Molecular Approaches to the Nitrogen Cycle

Bethany D. Jenkins *and* Jonathan P. Zehr

Contents

1. Introduction

Nitrogen (N) is a key element whose availability regulates the productivity of marine and terrestrial ecosystems. Nitrogen availability is controlled by biogeochemical transformations, many of which are catalyzed only by microorganisms. Although the concentrations of nitrogenous compounds and rates of transformations can be measured using various methods, the key to understanding nitrogen cycling in the marine environment is linking the abundance and activity of specific microorganisms to observed patterns and rates of individual processes. In the past 20 years, the application and development of molecular, genetic, and genomic approaches

have provided the means to examine microorganisms involved in the nitrogen cycle, and to investigate the factors that control the rates of transformations, through mechanisms from the level of gene expression to enzyme activity (Zehr and Ward, 2002).

There are many ways molecular biological approaches contribute to our understanding of the nitrogen cycle:

- Molecular methods have proved powerful for delineating the remarkable diversity of uncharacterized organisms that contribute to various aspects of nitrogen cycling.
- Molecular biology provides a means for elucidating the ecological function of microorganisms, i.e. by relating temporal and spatial patterns in microbial distribution to N cycling processes.
- Molecular tools can be used to interrogate the physiological status of microorganisms that perform specific biogeochemical reactions, to evaluate whether those organisms are active, and to determine factors that control their growth and distribution. Ultimately it may be possible to link activity to models of nitrogen fluxes.

This chapter aims to provide an overview of studies of key protein coding genes, enzymes, and other functional markers, "functional gene" approaches, that have been used to dissect the contributions of uncultivated organisms to various nitrogen transformations. Since other chapters in this book contain detailed discussions of specific processes in the nitrogen cycle, we will focus our discussion at the beginning of this chapter to describe recent progress in the application of molecular methods to study the function of microbial organisms in the marine environment. We will then conclude by discussing how these methods are applied to studies of major components of the marine N cycle. The field of molecular biology is advancing so rapidly that there will likely be technological breakthroughs in the near future that are not discussed in this chapter. Therefore, this chapter is not meant to be exhaustive, but aims to highlight how molecular biological methods have illuminated our understanding of the marine nitrogen cycle to date.

2. RECENT ADVANCES IN MOLECULAR METHODS FOR STUDYING UNCULTIVATED MARINE MICROORGANISMS ACTIVE IN NITROGEN CYCLING

Advances in molecular biological techniques in the past two decades have demonstrated unequivocally that the diversity of organisms in the marine environment is poorly represented by extant organisms in culture collections. Molecular approaches are now essentially an integral part of many, if not most, studies of microbially mediated processes, as evidenced by other chapters in this book. Initial efforts applying molecular biology to studies of organisms in the marine environment used the polymerase chain reaction (PCR) to amplify ribosomal RNA (rRNA) genes from DNA extracted from natural samples (DeLong, 1992;

Fuhrman *et al.*, 1993; Giovannoni *et al.*, 1990). rRNA genes are widely used for sequence detection and establishing the relationship between organisms with phylogenetic analysis for several reasons: universal PCR primers have been developed that target all the rRNA genes in broad taxonomic groups (i.e. eubacteria, archaea, eukaryotes), the rRNA gene has evolved at a fairly constant rate and has not been subject to lateral gene transfer (Woese, 1987), and rRNA genes are often present in multiple copies, increasing detection limits. Phylogenetic information based on rRNA sequences sheds light on the physiological role of microorganisms in cases where biochemical potential is restricted to specific phylogenetic lineages. In many instances, biochemical capacity is dispersed in distantly related taxonomic groups and cannot be detected on the basis of rRNA gene sequences. In the case of the nitrogen cycle, this is true particularly for denitrifiers and nitrogen fixers. To better understand the diversity of biochemical potential in the environment, approaches have been developed to target genes with specific enzymatic or regulatory function, "functional genes" (Ward, 1996; Zehr and Capone, 1996; Zehr and McReynolds, 1989). Studies directed at functional genes also allow for detection of gene expression directly in the environment and identification of those microorganisms that may be active in N cycling processes. It has been argued that gene expression data can be correlated with a rate determining process such as rates of enzymatic activity (Corredor *et al.*, 2004). Although this may be the case in some instances, the link between gene expression and rates of a reaction catalyzed by an enzyme are governed by many processes, including the relationship between transcription and translation, and post-translational protein regulation. The expression of many genes is also subject to control by the activity of regulatory factors, nutrient availability, and time of day. For example, some genes are transcribed in a daily cycle, such as those encoding nitrogenase in cyanobacteria, where gene transcription often starts prior to the function of the protein (Chen *et al.*, 1997). A temporally changing magnitude of gene expression makes the correlation between enzyme rates and gene expression sensitive to the time of day that the RNA sample is collected and processed. Thus, measurements of gene expression are probably best used as a first order approach to identify microorganisms that are active in a process, or determine factors that regulate activity. Studies with cultivated organisms are critical for interpreting patterns of gene expression in different organisms and for identifying genes whose expression patterns are useful to target in the environment.

Most approaches analyzing the diversity of functional genes in the environment rely on the same basic techniques: the design and optimization of PCR primers that target the gene of interest followed by cloning and sequencing of the PCR product amplified from the environmental sample. Since the PCR product can represent a heterogeneous group of organisms, it is often necessary to sequence many clones to detect all the sequence types represented in any single sample. A very similar approach can be used to study the diversity of expressed genes in the environment by reverse transcribing RNA prior to PCR amplification (RT-PCR). Studies assaying the diversity of nitrogen cycling genes continue to demonstrate a remarkably high diversity in natural populations, and that the bulk of microorganisms involved in the nitrogen cycle have yet to be cultivated. Although libraries of

sequence data from the environment are informative for diversity studies, they can be time consuming and costly to generate, limiting throughput.

In the last decade, new tools have been developed to assess species diversity and distribution without extensive cloning and sequencing. Denaturing Gradient Gel Electrophoresis (DGGE) (Piceno and Lovell, 2000) resolves differences in bulk PCR products amplified from environmental samples based on melting temperature differences between individual sequences in the PCR products. The complexity of a DGGE pattern can be used to infer diversity and profiles can be compared between samples. Although it can be difficult to assign a taxonomic relationship between DGGE patterns, it is possible to excise bands from a DGGE gel, clone and sequence them to identify their origin. rRNA sequence diversity in mixed-community DNA can be analyzed with automated rRNA intergenic spacer analysis (ARISA), which amplifies 16S–23S ribosomal DNA internally transcribed spacer regions and detects the separated products on a fragment analyzer (Fisher and Triplett, 1999; Hewson and Fuhrman, 2004). Restriction fragment length polymorphism (RFLP) is another way to compare sequence heterogeneity in PCR products from natural communities on the basis of differences in restriction enzyme digestion patterns and their resolution by size using gel electrophoresis. Terminal restriction length polymorphism (T-RFLP) (Horz et al., 2000; Moeseneder et al., 1999; Scala and Kerkhof, 2000) is a similar method whereby one of the PCR primers is labeled with a fluorophore and the resulting fragment pattern is resolved by using a DNA sequencer. Similar to DGGE, these fragment analysis methods work well for comparing relative sequence complexity and patterns of complexity between samples. These methods can also be used to assign a phylogenetic relationship between patterns of fragments in instances where different restriction enzymes discriminate well between different taxonomic groups of sequences. This is not always the case, and it can sometimes be difficult to interpret T-RFLP patterns in terms of sequence phylogeny. A database of sequence information is invaluable in interpreting whether or not T-RFLP patterns are phylogenetically coherent.

