed 1 μM, indicating NH_4^+ flux from the sediments (Naik, 2003), and even higher values (up to ∼20 M) are found in the water column affected by sulphate reduction (see Section 3.2.1).

Apart from an extensive data set on total organic nitrogen (TON) – most of which is expected to be present as the dissolved organic nitrogen (DON) – generated by D. Hansell as a part of US JGOFS in the Arabian Sea (http://usjgofs.whoi.edu/jg/dir/jgofs/), there has not been any recent study focusing on organic nitrogen in the Indian Ocean, the earlier works (Fraga, 1966; Sen Gupta *et al.*, 1977) being largely of historical significance. Hansell's measurements (e.g., Fig. 14.7) reveal TON concentrations exceeding 5 μM in the surface layer, decreasing rapidly across the thermocline to rather constant values between 1 and 2 μM in deep waters. As expected, coastal waters have relatively higher TON content, and with the exception of waters affected by upwelling and convective mixing, organic nitrogen dominates the combined nitrogen pool in both coastal and offshore areas. It is not clear what fraction of this TON pool is bioavailable, though (see Aluwihare and Meador, this volume). The much higher surface levels relative to the nearly uniform deep-water concentrations of TON (expected to be largely refractory) imply that that a substantial portion of the TON in surface waters is labile. However, the limited information available from the Arabian Sea on the distribution of urea, a major labile DON compound (see Mulholland and Lomas, this volume), indicates that its concentrations are generally below the limit of detection in the open ocean (Woodward *et al.*, 1999). Variability of suspended particulate organic nitrogen (PON) will be dealt with together with its isotopic composition in Section 4.2.

3. Nitrogen Cycle Processes

3.1. Remineralization ratios

Ratios between O_2 consumption and inorganic carbon and nutrients regeneration, called the remineralization ratios, provide useful insights into biogeochemical cycles in the oceans (e.g., export of material to the deep sea and depth-dependent preferential regeneration, if any, of one constituent over the others). For the Indian Ocean, these ratios have been derived from observed variations in concentrations of O_2, nutrients and inorganic carbon. Utilizing linear relationships between NO_3^- and
Figure 14.7 Vertical section of total organic nitrogen (TON) constructed using hitherto unpublished data collected by D. Hansell along US JGOFS southern leg (Cruise TN043 of *Thomas G. Thompson*; http://usjgofs.whoi.edu/jg/dir/jgofs/).

phosphate (PO_4^{3-}) with the AOU in subsurface waters above the AOU maximum, and assuming the organic matter to have a composition of $(CH_2O)_n(NH_3)_{15}H_3PO_4$, Sen Gupta and Naqvi (1984) computed average $-\Delta O_2 : \Delta C : \Delta N : \Delta P$ to be 126:96:15:1 in the North Indian Ocean, as compared to widely used values of 138:106:16:1 proposed by Redfield *et al.* (1963). The N:P ratio was based on measured nitrogen and phosphorus contents of several cultured and natural plankton from the Arabian Sea (Sen Gupta *et al.*, 1976), and the value of *n* was obtained by averaging published slope values for the AOU-PO_4^{3-} regression.

A binary mixing analysis along two isopycnal surfaces ($\sigma_\theta = 27$ and 27.2) in the Atlantic and Indian Oceans by Takahashi *et al.* (1985) yielded relatively constant mineralization ratios implying nearly uniform degradation of organic matter, with the Indian Ocean GEOSECS (Geochemical Ocean Section Study) data giving an average $-\Delta O_2 : \Delta C : \Delta N : \Delta P$ estimate of 172:119:14.9:1. The slightly lower $\Delta N : \Delta P$ for the Indian Ocean as compared to the Redfield value, as well as the corresponding

average for the Atlantic Ocean (17), was ascribed to the loss of NO_3^- through denitrification in the Arabian Sea. Several researchers have since challenged the notion of constancy of remineralization ratios in the oceans. But their findings have not been very coherent with some of the disagreement apparently stemming from methodological differences. For example, reprocessing the GEOSECS data, Minster and Boulahdid (1987) reported that while $\Delta O_2:\Delta N$ was indeed invariable with depth and geographical location, $-\Delta O_2:\Delta P$ decreased to 115 in the sub-pycnocline waters. In contrast, examining property distributions upon 20 neutral surfaces between 400 and 4000 m with a non linear inverse method, Anderson and Sarmiento (1994) found that while $-\Delta O_2:\Delta P$ was more or less constant, averaging around 170 throughout the oceans, $\Delta N:\Delta P$ varied with depth, exhibiting a minimum value of 12 at $\sim$2000 m that was attributed to sedimentary denitrification. The overall averages for the depth range 1000–3000 m and for the rest of the water column examined were $-\Delta O_2:\Delta C:\Delta N:\Delta P$ = 170:117:12:1 and 170:117:16:1, respectively.

The high-quality data generated during the JGOFS and WOCE led to a number of studies focusing on the Indian Ocean. Utilizing the US JGOFS data, Millero *et al.* (1998) derived vastly different $-\Delta O_2:\Delta C:\Delta N:\Delta P$ ratios for waters above (118:125:14.2:1) and below (145:42:6.3:1) the ODZ ($O_2 < 10$ μM) in the Arabian Sea. For the shallower layer, the decomposition of each ''mole'' of organic matter $[(CH_2O)_{125}(NH_3)_{14}H_3PO_4]$ was computed to require 153 moles of O_2, against the observed $-\Delta O_2:\Delta P$ of 118, indicating that degradation with O_2 accounts for 77% (118 $\times$ 100/153) of total respiration, with denitrification contributing the rest. However, the effects of denitrification and anthropogenic CO_2 penetration as well as of mixing of waters with different preformed concentrations were not considered in computation of the ratios themselves. These were taken into account by Hupe and Karstensen (2000) who used a linear inverse mixing model within the depth range 550–4500 m assuming mixing between three predefined water masses: Red Sea/ Persian Gulf Water, Indian Ocean Deep Water and modified Antarctic Intermediate Water. The ratios were again found to vary with depth: $-\Delta O_2:\Delta C:\Delta N:\Delta P$ = 139:90:14.4:1 within 550–1200 m, 152:107:14.9:1 within 1200–2000 m, and 158:127:15.3:1 below 2000 m. The decrease in $\Delta N:\Delta P$ at $\sim$2000 m reported by Anderson and Sarmiento (1994) could not be reproduced in this study. These results implied considerable vertical fractionation between nutrients and carbon during downward transport and decomposition of organic matter, consistent with the results of Shaffer *et al.* (1999). Specifically, it was proposed that phosphorus- and nitrogen-rich compounds such as phospholipids and nucleic acids as well as proteins could be preferentially degraded in the upper 100 m of the water column. Rixen and Ittekkot (2005) calculated $-\Delta O_2:\Delta P$ for depths exceeding 150 m in the Arabian Sea using the US JGOFS data and a mixing model involving three end members: Indian Ocean Deep Water, Indian Ocean Central Water and a mixture of Persian Gulf Water, Red Sea Water and Arabian Sea Surface Water. Their results are in broad agreement with those of Hupe and Karstensen (2000). However, in the upper water column that was not examined by Hupe and Karstensen (2000), Rixen and Ittekkot (2005) found a maximum in $-\Delta O_2:\Delta P$ located near the core of the ODZ, with values similar to those in deep waters. This is counter intuitional since ΔO_2 should reach a plateau value within the ODZ and any further oxidation of organic matter with NO_3^- would

only release PO_4^{3-}, thereby lowering $-\Delta O_2:\Delta P$. This anomaly was attributed to decomposition of organic matter synthesized by cyanobacteria including nitrogen fixers, which is believed to have higher than Redfieldian C:P and N:P ratios (the C: N ratio is, however, not too different from the Redfield value; see Mulholland, 2007). Despite a lack of indication of degradation of organic matter with a non-Redfieldian stoichiometry in the AOU-nutrients relationships in the upper water column (Millero et al., 1998; Naqvi et al., 1982; Sen Gupta et al., 1976), this hypothesis is, nevertheless, supported by N_2:Ar data, as we will see in Sect. 3.2.1.