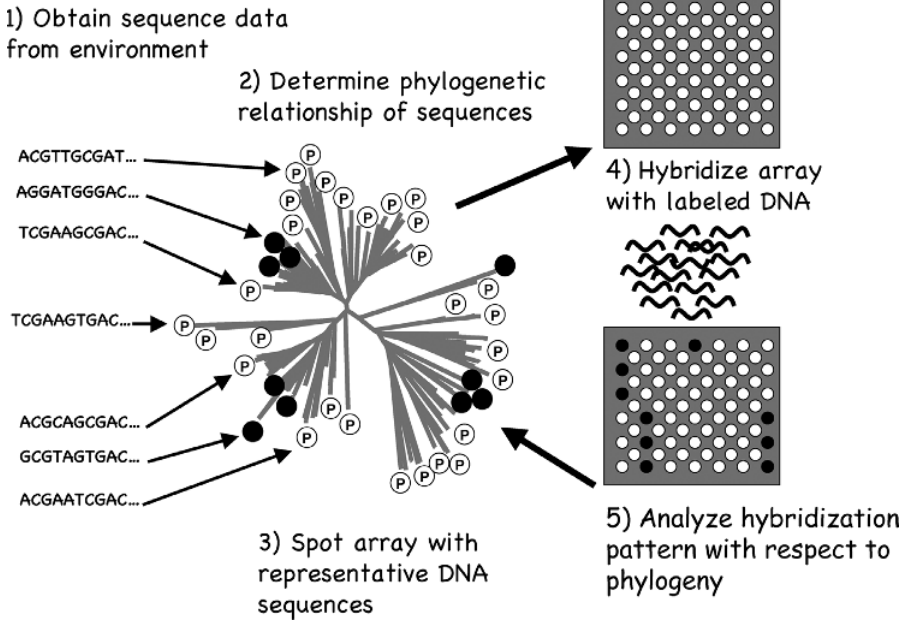
More recently, methods using DNA array technology have been developed to profile gene sequence diversity and "fingerprint" the taxonomic relationships between genes sequences derived from the environment (Jenkins et al., 2004; Moisander et al., 2006, 2007; Steward et al., 2004; Taroncher-Oldenburg et al., 2003; Tiquia et al., 2004, 2006; Wu et al., 2001). DNA arrays, either macroarrays (membranes) or microarrays (glass slides) are spotted with oligonucleotides or amplified gene sequences. The arrays are hybridized with labeled DNA, commonly an amplified PCR product from an environmental sample. Each array spot will bind to DNA in the hybridization pool with varying degrees of sequence similarity depending on the stringency of hybridization (Fig. 30.1). The signal at each spot not only contains sequences that are an identical match to the array probe but also other sequences that are a close match to the array probe (Moisander et al., 2006, 2007; Steward et al., 2004; Taroncher-Oldenburg et al., 2003). Therefore, relative abundances of different sequence types may not necessarily be inferred from the hybridization intensity of individual spots but the hybridization patterns are a useful phylogenetic comparison between samples (Jenkins et al., 2004; Moisander et al., 2006). A limitation of hybridization-based methods, such as gene arrays, is that probe


Figure 30.1 DNA array methodology to study the presence of sequence types in the environment. These experiments are based on previous knowledge of the sequence types in the area of interest (1) and their phylogenetic relationships (2). Arrays are spotted with DNA or oligonucleotide sequences of interest, indicated with a P (3) and hybridized with labeled DNA or cDNA (RNA copy) (4). The hybridization pattern is interpreted in terms of the phylogenetic relationship of the array probes with signal (5).

development depends upon *a priori* knowledge of sequence types likely to be present in the environment being assayed. This can require a large sequence database prior to array construction, since diversity can be high in many environments. Probes can also cross-hybridize to varying extents, depending upon sequence relatedness and binding specificities. Thus, all the array approaches require "ground-truth" sequence data in order to be appropriately interpreted.

To date, all of the methods discussed above rely on the amplification of DNA or RNA from an environmental sample, typically by PCR. PCR amplification can be biased (Becker *et al.*, 2000; Lueders and Friedrich, 2003; Speksnijder *et al.*, 2001; Suzuki *et al.*, 1998; Webster *et al.*, 2003). It is possible to eliminate an amplification step with array technology (Peplies *et al.*, 2003; Taroncher-Oldenburg *et al.*, 2003; Tiquia *et al.*, 2004), but sensitivity can be an issue when assessing functional gene sequences in the environment because they are often less abundant than rRNA sequences and specific taxonomic groups are only a fraction of the total biomass present.

The advent of quantitative PCR techniques makes it possible to quantify the abundance and expression of a specific gene and closely related sequences, or the abundances of taxonomic groups depending on the specificity of quantitative PCR

primer design (Short *et al.*, 2004; Wawrik *et al.*, 2002). A variety of quantitative PCR methods have been used to determine the abundance of sequence types in different aquatic environments including SYBR green dye binding (Lopez-Gutierrez *et al.*, 2004; Wawrik *et al.*, 2002), and the use of fluorogenic Taqman® probes (Church *et al.*, 2005a; Foster *et al.*, 2007; Harms *et al.*, 2003; Short *et al.*, 2004) and molecular beacons (Harms *et al.*, 2003). Design and optimization of quantitative PCR techniques also requires a database of sequence information to determine the specificity of primer design. For example, if a gene is highly conserved, it can be difficult to design primers specific to an individual sequence type because primers may amplify other sequences, sometimes even those that are distantly related. Quantitative PCR can be used to estimate abundances of organisms (Harms *et al.*, 2003) in the environment when copy number of a target gene is known and primers specific to the organism of interest are used. Quantitative PCR is also a very powerful technique to compare gene expression between samples (Wawrik *et al.*, 2002), and correlate gene expression with gene copy number (Church *et al.*, 2005a).

Numerous techniques have been used to visualize cells on the basis of recognition of specific molecular sequences. To date, most of these approaches target 16S rRNA since it is abundant in cells and there are large sequence databases of rRNA sequences from cultivated organisms and the environment. Oligonucleotides corresponding to rRNA sequences obtained from the environment can be used for visualizing and enumerating cells *in situ* (Amann *et al.*, 1995). Most of these detection techniques rely on fluorescently labeled DNA probes that are hybridized directly to cell preparations (fluorescent *in situ* hybridization, or FISH). The fluorescing cells are identified by recognition of the hybridizing probe DNA sequence and visualized by microscopy (Amann *et al.*, 1995; Pernthaler *et al.*, 2003) or flow cytometry (Sekar *et al.*, 2004). Therefore, these approaches work well to enumerate microorganisms that function in the nitrogen cycle for which the ribosomal RNA sequences are known, but do not work for uncultivated microorganisms where the rRNA phylogeny is not known. This is the case with N_2 fixing microorganisms, for example, since nitrogen fixation genes are dispersed amongst closely related phyla. In instances where rRNA phylogeny is not a useful indicator of biological function, visualization procedures are dependent upon hybridization to genes or transcripts of functional genes. Functional genes are constrained in this approach by the fact that mRNA transcript targets are lower in copy number than ribosomal RNA. Recent advances in FISH technology indicate that it is possible to detect mRNA of functional genes (Pernthaler and Amann, 2004), but this technique has yet to be applied to genes in the nitrogen cycle.

Molecular microbial ecology methods are being developed that link species identification with activity, typically combining molecular identification methods with isotope labeling. For a comprehensive review of these methods, see Neufeld *et al.* (2007). One of these approaches combines isotope labeling followed by microautoradiography and hybridization techniques such as FISH (FISH–MAR) and microarrays (isotope arrays). FISH–MAR has been done with ^{3}H labeled substrates (Cottrell and Kirchman, 2000; Lee *et al.*, 1999; Ouverney and Fuhrman, 1999), ^{14}C labeled substrates (Lee *et al.*, 1999), and [33]Pi labeled substrates (Lee *et al.*, 1999). Cottrell and Kirchman incubated estuarine water with ^{3}H labeled amino acids, proteins,

N-acetylglucosamine, and chitin and used MICRO-FISH to study bacterial community members actively using these dissolved organic nitrogen (DON) sources. Adamczyk et al. (2003) extracted RNA from nitrifying sludge samples labeled with ^{14}C bicarbonate and hybridized the RNA to a 16S oligonucleotide microarray to identify ammonia-oxidizers that were actively fixing CO_2. Unfortunately, the only usable radioactive isotope of N is ^{13}N, whose 9.96-min half-life precludes use in these applications.

Stable isotope probing (SIP) combines isotope labeling with density gradient centrifugation to separate nucleic acids corresponding to organisms by actively incorporating the label into biomass (recently reviewed in Friedrich, 2006 and Neufeld et al., 2007). Most SIP methods involve incubation of a microbial community with a ^{13}C labeled substrate followed by isolation of the ^{13}C labeled DNA (Radajewski et al., 2003). The labeled DNA can then be assayed by normal methods (PCR, cloning, sequencing) to determine the phylogenetic affiliation of organisms that used the ^{13}C labeled substrate. For example, this method has been used to identify autotrophic ammonia-oxidizers in freshwater sediments (Whitby et al., 2001). Successful separation of DNA following a stable isotope pulse is dependent on at least 15–20% incorporation of ^{13}C before it can be isolated by buoyant density (Radajewski et al., 2000). Therefore, the success of this technique depends on a high replication rate in the community being studied so that de novo DNA synthesis occurs and label is incorporated. To circumvent this problem, SIP methods have also been developed for RNA which has a higher turnover rate compared with DNA. As in DNA-SIP, RNA is separated by gradient centrifugation followed by RT-PCR of the isotopically enriched RNA (Manefield et al., 2002a,b). Techniques such as FISH, FISH-MAR, and even genome sequencing can then be used to identify microorganisms in each RNA fraction. For example, Ginige et al. (2004) used ^{13}C methanol as a substrate in a batch reactor and combined SIP, FISH, and microautoradiography to identify active anaerobic denitrifiers. The most recent SIP applications have been developed for use with ^{15}N labeled compounds to study identify active diazotrophs in soils (Buckley et al., 2007) and hold promise for the study of N cycling microorganisms in marine environments. SIP methods using ^{15}N incorporation are challenged by the need for a high amount of isotope incorporation and good nucleic acid separation by density gradient centrifugation (Buckley et al., 2007). Other new means to link metabolic activity and phylogenetic identification of individual cells in complex microbial communities combine rRNA based in situ hybridization methods with stable isotope imaging techniques. Orphan et al. (2001) pioneered the use of FISH with secondary-ion mass spectrometry (SIMS) to identify methane-consuming Archaea in anoxic marine sediments. The resolution of SIMS and sensitivity of micro-autoradiography has been improved by the use of nanometer-scale SIMS (NanoSIMS) to study the fate of ^{13}C and ^{15}N labeled substrates in microbial communities. Behrens et al. (2008) evaluated NanoSIMS for studying a simple consortium consisting of a filamentous cyanobacterium and a heterotrophic α-Proteobacterium in complex microbial aggregates obtained from human oral biofilms. Raman microscopy can also be used to follow stable isotope incorporation into cells and was coupled with FISH by Huang et al. (2007) to identify Pseudomonas populations active in degrading ^{13}C-napthalene in groundwater microcosm experiments. In a similar experiment, Neufeld et al. (2008) identified methylotrophic communities in surface water samples by cloning and sequencing high

molecular weight DNA generated from a genomic DNA amplification step after isolation via gradient centrifugation. Continued development of these exciting new methods will help us not only identify the metabolically active consortia in marine systems but also indicate preferred substrates for their activity.

Methods have also been developed to use oligonucleotides to capture RNA of specific phylogenetic groups and measure natural abundances of carbon isotopes of the captured RNA. MacGregor *et al.* (2006) used streptavidin–coated magnetic beads and biotinylated oligonucleotides to capture rRNA from North Sea sediment cores incubated with ^{13}C–labeled acetate, proionate, amino acids or glucose and measured the natural abundances of the carbon isotopes of the captured RNA. Pearson *et al.* (2008) used a similar method to investigate bacterial incorporation of petroleum hydrocarbons from a simulated oil spill on a salt marsh ecosystem to identify bacteria active in the remineralization of hydrocarbons.

A ''full cycle'' molecular approach directed at functional genes in the nitrogen cycle can be devised that combines many of the methods described above. It begins with the extraction of nucleic acids from the environment (or isotopically labeled nucleic acids), followed by the identification of specific sequences types, the use of sequence data to design amplification (e.g. PCR, quantitative PCR) or hybridization (e.g. FISH, DNA arrays) approaches for probing species diversity in the environment, and the use of these methods in the environment to determine the autecology and gene regulation of individual genotypes, species, or strains (Fig. 30.2).

3. The Power of Genomics to Reveal Metabolic Potential

Genome sequencing provides us with the ability to ascertain the genetic capacity of organisms to transport and metabolize various nitrogen sources and understand nitrogen metabolism in the context of other metabolic pathways present in the organism. Genome sequencing can also explain different niches inhabited by different organisms in the marine environment. For example, the recently completed genome sequencing of a number of marine unicellular cyanobacteria allows us to compare these closely related (96% identical rRNA sequences) phytoplankton in terms of their potential to compete for and utilize different nitrogen sources. In marine *Synechococcus* strains, genes are present for transporting and assimilating nitrate and nitrite (Palenik *et al.*, 2003). Genome sequences from *Prochlorococcus* strains (MIT9303, MIT9312, MIT9313, MIT9515, NATL1A, AS9601, CCMP1986, CCMP1375, MED4, SS120) show an absence of nitrate reductase (*narB*) genes. The genomic data confirms studies showing that cultivated *Prochlorococcus* strains lack the ability to assimilate nitrate (Dufresne *et al.*, 2003; Rocap *et al.*, 2003a). Some Prochlorophytes cannot assimilate nitrite, although several strains adapted to low–light regimes can grow on nitrite (Moore *et al.*, 2002). Genome sequencing shows that several low–light adapted *Prochlorococcus* strains (MIT9313, MIT9211, NATL2A) have retained the assimilatory nitrite reductase gene (*nirA*), which suggests that some strains are capable of exploiting the nitrite maximum found at the base of the photic zone (Rocap *et al.*, 2003a).
Figure 30.2 Molecular strategies based on nucleic acid analysis to study microbes involved in the nitrogen cycle. Grey arrows show a "full cycle" analysis where DNA sequences extracted from the environment are used to construct probes for detection of organisms directly by hybridization-based assays (FISH; arrays) or PCR based methodology. The "closure" of the circle is represented by arrows pointing back to the water sample to indicate the probes can be used again to enumerate organisms or gene expression in the environment. Other arrows indicate methods such as cultivation and laboratory experiments that are useful for interpreting gene expression data in environmental samples.