The studies cited above, with the exception of Anderson and Sarmiento (1994), involved a prior knowledge of the composition of source water masses (end members). In order to eliminate uncertainties associated with subjective choice of end-member characteristics, Li and Peng (2002) introduced a three-end-member mixing model that was applied to selected WOCE and GEOSECS data. The results revealed that remineralization ratios in deep waters ($\theta \leq 12°C$) change more or less systematically along the circulation route of deep waters (from mean $-\Delta O_2:\Delta C:\Delta N:\Delta P$ of 137:73:16.1:1 in the North Atlantic to 162:124:13.3:1 in the North Pacific). Estimates for the deep equatorial Indian Ocean (130:94:10.3:1) are quite different from those for the South Indian Ocean (134:83:14.8:1). The abnormally low $\Delta N:\Delta P$ in the former case was hypothesized to result from partial conversion of organic nitrogen to N_2 and/or N_2O during nitrification by some hitherto unknown microorganisms or alternatively/additionally by heterotrophic denitrification and recently-discovered anaerobic ammonium oxidation (anammox; Strous et al., 1999; see Devol, this volume) in O_2-depleted microenvironments (Li and Peng, 2002).

The "partial nitrification hypothesis" has since been examined in a greater detail by Li et al. (2006) using additional WOCE data from the Indian Ocean. The newly calculated $\Delta N:\Delta P$ also decreases from ~15:1 in the Southern Ocean to 10:1 in the deep equatorial Indian Ocean. In contrast to this, the mean $-\Delta O_2:\Delta C:\Delta N:\Delta P$ ratios (159:110:15.6:1) for the shallower warm water masses ($\theta \geq 10°$) are comparable to the traditional Redfield values. Thus, while NO_3^- is linearly related to PO_4^{3-} in shallow, warm waters with a slope of approximately 16.5, the data points for the Antarctic Bottom Water, the Circumpolar Deep Water, and the Antarctic Intermediate Water (or the Equatorial Indian Phosphate Maximum Water) in the equatorial and subtropical South Indian Ocean fall below the straight line defining this linear trend. The $NO_3^- : PO_4^{3-}$ relationship resulting from in situ oxidation of organic matter and the mixing of the Antarctic Intermediate Water (or the Equatorial Indian Phosphate Maximum Water) with the Sub-Antarctic Oxygen Maximum Water (or the eastern Equatorial Indian Central Water) was derived by fitting the data to an empirical cubic equation, and for the data points lying between these curves and regression lines for the shallow, warm waters, NO_3^- deficits were proposed to be caused by partial nitrification. Any further departures from the values predicted by the cubic functions, conspicuous in data from the northwestern Indian Ocean, were attributed to denitrification (Li et al., 2006). NO_3^- deficits attributed to partial nitrification exhibit a maximum that intensifies from ~2–3 μM around the Hydrochemical Front to ~8 μM in the northern Arabian Sea, coinciding with O_2 minimum in the south and oxycline below denitrification zone in the north. In comparison, deficits resulting from denitrification are spatially less widespread. Peak values (~10 μM)

expectedly occur within the SNM zone of the Arabian Sea, decreasing southward and becoming insignificant in the equatorial region. Irrespective of the formative mechanism(s), if such large NO_3^- deficits, unrecognized by previous studies except for Anderson and Sarmiento (1994), do occur in deep waters, they have important implications for the regional and global nitrogen budgets.

3.2. Denitrification and nitrous oxide

3.2.1. Denitrification

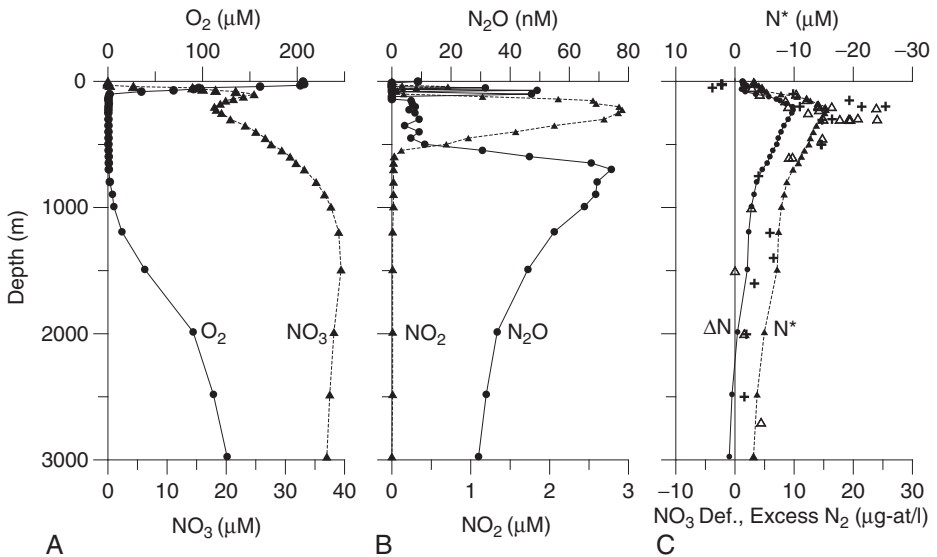
Although almost the entire North Indian Ocean experiences severe O_2 depletion at mid-depth, vigorous denitrification, as indicated by the accumulation of the intermediate NO_2^-, is confined only to a relatively small, well-defined part of the Arabian Sea (Figs. 14.3, 14.6, and Fig. 14.8). Interestingly, while this zone includes comparatively oligotrophic central Arabian Sea, the most productive upwelling centres off the northeast African and Arabian coasts are outside its borders (Naqvi, 1991a). The boundaries of denitrification zone have been fairly stable with no discernable shift in the intensity of the process occurring over the past four decades for which data are available (Banse *et al.*, in preparation). Nevertheless, significant changes in chemical composition of suboxic waters do occur on the seasonal as well as inter-annual time


Figure 14.8 Vertical profiles of properties at 19°N, 67°E in the Arabian Sea (all data except for N_2 collected on TN039 cruise of US JGOFS on 1–2/10/1994). (A) O_2 (circles) and NO_3^- (triangles); (B) N_2O (circles) and NO_2^- (triangles); (C) NO_3^- deficit according to Codispoti *et al.* (2001) (dots connected by the solid line), N⋆ according to Gruber and Sarmiento (2002) (small filled triangles connected by the dashed line), and "excess N_2" calculated from the N_2/Ar ratio (larger unconnected symbols – crosses for data collected on two different cruises from this site and triangles for those from other stations also located within the denitrification zone).

scales (Bange *et al.*, 2001a; Morrison *et al.*, 1999; Naqvi, 1987; Naqvi *et al.*, 1990) indicating quick renewal of the ODZ (Howell *et al.*, 1997; Naqvi and Shailaja, 1993; Somasundar and Naqvi, 1988).

For vigorous denitrification to take place, ambient O_2 concentration should fall below a certain threshold value, which is ~0.7 μM or 0.015 mL L^{-1} in the Arabian Sea (Figs. 14.6 and 14.8; Morrison *et al.*, 1999; Naqvi *et al.*, 2003), consistent with observations in the eastern tropical Pacific Ocean (e.g. Cline and Richards, 1972). Outflows from the Red Sea and the Persian Gulf and advection of waters from the south are probably responsible for keeping the minimum O_2 levels marginally above this threshold in the western Arabian Sea, and a seasonal undercurrent (indicated by property distributions in Fig. 14.3), which brings somewhat more oxygenated waters from the south during the SWM, appears to suppress the process off the Indian continental margin up to about 17°N latitude (Naqvi *et al.*, 2006b,c). It has been proposed that ballast provided by copious lithogenic material received by the Bay of Bengal causes rapid sinking of particulate organic matter to deep sea (Ittekkot *et al.*, 1992). The O_2 supply needed to meet the resultant low remineralization rates (Naqvi *et al.*, 1996) could be just met by renewal, especially from the deeper O_2-rich water column given the absence of high-salinity outflows (because of which the transition from intermediate to deep waters occurs at shallower depths; Rao *et al.*, 1994). This is perhaps what prevents the Bay of Bengal from becoming denitrifying (Fig. 14.9). Support for this hypothesis comes from the sediment trap data (Table 14.1), which
Figure 14.9 Vertical profiles of properties at 19.11°N, 92.65°E in the Bay of Bengal (WOCE Leg I09N; sampling date 24/02/1995). (A) O_2 (circles) and NO_3^- (triangles); (B) N⋆ according to Gruber and Sarmiento (2002) (circles) and NO_2^- (triangles).

Table 14.1 $^{15}N/^{14}N$ ratio in sinking organic matter (from Schäfer and Ittekkot, 1995)

Region	Depth (m)	$\delta^{15}N$ (‰ vs. air)		Nitrogen flux (mg m^{-2} day^{-1})	
		Range	Mean	Range	Mean
Bay of Bengal					
Northern	1700–2100	3.0–4.6	3.5	0.43–1.77	0.83
Central	2300	2.2–6.2	4.2	0.29–2.65	0.97
Southern	3000	3.8–5.9	4.6	0.35–1.48	0.66
Arabian Sea					
Western	3000	5.3–8.8	7.1	0.006–3.97	1.10
Central	2900–3100	6.3–8.7	7.4	0.004–1.48	0.63
Eastern	2800–2900	4.7–8.0	5.9	0.004–1.66	0.68
Lofoten Basin	3000	2.7–8.8	4.2	0.02–2.32	0.62
Sargasso Sea	3200	0.1–2.8	1.2	0.01–0.46	0.15

show that despite the much lower primary production, sinking PON fluxes to the deep Bay of Bengal are comparable to those in the Arabian Sea (Schäfer and Ittekkot, 1995).

The very large volume of nearly suboxic waters in the North Indian Ocean makes it extremely vulnerable to changes in either or both of the two forcing processes – surface organic production and subsurface ventilation – that may result from human activities both on local or regional (eutrophication) and global (greenhouse warming and changes in subsurface circulation) scales. In fact, such alterations are already beginning to be noticed in coastal waters. Along the west coast of India, for example, seasonal upwelling (from May to November) brings low-O_2 water over the shelf where its O_2 content is further depleted due to respiration. This water is generally prevented from surfacing by a low-salinity lens that is formed due to intense SWM rainfall in the coastal zone (Fig. 14.10), which contributes to sustenance of severe O_2 depletion at very shallow depths and maintenance of distinct zonations where various electron acceptors are sequentially utilized: hypoxia over the outer shelf, suboxia (denitrification) over the mid shelf, and anoxia (sulphate reduction) over the inner shelf north of about 12°N latitude (Fig. 14.10). This shallower ODZ, the largest of its kind in the world, has been known for almost half a century (Banse, 1959; Carruthers *et al.*, 1959), although until recently it had not been investigated in detail for nitrogen cycling. An examination of the available data going back to the 1970s suggests that the waters over the inner shelf used to experience seasonal denitrification but no sulphate reduction until the 1980s (supplementary information in Naqvi *et al.*, 2000; Naqvi *et al.*, 2006b). The latter process, recurring every year since systematic monitoring began in 1997, is thus most likely of recent origin, representing an ecosystem shift caused by increased nutrient loading through runoff and atmospheric deposition (Naqvi *et al.*, 2000, 2006b).

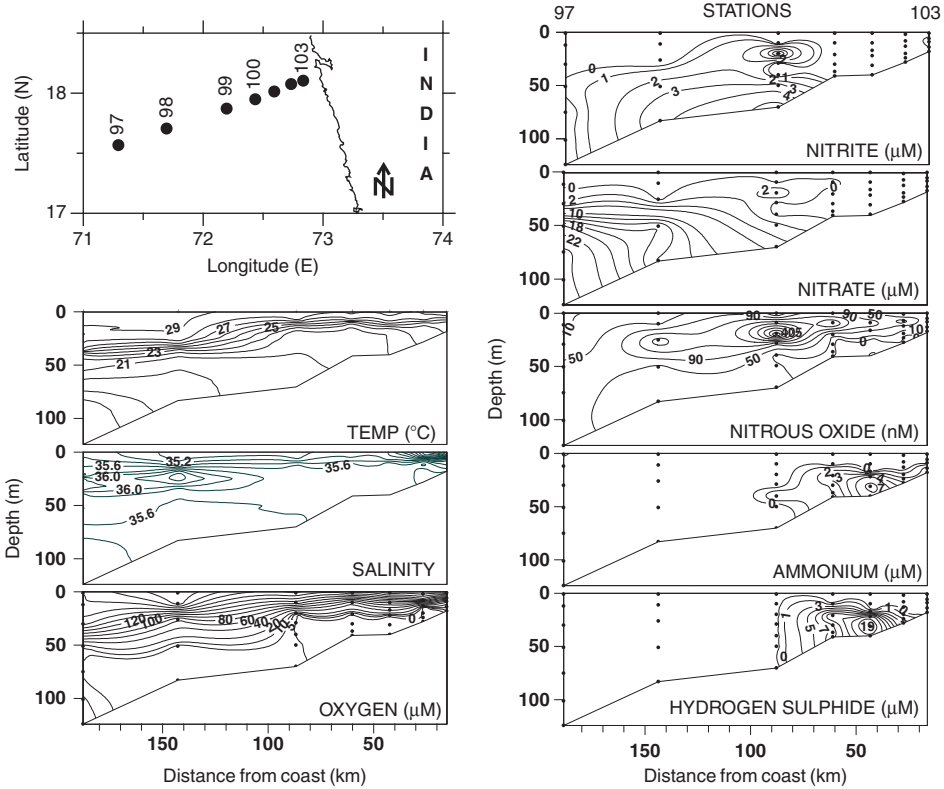
In the open-ocean suboxic zone denitrification does not reach completion, but a minimum in NO_3^- profile invariably occurs within the SNM (Figs. 14.3 and 14.8).