Tolonen *et al.* (2006) used whole genome microarrays to examine the response of the high-light adapted *Prochlorococcus* strain MED4 and the low-light adapted strain MIT9313 to nitrogen starvation. Although both strains had elevated expression levels of many genes involved in nitrogen sensing and transport, the strains differ in expression patterns of carbon metabolism genes (Tolonen *et al.*, 2006). These findings in *Prochlorococcus* strains, linking the ability to use different nitrogen sources to adaptation to the light field, suggest an evolution of genomes in response to the habitats found in the vertical structure of the surface waters of the ocean, and more importantly suggest a genetic basis for variability in the use of "regenerated" and "new" nitrogen.

Genome sequencing also reveals other differences in utilization of nitrogen sources between cyanobacteria (see also Chapter 24, Scanlan and Post, this volume).

Some *Prochlorococcus* strains can assimilate urea and some can assimilate cyanate, whereas some strains (e.g. SS120) only appear to utilize ammonium. Genome sequencing also shows that *Synechococcus* sp. WH8102 is a transport generalist relative to *Prochlorococcus* strains and can utilize organic N sources (Palenik *et al*., 2003). The recently completed sequencing of the N_2 fixing cyanobacteria *Crocosphaera watsonii* and *Trichodesmium erythraeum* should reveal information regarding the different strategies these cyanobacteria employ to fix nitrogen. *Crocosphaera* is a unicellular diazotroph that separates oxygenic photosynthesis and N_2 fixation by fixing N at night. *Trichodesmium* fixes N_2 during the day when it is photosynthetically active.

The genome sequence of heterotrophic *Silicibacter pomeroyi*, a member of the marine *Roseobacter* clade that is abundant in surface waters, contains high numbers of peptide and amino acid transporters as well as the transporters and assimilatory genes for ammonium and urea (Moran *et al*., 2004). The genome is lacking genes for the transport and assimilation of other inorganic nitrogen sources (Moran *et al*., 2004). Therefore, the nutrients *Silicibacter* can utilize are consistent with a lifestyle in the surface ocean where other N sources are not abundant.

Genomics can also reveal unexpected biochemical potential. For example, the genome sequencing of the diatom *Thalassiosira pseudonana* revealed genes encoding all the enzymes in a complete urea cycle, which is unprecedented in other eukaryotic photoautotrophs. It is hypothesized that intermediates from the urea cycle may be used to synthesize polyamines including those required for frustule formation (Armbrust *et al*., 2004).

Genomic technology has also been employed to obtain sequence information from large fragments of DNA from uncultivated marine microbes. High molecular weight DNA from seawater can be cloned as large fragments into bacterial artificial chromosomes (BACS) (Zeidner *et al*., 2003) and fosmids (Beja *et al*., 2000; Stein *et al*., 1996). Fosmid and BAC libraries can be screened for genes of interest (either for 16S or functional genes). Complete sequencing of BACs and fosmids can reveal novel biochemical potential present in marine bacterial populations such as a light-driven proton pumps encoded by proteorhodopsin (Beja *et al*., 2001) and the presence of enzymatic pathways consistent with reverse methanogenesis in bacteria from anoxic sediments (Hallam *et al*., 2004). Screening BAC and fosmid libraries should prove fruitful for identifying genomic regions associated with functional genes involved in nitrogen transformations or discovering more information about uncultivated microbes such as planctomycetes that have recently been shown to perform novel nitrogen transformations (e.g. Annamox). BAC and fosmid library data can be used to compare genomic organization of individual genes between closely related organisms (gene synteny) and to compare the diversity within populations (Fig. 30.2). Improvements in sequencing throughput and sequence assembly algorithms allow for whole genomes to be assembled from consortia of complex microbial populations, "metagenomics". Venter *et al*. (2004) pioneered the use metagenomics to analyze microbial communities in Sargasso Sea surface water (Venter *et al*., 2004). The staggering size of the database from the Venter *et al*. (2004) project (over one billion base pairs of DNA sequence) and the identification of over a million new genes in 2000 L of sea water highlights the genetic diversity in marine ecosystems. This work has been extended as part of the J. Craig Venter Institute's

Global Ocean Sampling Expedition (Rusch *et al.*, 2007). The resulting database is available to the public (Seshadri *et al.*, 2007) and has identified 6.12 million predicted proteins from mainly surface water samples; doubling the number of known proteins and shows that we have yet to identify most metabolic potential in the environment (Yooseph *et al.*, 2007). Metagenomic methods have also been used for a global survey of marine viruses (Bench *et al.*, 2007; Angly *et al.*, 2006) and for studies of picoeukaryotic diversity (Massana *et al.*, 2008). Once caveat to direct shotgun cloning from the environment (Venter *et al.*, 2004) is that important microbes in the N cycle can escape detection. For example, diazotrophs may not be detected, since they are often present in low abundances relative to other prokaryotes. Libraries of expressed genes from the environment, ''metatranscriptomes'' are useful for identifying active genes and can show pathways of nitrogen acquisition (Frias-Lopez *et al.*, 2008; Poretsky *et al.*, 2005) and also provide exciting information regarding where and when genes are active in the environment.

Metagenomic methods are also powerful ways to assemble genomes of organisms that dominate enrichment cultures, but have yet to be isolated in pure culture. The genome of the uncultured anammox bacterium *Kuenenia stuttgartiensis* was assembled this way from bioreactor consortia and many new genes likely involved in the anammox pathway were identified (Strous *et al.*, 2006). Metagenomic data can also be analyzed to look at evolutionary relationships between organisms in different marine environments. Zehr *et al.* (2007) analyzed metagenomic data from the unicellular nitrogen fixing cyanobacteria, *Crocospheara watsonii*, and found extremely low genomic diversity in widely distributed populations.

In the coming years, we are likely to see an explosion of genome sequence data and genome sequencing methods coupled with other methods to assist in identification of target organisms. New sequencing technology will improve the throughput of whole genome shotgun sequencing projects (Goldberg *et al.*, 2006; Sogin *et al.*, 2006). Methods such as flow cytometry and whole genome amplification have been coupled in order to sequence genomes from single cells of marine microorganisms (Stepanauskas and Sieracki, 2007; Zhang *et al.*, 2006). Various gene expression profiling methods are being used to study the dynamics of organisms such as dinoflagellates and coccolithophores that are not represented by full genome sequences (Dyhrman *et al.*, 2006; Erdner and Anderson, 2006; Lidie *et al.*, 2005). Additional genome sequencing data will provide the foundation for the analysis of N fluxes in terms of whole genome responses on both the gene expression and proteomic level.