Figure 14.10 Vertical sections of temperature, salinity, O_2, inorganic nitrogen species and hydrogen sulphide off Mumbai based on observations during 6–7 October 1999 (from Naqvi *et al.*, 2000).

The magnitude of depression of $NO_3^- + NO_2^-$ concentration below the expected value (NO_3^- deficits) provides a quantitative measure of denitrification. The expected NO_3^- concentrations have been computed, except in once case (Deuser *et al.*, 1978), using remineralization ratios (Bange *et al.*, 2000; Codispoti *et al.*, 2001; Howell *et al.*, 1997; Mantoura *et al.*, 1993; Naqvi, 1987; Naqvi and Sen Gupta, 1985; Naqvi *et al.*, 1982; 1990; Sen Gupta *et al.*, 1976). The procedure that has been followed in the majority of recent studies utilizes the relationships between the geochemical tracer "NO," defined by Broecker (1974) as $O_2 + NO_3^- \times |\Delta O_2/\Delta N|$ and temperature for estimating expected NO_3^- (Naqvi and Sen Gupta, 1985). The regional denitrification rate estimate of $\sim$30 Tg N year^{-1} is based on NO_3^- deficits derived from this approach (Bange *et al.*, 2000; Naqvi, 1987). However, as demonstrated by Codispoti *et al.* (2001), this method yields systematically low deficits presumably because the data used to derive the "NO"- temperature relationship were affected by mixing with denitrification-affected waters having low NO_3^-. Defining the NO_3^- deficit as -N* (*cf.* Gruber and Sarmiento, 1997) and using a locally derived relationship between NO_3^- and PO_4^{3-} [NO_3^- deficit $= NO_3^- + NO_2^- - 0.86 \times 14.89$ ($PO_4^{3-} - 0.28$)], these authors found significant deficits to extend to $\sim$2500 m depth.

As exemplified in Fig. 14.8 for a station located close to the heart of the denitrification zone, this equation still yields negative deficits for deep waters, and generally lower values at all depths, as compared to the deficits ($-N\star$) obtained from the global equation of Gruber and Sarmiento (2002), *viz.* $N\star = NO_3^- - 16 \times (PO_4^{3-}) + 2.9$. Note that the factor (0.86) used by Codispoti *et al.* (2001) corrects for the PO_4^{3-} regenerated during denitrification. This factor will be closer to unity if some of the deficits are produced by incomplete nitrification as suggested by Li *et al.* (2006). The removal of this factor from the equation of Codispoti *et al.* (2001) or its inclusion in that of Gruber and Sarmiento (2002) would bring the estimated deficits slightly closer. Moreover, the $N\star$ procedure gives cumulative nitrate deficits (resulting from both local and far-field denitrification) as against only the locally produced deficits quantified by the method of Codispoti *et al.* (2001). The latter values are, therefore, expected to be somewhat lower. Anyhow, the two methods provide the lower and the upper limits of NO_3^- deficits in the Arabian Sea, as confirmed by the N_2:Ar data for deep waters (see below).

The equation of Gruber and Sarmiento (2002) yields relatively constant but significantly negative $N\star$ values below the surface layer in the Bay of Bengal, a region without a SNM (Fig. 14.9; Howell *et al.*, 1997; Rao *et al.*, 1994). While it is possible that these values reflect some loss of NO_3^- through denitrification in microenvironments or in sediments, it must be borne in mind that the actual ΔN:ΔP ratio in the North Indian Ocean is probably less than 16, as discussed above, and also that the absolute value of $N\star$ is dependent on the constant used for its computation. These factors may systematically offset $-N\star$ from the actual, locally-generated deficits.

With N_2 being its end product, denitrification should cause an increase in the ratio between concentrations of N_2 and argon (Ar) in water (Richards and Benson, 1960). Recently-acquired data on N_2:Ar from several sites in the Indian Ocean, presented in Fig. 14.11 as composite depth profiles, conform to this expectation. Data from four stations located outside the denitrification zone (crosses in Fig. 14.11) between Lats. 29°S and 8.5°N (along WOCE Leg I07) do not exhibit much geographical variability, and are also quite similar to data from other oxygenated parts of the ocean (Devol *et al.*, 2006a,b). The commonly observed increase in N_2:Ar with depth is believed to be an artifact of bubble injection and the gases' solubilities. In contrast, N_2:Ar profiles within the denitrifying zone are characterized by a pronounced peak within the SNM where the solubility-normalized ratio climbs up to 1.030–1.035 (circles in Fig. 14.11). One can calculate the amount of "excess" nitrogen by subtracting from each observed ratio within the denitrification zone the corresponding value at the same density outside this zone (derived from the best fit equation N_2:$Ar = -1.5976 + 0.3263\sigma_t - 0.013654\sigma_t^2 + 0.000190526\sigma_t^3$), and then multiplying the "excess" N_2:Ar by the equilibrium saturation of N_2 gas for the given temperature and salinity (Hamme and Emerson, 2004). Surprisingly, the "excess" N_2 (maximum value at 19°N, 67°E = 25.5 µg-at L^{-1}) far exceeds peak NO_3^- deficits (9.8–15.4 µM computed from the two approaches described above) at the core of the SNM (Fig. 14.8). Below the SNM, in contrast, "excess" N_2 concentrations generally fall between those expected from the two profiles for NO_3^- deficits with some indication of a less-pronounced secondary N_2 peak occurring between 1000 and 1500 m. This is about the same depth range where Li *et al.* (2006) found
Figure 14.11 N_2/Ar ratio normalized by equilibrium saturation values within (circles) and outside (crosses) the denitrification zone. Note that stations outside the denitrification zone were located within a broad latitudinal band (29°S–8.5°N) (from Devol *et al.*, 2006b).

peak "NO_3^- deficit due to nitrification," but several hundred meters deeper than the secondary peak in N_2O (Fig. 14.8), indicating that some nitrogen may indeed be lost at this level mostly as N_2, even though the mode of loss cannot be established. Incidentally, the lower suboxic/oxic interface located just above this depth range has been found to be a zone of high biological activity, POC concentration as well as particle aggregation (Morrison *et al.*, 1999; Wishner *et al.*, 1998), and the secondary N_2 peak is possibly related to this phenomenon, most likely through denitrification within particle aggregates.