4. Nitrogen as a Nutrient

All organisms need to assimilate nitrogenous compounds for the biosynthesis of cellular material. Since nitrogen acquisition from the environment is largely mediated by active transport mechanisms (Falkowski, 1975) that obey Michaelis–Menton enzyme kinetics, variations in uptake kinetics among species (Eppley *et al.*, 1969) provide a fundamental mechanism for ecological competition. The uptake of inorganic nitrogen is also the basis of conceptual models of ''new'' and

''regenerated'' productivity (Dugdale and Goering, 1967), which couples nitrogen metabolism to the cycling and export of carbon (Eppley and Peterson, 1979). Although there are questions as to the relationship between productivity, nitrogen uptake, and export, measurements or estimates of nitrogen uptake are still often used to estimate export or ''new'' production (Armstrong, 1999; Laws *et al.*, 2000; McCarthy *et al.*, 1999; Yajnik and Sharada, 2003). Our understanding of nitrogen uptake and growth can be limited because these processes are often uncoupled in experiments measuring N incorporation rates. It is also difficult, if not impossible, to determine which organisms are responsible for observed N uptake. Furthermore, it is still a challenge to assess where and when N is a limiting nutrient for growth. The subject of N uptake and metabolism is extremely broad, and it is not our intent to review this subject comprehensively (we refer you to Chapter 7 by Mulholland and Lomas, this volume), but to provide examples of how molecular (and cellular) biological approaches can contribute to our understanding of nitrogen uptake in the sea.

5. Identifying Microorganisms Involved in Nitrogen Uptake

The biochemistry of nitrogen uptake involves membrane transport, assimilation (conversion of inorganic N into small organic metabolites), incorporation (synthesis of macromolecules) and catabolism (breakdown of macromolecules into small metabolites) (Frost *et al.*, 2005). Nitrogen uptake is typically studied by using isotopically labeled compounds (Lipschultz, 1995; and Chapter 31 this volume; Zehr *et al.*, 1989), but isotope uptake does not easily distinguish between transport, assimilation, and incorporation (Lomas, 2004). Rates of uptake are generally determined in bulk water, which makes it impossible to discern the contributions of individual microorganisms to N cycling. To overcome this problem, size fractionation methods are used to identify the major groups of microorganisms involved in N uptake (Wafar *et al.*, 2004). These experiments are often difficult to interpret because of the inefficiency of separating organisms with different functions, or even individual size classes, by filtration. For example, the potential contribution of heterotrophic bacteria to total community uptake is a major complication in interpreting inorganic nitrogen uptake data (Wheeler and Kirchman, 1986). Size fractionation experiments are also often used to separate larger phytoplankton from heterotrophic bacteria but these are confounded since the sizes of heterotrophic bacteria and smaller phototrophs, such as *Prochlorococcus,* overlap. Molecular methods can aid in the interpretation of size fractionation data since they can be used to identify species and populations in different size fractions, and more importantly, to assay the expression of functional (protein coding) genes to identify the major organisms involved in N assimilation in different size fractions.

It is clear that there are species level differences in the ability to use different nitrogen sources. Some of these differences can be explained by the simple presence or absence of key nitrogen assimilation genes. For example, some bacteria and

cyanobacteria cannot grow on nitrate or nitrite as their sole nitrogen source because they lack the necessary genes to assimilate these inorganic nitrogen sources. Some heterotrophic bacteria lack nitrate reductase genes necessary for the reduction of nitrate to ammonium (Allen *et al.*, 2002). Some marine *Synechococcus* strains cannot grow on nitrate as a sole nitrogen source (Moore *et al.*, 2002). A *Synechococcus* sp. (strain SH-94-5) isolated from a hot spring lacks both nitrate and nitrite reductase genes and cannot grow on nitrate or nitrite as a sole nitrogen source (Miller and Castenholz, 2001). Most strains of *Prochlorococcus* cannot grow on nitrate as a sole N source (Lopez-Lozano *et al.*, 2002; Moore *et al.*, 2002; Scanlan, 2003) and all sequenced *Prochlorococcus* genomes, to date, lack nitrate reductase (*narB*) genes (Dufresne *et al.*, 2003; Rocap *et al.*, 2003b). However, recent data from flow-cytometrically sorted *Prochlorococcus* populations from the Sargasso Sea show assimilation of significant fractions of nitrate; indicating that these organisms have yet to be cultivated (Casey *et al.*, 2007). *Prochlorococcus* also differ in their ability to assimilate nitrite. Some *Prochlorococcus* strains cannot assimilate nitrite (Moore *et al.*, 2002) and genome sequencing shows some *Prochlorococcus* to be lacking nitrate/nitrite transporters and nitrite reductase (*nirA*) genes (Dufresne *et al.*, 2003; Rocap *et al.*, 2003b). Therefore, the response of natural communities to different nitrogen sources partially reflects the genetics of the populations. Some species contribute to ''new'' production, and others do not, depending upon the presence of the genes for nitrogen assimilation. In many cases, this can only be determined by probing directly for the genes encoding the pathway of interest, such as nitrate reduction.

6. Nitrogen Uptake and Growth

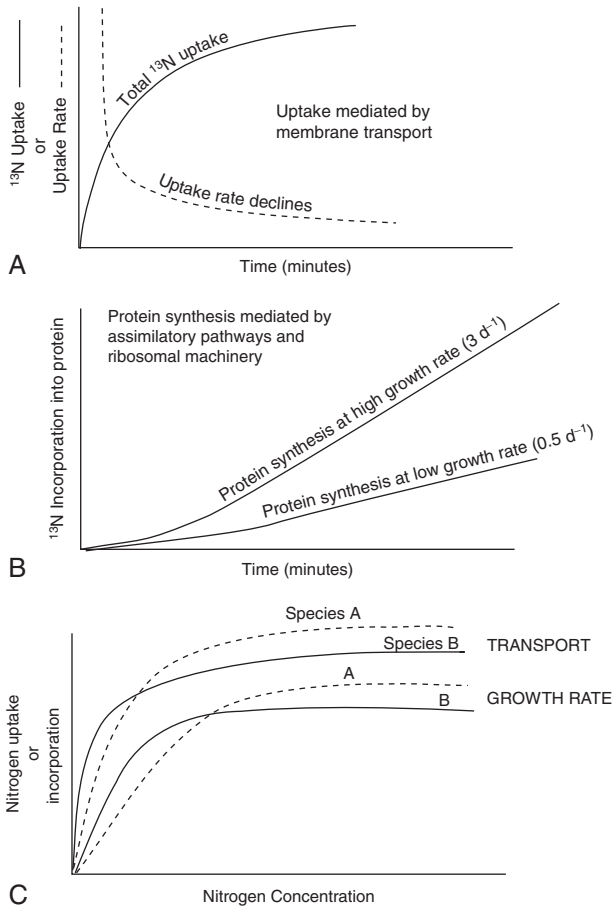
Observed differences in nitrogen uptake between organisms can also be due to variations in genetic controls on each of the processes governing net uptake capacity. Experiments show that transport of inorganic nitrogen is more rapid than incorporation and assimilation (Fig. 30.3A; Zehr *et al.*, 1988; see also Chapter 7, Mulholland and Lomas, this volume) the latter processes controlled by the availability of cellular intermediates and the protein synthesis machinery (Fig. 30.3B). The difference between uptake/transport capacity and assimilation/incorporation results in ''enhanced nitrogen uptake'' that is related to growth rate and N status in phytoplankton (McCarthy and Goldman, 1979) and bacteria (Goldman and Dennett, 2000). Transport capability can exceed the ability of the intracellular machinery to assimilate N (Beardall *et al.*, 2001) if either the numbers of transporters increase with N limitation, or if the protein synthesizing machinery is regulated at a low growth rate. Over long time intervals, the uptake rate becomes equivalent to the assimilation rate, since the buildup of internal pools inhibits membrane transport, and the overall observed uptake rate becomes equal to the rates of assimilation and growth (Flynn, 1998; Glibert and Goldman, 1981; Goldman and Glibert, 1983). Nitrate uptake in excess of growth requirements may serve as an electron sink as well as a nitrogen source (Lomas and Glibert, 1999).


Figure 30.3 Difference between nitrogen uptake and growth kinetics from ^{13}N experiments, after Zehr *et al.* (1988). Short-term uptake kinetics (A) are driven by membrane transport processes, and usually exceed assimilation and incorporation into protein. Short-term uptake declines as feedback from internal pools and regulatory mechanisms are affected by influx of N. (B) Longer term N uptake is driven by protein synthesis rate, which is equivalent to the growth rate. (C) Model of competition between two species showing that competition can be affected by both transport and growth.

Some species have a high nitrate uptake capability that may provide a selective advantage in variable environments (Collos *et al.*, 1992; Fig. 30.3C).

Uptake capacity is dependent on the number and efficiency of membrane transport proteins. It is not really known how the numbers of transporters (e.g. ammonium or nitrate) per cell varies as a function of physiological state, or how the kinetics of transport may be a function of the protein structure of the transporters themselves. Some studies indicate that the number of transporters per cell increase with nitrogen limitation, but kinetic data suggests otherwise and that transporter numbers are more or less constant as a function of growth rate under N limitation

(Zehr *et al.*, 1988). This is an area where molecular biology and biochemistry will certainly provide new information for understanding the competition and coexistence of species. Relatively little is yet known about the functioning of ammonium, nitrate and nitrite transporters in marine microorganisms, but they have been genetically characterized in a variety of microorganisms, and tentatively identified in genomes of marine cyanobacteria and diatoms. Three ammonium transporters (*amt* genes) were described in the freshwater cyanobacterium *Synechocystis* PCC 6803, that varied in their uptake affinity (Montesinos *et al.*, 1998). Ammonium transporters were cloned from the diatom *Cylindrotheca fusiformis*, and were expressed most highly in N starved cells (Hildebrand, 2005). Although these proteins are related members of a gene family, one transporter is consistently expressed at much higher levels than others regardless of the N source (Hildebrand, 2005). Two nitrate transporter genes were also characterized in *C. fusiformis* and found to be regulated in response to nitrogen source (Hildebrand and Dahlin, 2000). Nitrate transporters have also been identified in several marine cyanobacteria and are nitrate/nitrate bi-specific permeases (*nrtP*) (Bird and Wyman, 2003; Wang *et al.*, 2000). The expression of *nrtP* was upregulated in the marine *Synechococcus* sp. WH 8103 in response to N starvation and nitrate addition and was more strongly repressed by ammonium in low-light conditions (Bird and Wyman, 2003). Many *Prochlorococcus* genes for nitrogen assimilation and transport are activated during N starvation (Tolonen *et al.*, 2006). Therefore, assaying the expression of nitrate transporters in diatoms and cyanobacteria can potentially identify conditions of N limitation or whether nitrate or ammonium are being used as nitrogen sources. Future experimental work holds much promise for determining how transporter abundance and activity are linked to the kinetics of cellular transport and possibly redox potential.

7. MOLECULAR CHARACTERIZATION OF NITROGEN ASSIMILATORY PATHWAYS

Molecular methods have been used extensively to study the activity of enzymes the major nodes of N assimilatory pathways in marine organisms. These enzymes include glutamine synthetase (ammonium assimilation), nitrate reductase (nitrate assimilation), urease (urea assimilation), and nitrogenase (nitrogen fixation), Table 30.1 (see also Berges and Mulholland, Chapter 32, this volume). The transcription of a plastid-localized glutamine synthetase (glnII) in the diatom *Skeletonema costatum* is induced to assimilate NH_4^+ derived from reduction of NO_3^- rather than from NH_4^+ directly transported into the cell (Takabayashi *et al.*, 2005). Therefore, quantification of glnII mRNA may be useful for indicating new production by phytoplankton. PCR primers have been developed for detecting assimilatory nitrate reductase genes in bacteria and cyanobacteria (Allen *et al.*, 2001; Jenkins *et al.*, 2006; Paerl *et al.*, in press) and for diatoms and other phytoplankton (Allen *et al.*, 2005) in the environment. Analysis of diatom nitrate reductase (NR) protein sequences have provided hints to the underlying mechanism of relatively low NR

Table 30.1 Catalytic enzymes essential for nitrogen transformations processes used in molecular studies

Process	Organism(s)	Function	Protein	Gene	Reference
Nitrogen assimilation	*Bacteria*	NO_3^- to NO_2^-	Assimilatory nitrate reductase	*nas*, *nar*	Allen *et al.*, 2001; Allen *et al.*, 2005; Jenkins *et al.*, 2006
		NH_3 to L-glutamine	Glutamine synthetase	*gln*	Gibson *et al.*, 2006
Nitrogen fixation	*Bacteria* and *Archaea*	N_2 to NH_3	Nitrogenase iron protein	*nifH*	Affourtit, 1997; Church *et al.*, 2005; Foster *et al.*, 2007; Jenkins *et al.*, 2004; Langlois *et al.*, 2008; Lovell *et al.*, 2000; Moisander *et al.*, 2007; Omoregie *et al.*, 2004; Piceno *et al.*, 1999; Short *et al.*, 2004; Steward *et al.*, 2004; Tiquia *et al.*, 2006a; Zani *et al.*, 2000; Zehr and McReynolds, 1989
			Nitrogenase alpha subunit	*nifD*	Holmes *et al.*, 2004; Roeselers *et al.*, 2007; Sroga *et al.*, 1996
DON processing	*Bacteria*	N-acetylglucosamine to oligosaccharides	Chitinase	*chiA*	Cottrell *et al.*, 1999

Cited references were selected because they provide the foundation for targeting these functional genes in the environment. The use of these targets is expanding rapidly and a comprehensive list of every study referencing their use is much too long to include here. Therefore, researches interested in following a specific process should be sure to refer to current literature.

temperature optima in diatoms, as have studies of protein activity and protein abundance using immunoassays (Allen *et al.*, 2005; Gao *et al.*, 2000; Smith *et al.*, 1992). Berges and Harrison (1995) found that NR activity was the rate limiting step in nitrate utilization in a diatom, and thus probing for NR activity or gene expression can identify cells that are adapted to nitrate utilization, even on the single-cell level (Jochem *et al.*, 2000). Assays of gene expression also help to identify temporal patterns that relate to daily cycles of activity, and to identify constitutive and regulated responses. Daily cycles in nutrient uptake driven by light-dependent species-specific characteristics can influence competition for dissolved nutrients (Litchman *et al.*, 2004; Riegman *et al.*, 2000). The daily cycle of nitrate reductase activity in a diatom was suggested to be driven by transcriptional regulation (Vergara *et al.*, 1998). Shifts in gene expression in response to the presence of different N sources are implicated in the mechanism of preferential uptake and utilization of individual N sources.