Potential processes that may be called upon to explain the large discrepancy between "excess" N_2 and NO_3^- deficits within the SNM are: (1) sedimentary denitrification, (2) anammox, (3) metal (Fe, Mn)-catalyzed denitrification, and (4) non-Redfieldian organic matter mineralization (Codispoti *et al.*, 2001; Devol *et al.*, 2006a,b). The first of these possibilities requires a decoupling between nitrogen and phosphorus cycles (e.g. possible greater burial of phosphorus in continental margin sediments). The less likely additional requirement is that the maximal inputs from the sediments should occur at the same depth as the water column peak of NO_2^-. In other words, the exact coincidence of the extrema in NO_3^-, NO_2^-, NO_3^-

deficit and excess N_2 strongly favors an in situ production mechanism of the N_2 anomaly. One such mechanism is anammox, a process that, in fact, has been reported to be responsible for the bulk of the N_2 production in the Black Sea (Kuypers et al., 2003) and over the Namibian shelf (Kuypers et al., 2005). However, in the open ocean anammox is expected to be constrained by the availability of NH_4^+, and its inclusion would only enhance N_2 production by ~17% (Devol et al., 2006a,b). The importance of metal-catalyzed reactions (e.g. oxidation of NH_4^+ and reduction of NO_3^- by the reduced and oxidized Mn species, respectively; Luther et al., 1997) is probably also not very significant in the open ocean (Codispoti et al., 2001). That leaves the last explanation (d) as the most plausible.

It has been suggested that the organic matter degraded during denitrification may be primarily proteins (Van Mooy et al., 2002), which may lead to a greater production of N_2 relative to mineralization of phosphorus in suboxic environments (Codispoti et al, 2001; Devol et al., 2006a,b). In addition to this, as will be discussed in Section 3.3, the Arabian Sea is a site of substantial N_2-fixation, and since organic matter produced by N_2-fixers is characterized by high N:P ratios (40–125; Gruber, 2004; Gruber and Sarmiento, 1997; Karl et al., 1992), its degradation would enhance the yield of N_2 during denitrification. As an example, Devol et al. (2006a,b) showed that this enhancement would be as much as about 50% if 20–30% of the primary production is carried out by the N_2-fixing organisms.

The higher NO_3^- deficits derived from their procedure (relative to the "NO"-temperature approach) and still higher "excess" N_2 led Codispoti et al. (2001) to propose an upward revision of the Arabian Sea denitrification estimate to ~60 Tg N year^{-1}. This is substantially above the rates obtained from the ETS (electron transport system) assay (24–33 Tg N year^{-1}; Naqvi and Shailaja, 1993) and ^{15}N incubations (41 Tg N year^{-1}; Devol et al., 2006b). Codispoti et al. (2001) argued that even though these approaches do not employ NO_3^- deficits, they still do not take into account the higher yield of N_2 production to NO_3^- consumption indicated by the N_2:Ar data. With the earlier, arguably conservative estimates, the Arabian Sea would account for about one-third of global water-column denitrification. This share may go up to about half if the estimate for the region is pushed up as proposed while those for the other oceanic sites remain unchanged. However, it is not clear to what extent, if any, the latter estimates also need to be revised as processes causing excess N_2 production are probably not confined to the Arabian Sea alone.

3.2.2. Intermediate nepheloid layer and quantitative significance of denitrification in remineralization

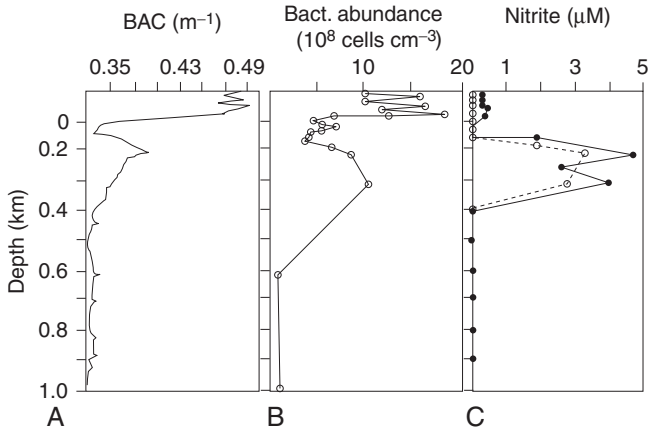
As in the suboxic zones of the eastern tropical Pacific Ocean (Garfield et al., 1983; Spinrad et al., 1989), a particle maximum [also called the intermediate nepheloid layer (INL)] occurs within the SNM in the Arabian Sea as well (Fig. 14.12; Gundersen et al., 1998; Morrison et al., 1999; Naqvi et al., 1993). The confinement of the INL only to the denitrifying zone, and its offshore intensification and shoaling preclude the advection of particle-rich layers from the continental margin; instead its association with the maxima in ETS activity and particulate protein point to an in situ biological origin (Naqvi et al., 1993). Further support for this view comes from a several-fold increase in total bacterial counts within the SNM from a minimum


Figure 14.12 Typical profiles of (A) beam attenuation coefficient (BAC, m^{-1}, from Naqvi *et al.*, 1993) and (B) bacterial abundance (10^8 cells L^{-1}, from Ducklow, 1993) within the denitrifying zone. The sampling sites, located close to each other (around 15°N, 67°E) had similar NO$_2^-$ distributions (μM) (C, open circles corresponding to microbial data). Subsequent measurements have confirmed the co-occurrence of these features (Naqvi *et al.*, in preparation).

located just above this feature (Fig. 14.12; note that the bacterial biomass maximum is also ubiquitous to all denitrifying zones – Spinrad *et al.*, 1989), with a substantial fraction of these bacteria capable of reducing NO$_2^-$ (B.B. Ward, unpublished data). While a lack of grazing by microzooplankton could also result in a higher bacterial biomass within the SNM, this would require the critical O$_2$ concentration for the exclusion of micrograzers to be the same as the threshold value for NO$_3^-$ reduction, which is possible but highly unlikely. A more reasonable explanation is that bacterial growth is limited by low O$_2$ concentrations just above the SNM, but once the O$_2$ concentration falls below the threshold for NO$_3^-$ reduction to occur, the environment becomes conducive for anaerobes to proliferate. Besides denitrifiers, these anaerobes probably also include anammox bacteria that are dependent on the availability of NO$_2^-$ arising from NO$_3^-$ reduction.