There is complex feedback between use of different N sources (e.g. ammonium and nitrate) and internal N pools. The preferential use of reduced vs. oxidized forms of inorganic nitrogen sources has been recognized since early studies of nitrate and ammonium uptake in microalgae (Dortch and Conway, 1984) and thought to be based on energetic differences between transport and assimilation. More recently, it is recognized that both N sources can be used simultaneously (Collos, 1998; Collos *et al.*, 2003). Lomas (2004) measured the activity and expression of NR and urease and saw different responses in the uptake and assimilation of nitrate and urea when challenged with other N substrates, suggesting that NR and urease may have different internal feedback controls. The NR gene was cloned from the green alga *Dunalialla tertiolecta*, and found to be regulated in response to internal N pools but not to depletion of external sources (Song and Ward, 2004). As described above, the nitrate transporter in diatoms is also regulated in response to different nitrogen sources (Hildebrand and Dahlin, 2000). Whole genome microarray experiments with two *Procholorococcus* strains grown on different nitrogen sources show genes in common that are upregulated when cells are grown on nitrite, urea or cyanate as opposed to ammonium and genes unique to each nitrogen source (Tolonen *et al.*, 2006). Thus, there are clearly complex regulatory mechanisms in species level responses to the availability of nitrogen that are involved in determining overall nitrogen uptake and growth rates.

Regulation of gene transcription is central to the response of transporters and enzymes to nitrogen sources. In cyanobacteria, expression of genes in nitrogen assimilatory pathways is mediated by a signal transducer (P_{II}, encoded by *glnB*) and the regulatory protein NtcA (Tandeau de Marsac *et al.*, 2001). *ntcA* gene expression was shown to be correlated with nitrate use (Lindell *et al.*, 1998) and has been used as a target to assay for use of ammonium and nitrate and nitrogen stress in marine *Synechococcus* spp. (Lindell and Post, 2001). However, the *ntcA* regulatory mechanisms may vary between species and strains; Bird and Wyman (2003) found that the oceanic strain *Synechococcus* sp. WH8103 had a number of unusual characteristics, including the fact that *ntcA* did not appear to be regulated by ammonium. *ntcA* is regulated by ammonium in *Prochlorococcus* (Tolonen *et al.*, 2006), but there are no nitrate assimilation genes to regulate and the ammonium transporter appears not to be regulated by NtcA (Lindell *et al.*, 2002). NtcA appears to be central in balancing carbon and

nitrogen metabolism (Tandeau de Marsac *et al.*, 2001), but its role in *Prochlorococcus* may differ from that in *Synechococcus* (Lindell *et al.*, 2002). The P_{II} protein is found in bacteria and cyanobacteria and plays a variety of regulatory roles in N assimilation including control of N fixation. The P_{II} protein is reversibly phosphorylated in cyanobacteria in response to sensing N assimilation through the glutamine synthetase–glutamate synthase pathway (GS–GOGAT) and not simply N source availability (Forchhammer, 2003, 2004). Additionally, the P_{II} protein also senses fluxes in CO_2 levels and may link N and carbon (C) assimilatory pathways (Forchhammer, 2003, 2004). In *Prochlorococcus*, there are strain differences in *glnB* regulation under nitrogen stress, indicating that P_{II} function may be independent of N utilization (Tolonen *et al.*, 2006). Future studies of the activity of the P_{II} protein will be exciting because they may reveal how cyanobacteria cope with both N and C fluxes in dynamic marine environments.

7.1. Assimilation of DON

Most microorganisms can use some organic compounds as nitrogen sources. Our comprehension of the metabolism of organic nitrogen is limited by our understanding of the composition of DON in the oceans (see also Aluwihare and Meador, Chapter 3, this volume). DON, as well as dissolved organic carbon (DOC), are dynamic components of marine systems but are poorly characterized due to a variety of technical limitations in analyzing both their composition and utilization (Benner, 2002; Berman and Bronk, 2003; Bronk, 2002). Amino acids, as dissolved free (DFAA) or combined (DCAA) amino acid forms, and urea are DON constituents present in relatively low concentrations (Aluwihare and Meador, Chapter 3, this volume) but are important labile sources of nitrogen as they are turned over rapidly. Urea and amino acid uptake by bacteria (Cho *et al.*, 1996; Wheeler and Kirchman, 1986) and phytoplankton (Collier *et al.*, 1999; Wheeler *et al.*, 1974) has been known for many years. However, despite the fact that analysis of these compounds is more straightforward than analysis of the majority of DON constituents, relatively little is known about their uptake and metabolism. A mechanism for utilization of organic nitrogen by phytoplankton was shown by the discovery of amino acid oxidases on the cell surface of some marine phytoplankton (Palenik and Morel, 1990). These enzymes have not received much attention, but could be important in phytoplankton metabolism of organic nitrogen, and could be good targets for molecular or immunological approaches. Dissolved proteins are also metabolized by bacteria (Hollibaugh and Azam, 1983; Keil and Kirchman, 1992; Taylor, 1995), presumably by cell surface proteases (Hollibaugh and Azam, 1983). The role of proteases may be particularly important in the cycling of DON in the ocean, and much could be learned from targeting proteases to identify the types of microorganisms involved in protein turnover, and what controls their distribution and activity. Chitin, a dominant macromolecule in marine systems, also contains N and is decomposed by a number of microorganisms (Keyhani and Roseman, 1999; Svitil *et al.*, 1997). Chitin comprises 60–80% of reactive high molecular weight DON (Aluwihare *et al.*, 2005). Diverse chitinase genes have been reported from a variety of aquatic environments and were found in the Sargasso Sea environmental libraries (LeCleir *et al.*, 2004).

The composition of the bulk of dissolved organic matter (of which DON is a part) has always been controversial, but was largely believed to be a result of the recalcitrant properties derived from chemical or bacterial processing and reprocessing (Bronk *et al.*, 1994). Recent studies indicate that this material may largely be derived directly from photoautotrophic production; organic matter synthesized primarily by cyanobacteria (McCarthy *et al.*, 2004). This suggests that the biochemical pathways of organic matter synthesis and release need to be examined in detail, in order to determine the factors that control DOM synthesis and export in the oceans.

7.2. Nitrogen fixation

A variety of prokaryotic microorganisms can use atmospheric dinitrogen (N_2) as a source of nitrogen for growth. This capability, conferred by the enzyme nitrogenase encoded by the *nif* genes (Table 30.1), appears to be limited to prokaryotic microorganisms, but is widely dispersed in prokaryotic taxa. Nitrogen fixation is energetically expensive and sensitive to oxygen, and is highly regulated at transcriptional and post-translational levels (Zehr and Capone, 2002).

Nitrogen fixation in the marine environment occurs in benthic (sediments and microbial mats) and pelagic environments, and in salt marsh soils (see Carpenter and Capone, Chapter 4, this volume). Since very diverse microorganisms that span the Bacteria and Archaea domains of life can fix nitrogen, it is often difficult to ascertain which organisms are responsible for observed nitrogen fixation rates. Our discussion of the application of molecular approaches to the study of marine nitrogen fixation is brief because it has been reviewed extensively elsewhere (Carpenter and Capone, Chapter 4, this volume; Foster and O'Mullan Chapter 27, this volume; Scanlan and Post, Chapter 24, this volume; Paerl and Zehr, 2000; Zehr and Ward, 2002; Zehr *et al.*, 2003).