In addition to the higher respiration rates suggested by the ETS maximum, another interesting issue concerns the mode of supply of labile carbon to the SNM. The traditional paradigm of the mesopelagic respiration being supported predominantly by the sinking flux of particulate organic carbon (POC) is probably not valid for this environment since such POC supply appears to be inadequate to sustain respiration rates derived from the ETS activity (Naqvi and Shailaja, 1993; Naqvi *et al.*, 1993) as well as bacterial production (Ducklow, 1993). This paradox is illustrated by the following calculation. If we convert the conservative denitrification rate estimate of 30 Tg N year^{-1} to the equivalent carbon demand using Richards (1965) stoichiometry, the organic carbon flux consumed by denitrifiers would on average be ∼21 g m^{-2} year^{-1} (29 Tg C year^{-1} divided by 1.4 × 10^{12} m^2, the area of the denitrification zone according to Naqvi, 1994). This is more than three-fourths of the annual mean POC export of 26.8 gCm^{-2} year^{-1} through the 100 m level quantified from the sediment trap data (Rixen *et al.*, 2005). The

[234]Th-based export production rate estimate is of a similar magnitude (28.5 gCm^{-2} year^{-1}; Lee *et al.*, 1998), making it unlikely that the sinking POC flux has been underestimated. On the other hand, it also seems highly improbable that the share of oxic metabolism in subsurface remineralization is so small. Note that the contribution of denitrification to total respiration would be over three times the above-mentioned estimate by Millero *et al.* (1998). Also, given the occurrence of the most intense denitrification in the least productive central region, carbon demand for denitrification and POC export in this region will be respectively much above and much below the average values considered here. This calls for additional supply of organic matter to the ODZ either quasi-horizontally from the continental margins (Somayajulu *et al.*, 1996), or vertically through diurnal migrations of organisms particularly myctophids (Banse, 1994; Morrison *et al.*, 1999) and episodic injections of transparent exopolymer particles (Kumar *et al.*, 1998). Alternatively, denitrifiers may efficiently utilize dissolved organic carbon introduced to subsurface waters through convective mixing (Naqvi *et al.*, 2002) or by the Persian Gulf outflow (Hansell and Peltzer, 1998). Of these possibilities, the one involving the myctophids is the most appealing because of the large biomass involved (>100 million tonnes according to Gjøsaeter (1984); however, more recent data call for a downward revision of this estimate – Sharon Smith, personal communication, 2006). Adapted to tolerate suboxic conditions, these fishes feed in the near-surface layer at night but migrate en-masse to the core of the ODZ during the day to escape from their predators (Morrison *et al.*, 1999).

3.2.3. Nitrous oxide

Nitrous oxide is produced as a by-product during nitrification and both produced and consumed during denitrification as an intermediate of the reduction sequence from NO_3^- to N_2 (see Bange, this volume). Denitrification is, of course, an anaerobic process, but the low ambient O_2 concentration also affects nitrification by elevating the yield of N_2O relative to NO_3^- (Goreau *et al.*, 1980). Therefore, O_2 deficient environments, such as those found in the North Indian Ocean, are conducive for vigorous production as well as consumption of N_2O, but serve as strong net sources of this important greenhouse gas (Codispoti and Christensen, 1985; Cohen and Gordon, 1978; Elkins *et al.*, 1978; Nevison *et al.*, 2003). In contrast, N_2O cycling in well-oxygenated water columns is less interesting with the surface waters being slightly supersaturated with respect to atmospheric N_2O, driving a small flux to the atmosphere (Butler *et al.*, 1989; Weiss, 1978), and the depth profile of N_2O being a mirror image of that of O_2 (Yoshinari, 1976). As a consequence, studies on N_2O in the Indian Ocean have been largely restricted to the Arabian Sea and the Bay of Bengal.

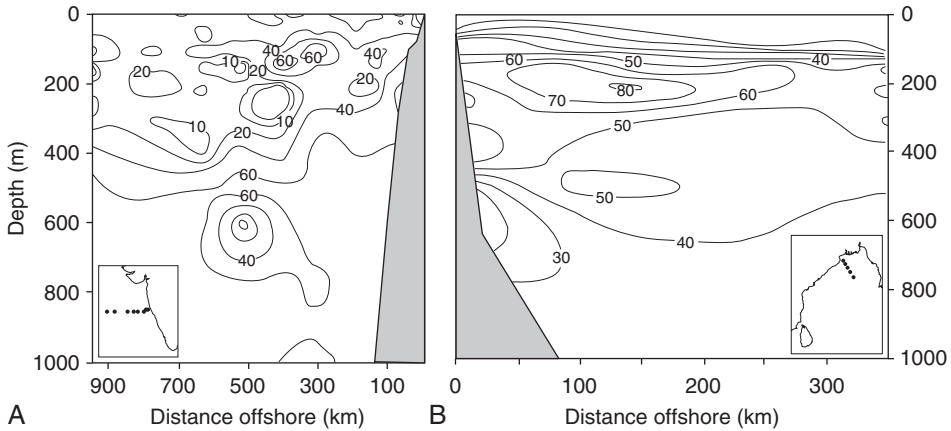
Surface waters of the Arabian Sea exhibit unusually high supersaturation, especially during periods and within zones of upwelling [up to 330% off Somalia (de Wilde and Helder, 1997), 230% off Oman (Bange *et al.*, 1996) and 8250% off India (Naqvi *et al.*, 2005, 2006b,c)]. This is because N_2O concentrations always rise steeply to several tens of nanomolar just below the mixed layer. Within the SNM, the concentration falls below <10 nM, resulting in a two-peaks structure (Figs. 14.8 and 14.13) common to all open ocean denitrification zones (Codispoti and Christensen, 1985; Cohen and Gordon, 1978). The close proximity of intense


Figure 14.13 Vertical sections of N_2O (nM) in (A) the Arabian Sea and (B) the Bay of Bengal based on observations during 26 April–4 May, 1996, and 17–19 March, 1991, respectively. Station locations are shown in the insets (from Naqvi *et al.*, 2006a).

sources and sinks results in a very rapid turnover of N_2O (Naqvi and Noronha, 1991). Below the deeper maximum, N_2O concentration declines steadily with depth but remains well above saturation at least down to 2500 m (Fig. 14.8: Naqvi and Noronha, 1991; Naqvi *et al.*, 1998a,b). Outside the SNM zone in the southern and western Arabian Sea, vertical N_2O distribution is characterized by only one broad maximum within the O_2 minimum layer (Bange *et al.*, 2001a; Law and Owens, 1990; Naqvi and Noronha, 1991). A similar trend is also seen in the Bay of Bengal (Fig. 14.13), which, as pointed out previously, does not contain a SNM (Naqvi *et al.*, 1994). Results not conforming to this pattern have been published by Hashimoto *et al.* (1998) for the central Bay of Bengal; however, the lack of accumulation of N_2O within the ODZ reported in this study was not observed during subsequent surveys conducted by the author's group (unpublished data), and is probably an artifact of N_2O loss during sample storage. Also, Butler *et al.* (1989) reported substantially higher N_2O concentrations in the southern part of the Bay of Bengal than those observed by Law and Owens (1990) from the southern Arabian Sea for comparable O_2 levels. Nevison *et al.* (2003) ascribed this difference to dilution by low N_2O water from the SNM in the Arabian Sea. However, there is no indication of such a dilution in the data set of Naqvi and Noronha (1991).

The cause of N_2O depletion within the SNM is obvious (reduction to N_2 by denitrifiers), but there persists considerable disagreement in the literature as to what brings about N_2O accumulation in low O_2 waters. In the well-oxygenated waters, ΔN_2O (excess concentration over the saturation value) is positively correlated with AOU, albeit with separate relationships in the upper and deeper water columns in both the Arabian Sea (Law and Owens, 1990; Naqvi and Noronha, 1991) and the Bay of Bengal (Naqvi *et al.*, 1994). Although such linear relationships have been interpreted to reflect N_2O production through nitrification (e.g. Butler *et al.*, 1989; Elkins *et al.*, 1978; Oudot *et al.*, 1990), Nevison *et al.* (2003) pointed out that their

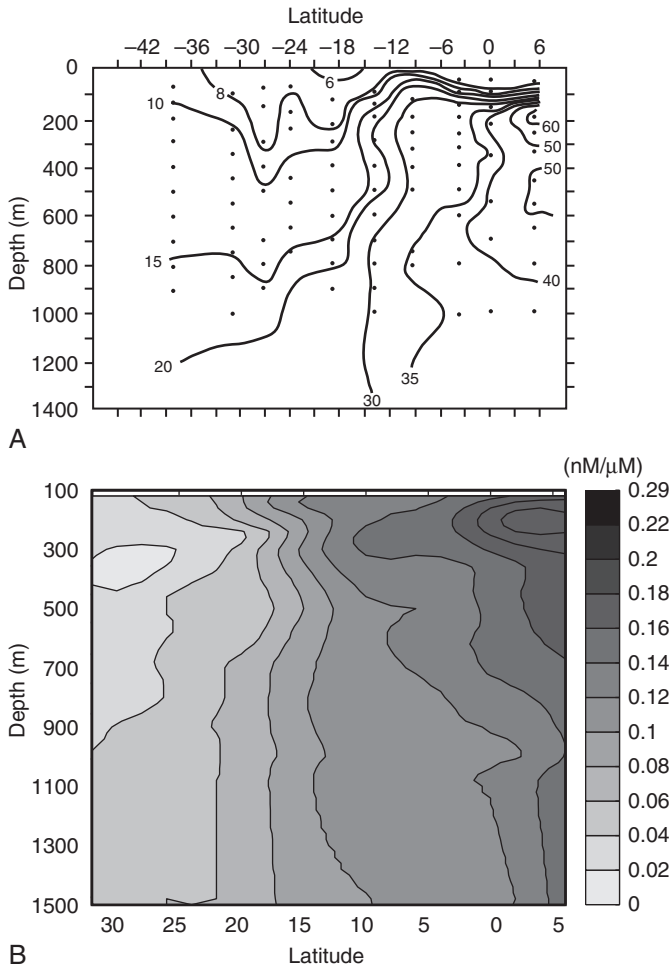
slopes do not provide accurate estimates of N_2O yield per mole of O_2 consumed because of the effect of mixing between various water masses. Still the observed increases in ΔN_2O:AOU with decreases in O_2 concentration in various areas of the ocean (including the Indian Ocean where this ratio increases northward; Fig. 14.14B) could be explained by the nitrification source (Nevison *et al.*, 2003). At O_2 levels slightly above the denitrification threshold, however, production through nitrification and/or nitrification–denitrification coupling (Naqvi, 1991b; Naqvi and Noronha, 1991; Yoshida *et al.*, 1989) was not ruled out. In conflict with the conclusion of Nevison *et al.* (2003), Yamagishi *et al.* (2005) obtained low yield of N_2O per mole of O_2 consumed for organic matter mineralization in the western


Figure 14.14 Vertical sections of (A) N_2O (nM) and (B) ΔN_2O/AOU ($\times 10^{-3}$) along the 90°E transect in the eastern Indian Ocean based on observations in May–July 1987 (from Butler *et al*, 1989 and Nevison *et al.*, 2003).

North Pacific and asserted that nitrification in aerobic deep waters is a minor source of oceanic N_2O. As will be shown in Section 4.1, isotopic measurements reveal different compositions of N_2O at the shallower and deeper maxima, suggesting the involvement of various formative mechanisms.

Data from the suboxic zone over the Indian continental shelf show distinct departures from the trends observed in the open-ocean suboxic zone. Not only are the peak concentrations of N_2O much higher (up to $\sim$0.8 μM), they are often associated with very high NO_2^- (up to 16 μM) and low NO_3^- (near exhaustion) levels (Fig. 14.10) indicating production through denitrification, in stark contrast to observations within the open-ocean SNM (Fig. 14.8). Incubations of water samples collected from the Indian shelf, that were O_2-poor but not denitrifying to begin with, revealed transient N_2O accumulation at micromolar levels once the system turned reducing. It was hypothesized that frequent aeration due to turbulence in shallow, rapidly-denitrifying systems may suppress the activity of N_2O-reductase leading to a large fraction of nitrogen undergoing bacterial reduction ending up as N_2O (Naqvi et al., 2000). Because such production occurs within a few meters of the sea surface, surface N_2O concentrations (5–436 nM, mean 37.3 nM) during the upwelling season over the western Indian shelf are among the highest recorded in the world oceans, as is the emission rate of N_2O to the atmosphere (0.05–0.38 Tg N_2O year^{-1}). Considered together with the efflux of 0.33–0.70 Tg N_2O year^{-1} estimated by Bange et al. (2001b) for the Arabian Sea as a whole, it is obvious that the Arabian Sea is a globally important source of atmospheric N_2O, accounting for 7–23% of the oceanic source (4.7 Tg N_2O year^{-1}; Prather et al., 2001).

Nitrous oxide saturation in surface waters of the Bay of Bengal is relatively smaller, averaging 125% (range: 89–214%). The modest supersaturation, presumably caused by the strong thermohaline stratification, supports a lower flux to the atmosphere (0.04–0.12 Tg N_2O year^{-1}) from the Bay of Bengal than that from the Arabian Sea (Naqvi et al., 1994).

Apart from some limited surface measurements of N_2O along the GEOSECS cruises (Weiss, 1978), there is only one other report on N_2O from the Indian Ocean outside the Arabian Sea and the Bay of Bengal – by Butler et al. (1989) who carried out extensive measurements of N_2O in water and air in the western Pacific and eastern Indian Oceans during an El Nino event (May–July 1987). The Indian Ocean data, largely coming from a meridional (90°E) transect, show sharp northward increases in the N_2O concentration at all depths (Fig. 14.14A) across the Hydrochemical Front. While the concentrations within the O_2 minimum north of the discontinuity are only slightly below those in the Bay of Bengal, the much lower concentrations in the South Indian Ocean are typical of the oxygenated water columns well removed from the ODZs. A similar trend is exhibited by the surface saturation as well: surface waters are close to saturation south of Lat. 15°S, but north of this latitude saturation increases rapidly to a maximum of $\sim$137% at Lat. 8°S. The computed atmospheric emission rate (2.6–5.2 μmol m^{-2} day^{-1}) for this region is comparable to that in the Arabian Sea (Naqvi and Noronha, 1991). It is not clear whether these results are typical of this region or related to the SST anomalies associated with El Nino. During a similar but more severe event (the Indian Ocean Dipole of 1997), extensive cooling of surface waters was recorded in the eastern

equatorial Indian Ocean due to large-scale upwelling off Sumatra (Murtugudde et al., 1999). It is very probable that such events drive large episodic emissions of N_2O from this region.

3.3. Nitrogen fixation

Distribution of $N^\star$ suggests that the Atlantic Ocean serves as a net source of fixed nitrogen to the oceans whereas the Indian and the Pacific Oceans act as net sinks (Gruber, 2004; Gruber and Sarmiento, 1997). This observation sometimes creates an erroneous impression that N_2-fixation and denitrification occur in geographically separated regions (e.g. Gruber, 2004). On the contrary, the two processes should be coupled because denitrification creates an excess of PO_4^{3-} in surface waters that should stimulate the growth of diazotrophs. Results of a recent study by Deutsch et al. (2005) supports this view. These authors estimated N_2-fixation by combining an Ocean Biogeochemistry/General Circulation Model with observed global nutrient distributions in the upper water column. Of the total estimated N_2-fixation rate ($\sim$130 Tg N year^{-1}), over half (80 Tg N year^{-1}) was computed for the Pacific with the Indian and the Atlantic Oceans contributing roughly equally ($\sim$25 Tg year^{-1}) to the remainder (Curtis Deutsch, personal communication, 2005). The potential for denitrification in sustaining N_2-fixation may be quantified by using the N:P ratio for diazotrophs and the $-\Delta N{:}\Delta P$ ratio for denitrification. The ranges of values for the two are 40–125 (Gruber, 2004) and 60–94 (Devol et al., 2006b). Assuming that PO_4^{3-} regenerated during denitrification is eventually utilized by diazotrophs, for each atomic unit of NO_3^- lost through denitrification, 0.4–2 atomic units of N_2 will be fixed. Considering only the NO_3^- deficits-based water column denitrification estimate for the Arabian (note that anammox does not lead to production of PO_4^{3-}), the PO_4^{3-} excess created by denitrification can potentially sustain fixation of $\sim$12–60 Tg of N_2 annually, which brackets well the above-mentioned estimate of Deutsch et al. The same computation could be not extended to sedimentary denitrification because the sedimentary denitrification rate for the entire Indian Ocean is not available; moreover, it is not known what fraction of PO_4^{3-} regenerated from the organic matter diffuses out to the water column relative to the amount that is utilized for phosphatization. In any case, it would be reasonable to conclude that on a per area basis N_2-fixation rate in the Indian Ocean is higher than in the Atlantic.

Within the Indian Ocean, the model of Deutsch et al. (2005) identifies the Arabian Sea as the most important N_2-fixation site. But here, in contrast to the North Atlantic, geochemical signatures of N_2-fixation (positive $N^\star$ and lighter nitrogen isotopic composition of NO_3^- in subsurface waters; Gruber, 2004) are completely obliterated by the opposing effects resulting from denitrification. Although a strong increase in $N^\star$ occurs upward of the subsurface minimum, the values remain negative even in surface water due to its high PO_4^{3-} content. In contrast, surface waters in the Bay of Bengal are distinguished by positive $N^\star$ values arising from the depletion of PO_4^{3-} (Figs. 14.4 and 14.9). Thus, N_2-fixation in the Bay is most probably PO_4^{3-} limited. Low N_2-fixation in the Bay of Bengal is also reflected by the persistence of significantly negative $N^\star$ in subsurface waters in spite of the fact that the Bay of Bengal water column is not denitrifying; that is, if sizable

N_2-fixation were to occur in this region it would have led to much larger increases in $N^\star$ relative to the surface than is observed (Fig. 14.9).

Biological data also testify to widespread N_2-fixation in the Arabian Sea (Devassy *et al.*, 1978). Blooms of *Trichodesmium* have long been known to occur in this region during the intermonsoon seasons – especially in the weeks preceding the onset of SWM – when the environmental conditions, *viz.* high sea surface temperature, calm weather and low DIN concentration in surface waters, favor its growth (Devassy *et al.*, 1978; Qasim, 1970). The *Trichodesmium* blooms have been detected by satellite-borne ocean colour sensors both in the open ocean (Capone *et al.*, 1998) and coastal zone (Desa *et al.*, 2005). The bloom investigated by Capone *et al.* during 22–27 May, 1995, covered an area of $\sim 2 \times 10^6$ km^2 in the central Arabian Sea. It extended into the denitrification zone but was most intense just south of this region. Field measurements carried out at the same time suggested a regional N_2-fixation rate of around 1 Tg N year^{-1} (Capone *et al.*, 1998). As will be shown in Section 4.1, the natural isotope abundance data yield a higher rate ($\sim$6 Tg N year^{-1}; Brandes *et al.*, 1998). Since autotrophs other than the easily noticeable, colonial *Trichodesmium*, such as heterocystous embosymbiont *Richelia* and the recently discovered unicellular diazo-cyanobacteria (Montoya *et al.*, 2004; Zehr *et al.*, 2001; see Carpenter and Capone, this volume), also contribute to N_2-fixation, and also because the isotope data provide a time-integrated signal, the latter estimate is probably more accurate.

In the Bay of Bengal, not only are the *Trichodesmium* blooms less frequently encountered, they are also mostly confined to coastal areas (Adhikary and Sahu, 1992; Madhupratap *et al.*, 1980). This is perhaps also true for the rest of the Indian Ocean, in general, even though potential for substantial N_2-fixation is indicated by the positive $N^\star$ values extending over the upper 500 m or so in the region between the equator and Lat. 45°S (Gruber, 2004). There are several reports of the occurrence of *Trichodesmium* in waters along the Indian Ocean's eastern boundary – especially off the west coast of Australia (Carpenter and Capone, 1992; Creagh, 1985 and references therein) – as well as the western boundary (e.g., Kowalski, 2001; Kromkamp *et al.*, 1997).

4. Natural Isotope Abundance

4.1. Dissolved inorganic nitrogen

Water column distributions of $^{15}N/^{14}N$ in N_2, NO_3^- and N_2O and $^{18}O/^{16}O$ in N_2O (expressed as $\delta^{15}N$ and $\delta^{18}O$, relative to atmospheric N_2 and $O_2\star$) in the Arabian Sea show large changes bought about by microbial consumption/production of these dissolved nitrogen species (Altabet *et al.*, 1999; Brandes *et al.*, 1998; Naqvi *et al.*, 1998a,b; Yoshinari *et al.*, 1997). The most pronounced mass-dependent fractionations appear to occur through water column denitrification. Preferential

---

$\star$ The $^{18}O/^{16}O$ ratio in N_2O is also expressed as the per mil deviation from the standard mean ocean water (SMOW) instead of atmospheric O_2 with the two scales related by the equation (Kim and Craig, 1990):
$\delta^{18}O_{AIR} = -23.0 + \delta^{18}O_{SMOW} /1.0235.$

reduction of $^{14}NO_3^-$ in this process causes enrichment of ^{15}N in NO_3^- and its depletion in N_2: $\delta^{15}N$ of NO_3^- increases from ~6‰ in deep waters (2500–3000 m), comparable with values from other areas (Sigman *et al.*, 1997), to 15–18‰ within the core of the denitrifying layer; the $\delta^{15}N$ of N_2 concurrently decreases from ~0.6‰ to ~0.2‰ (Figs.14.15 and 14.16 Brandes *et al.*, 1998; Altabet *et al.*, 1999). Brandes *et al.* (1998) combined the isotopic data with NO_3^- deficits derived from