The *nifH* gene, encoding the nitrogenase iron protein is useful as a phylogenetic marker for identifying N_2 fixing microorganisms (Zehr *et al.*, 2003). The diversity of nitrogen fixing microorganisms has been studied by targeting *nifH* in a number of habitats including sediments (Burns *et al.*, 2002), salt marshes (Lovell *et al.*, 2000), marine microbial mats (Omoregie *et al.*, 2004b; Steppe and Paerl, 2002; Zehr *et al.*, 1995), hydrothermal vents (Mehta *et al.*, 2003), estuaries (Affourtit *et al.*, 2001; Jenkins *et al.*, 2004; Moisander *et al.*, 2007), and the open ocean (Falcon *et al.*, 2004; Hewson *et al.*, 2007; Mazard *et al.*, 2004; Zehr *et al.*, 1998, 2001). Current methods including DNA macro- and microarrays (Jenkins *et al.*, 2004; Moisander *et al.*, 2006, 2007) and quantitative PCR approaches (Church *et al.*, 2005a,b; Foster *et al.*, 2007; Short *et al.*, 2004) can provide information on the diversity of diazotroph communities and the abundance of individual phylotypes, respectively.

Expression of the *nifH* gene can indicate the activity of N_2 fixing microorganisms (Omoregie *et al.*, 2004a; Zani *et al.*, 2000), since nitrogenase is a highly regulated enzyme. Methods aimed at enumerating gene transcript abundance such as reverse-transcriptase quantitative PCR (RT-qPCR) can be used to identify *nifH* gene expression patterns; for example, diel cycles typical for cyanobacteria. These methods can also be used to assay for responses to environmental factors in experimental manipulations (Needoba *et al.*, 2007; Zehr *et al.*, 2007), or *in situ* (Church *et al.*, 2005b). Uptake

experiments can also be combined with gene expression assays. Experiments coupling *nifH* gene expression with $^{15}N_2$ uptake (Church *et al.*, 2005a; Montoya *et al.*, 2004; Zehr *et al.*, 2001), were important for showing the importance of previously unidentified unicellular cyanobacteria in the open ocean to upper water column nitrogen fixation. Prior to these experiments, it was traditionally believed that there were only a few dominant nitrogen fixing species in oligotrophic oceans, particularly the filamentous nonheterocyst forming cyanobacterium *Trichodesmium*, and the heterocystous cyanobacterial symbiont of diatoms, *Richelia* (Carpenter, 1983, pp. 65–103). Despite the identification of additional nitrogen fixing groups in the open ocean, in comparison, estuarine environments and coastal benthic environments contain much more numerous and diverse species of diazotrophs (Olson *et al.*, 1999; Omoregie *et al.*, 2004a,b; Jenkins *et al.*, 2004; Zehr *et al.*, 1995, 2003). A current challenge is to determine whether any of these groups in environments with dynamic N cycling are active and under what conditions they fix nitrogen. A recent study demonstrated nitrogen fixation in estuarine sediments from Narragansett Bay (Fulweiler *et al.*, 2007) and subsequently we detected *nifH* gene expression from the same N_2–fixing cores (Jenkins and Fulweiler, unpublished data). These experiments illustrate that use of molecular biological tools can be a powerful means for identifying new organisms active in N–cycling.

7.3. Identifying nitrogen limitation

Nitrogen availability constrains biomass (Liebig, 1840) and the rate of primary productivity (Blackman, 1905). This is true in marine systems (Falkowski and Raven, 1997) and has been noted early in the development of biological and chemical oceanography (Nixon and Pilson, 1983). It is still debated whether nitrogen, phosphorus or other nutrients are the proximate or ultimate (Tyrrell, 1999) limiting nutrients, and how nitrogen and phosphorus limitation constrains or is constrained by the elemental ratios of organisms in the sea (Falkowski, 2000; Geider and La Roche, 2002; Karl *et al.*, 2001; Klausmeier *et al.*, 2004; Redfield, 1958) (see Hutchins and Fu, Chapter 38, this volume). Information at the cellular or molecular level can be used as a proxy for nutrient stress by assessing physiological responses to nutrient limitation. Unbalanced growth results in shifts in gene expression and protein abundance that can be indicators of limitation in the Blackman sense (i.e. by one nutrient or the other). Molecules impacted by nutrient limitation include transporter molecules (see above), proteases (Berges and Falkowski, 1998), and other proteins (Geider *et al.*, 1993; LaRoche *et al.*, 1993; Leonardos and Geider, 2004; Plumley and Schmidt, 1989). A nitrogen regulated protein on *Emiliania huxleyi* cell surfaces was identified (Palenik and Koke, 1995) and could be used to interrogate individual cells for nitrogen stress. Monitoring expression of the global nitrogen regulator, *ntcA*, described above, is useful for identifying N limitation in cyanobacteria and their dependence upon different N sources in both the laboratory and in field populations (Lindell and Post, 2001; Lindell *et al.*, 2005). A variety of other genes and proteins in cellular metabolism, from transporters to response regulators and metabolic enzymes (e.g. glutamyl-tRNA synthetase in cyanobacteria) (Luque *et al.*, 2002) may be good indicators of physiological status that can be used to interrogate natural populations.

> ## 8. MOLECULAR BIOLOGICAL TOOLS FOR PROBING THE USE OF NITROGENOUS COMPOUNDS FOR CELLULAR ENERGY

8.1. Denitrification

Denitrification is the use of oxidized nitrogen compounds as terminal electron acceptors in respiration, resulting in the formation of dinitrogen gas. For a comprehensive discussion of marine dentirification, please see Devol, Chapter 6, this volume. Dentrification is important for fixed N budgets in the oceans since it is a primary loss mechanism for N. The balance between denitrification and N_2 fixation controls N limitation over long time scales (Capone, 2000; Codispoti *et al.*, 2001; Falkowski, 1997). Denitrification results in the production of N_2O and NO, contributing to greenhouse gas emissions which affects climate (Capone, 2000; Lashof and Ahuja, 1990). Denitrification is largely an anaerobic process, but can occur aerobically as well under some conditions (Robertson *et al.*, 1995). Denitrification occurs in organic–rich sediments at continental margins, and oxygen minimum zones (OMZ) in intermediate waters, such as the Arabian Sea, the eastern tropical North and South Pacific Oceans and the Baltic Sea (Gruber and Sarmiento, 1997) (see Devol, Chapter 6, this volume). The capacity for denitrification is widespread amongst prokaryotic lineages and cannot be deduced from 16S gene comparison. Therefore, studies targeting functional genes involved in denitrification pathways are invaluable for determining the distribution and function of denitrifying microorganisms in the environment.

During the denitrification process, nitrate is sequentially converted to nitrogen gas by the action of four metalloenzymes: the periplasmic and membrane bound nitrate reductases (encoded by the *narG* and *napA* genes) reduce NO_3^- to NO_2^-, the cytochrome cd_1 and Cu containing nitrite reductases (encoded by the *nirS* and the *nirK* genes, respectively) reduce NO_2 to NO, nitric oxide reductase (encoded by the *norB*) reduces NO to N_2O, and nitrous oxide reductase (*nosZ*) reduces N_2O to N_2. All the genes encoding the enzymes involved in denitrification contain conserved regions (Bothe *et al.*, 2000) which facilitates the development of molecular probes that target diverse species, Table 30.1.

Studies using functional genes as markers to study denitrifier diversity in the ocean demonstrate a high diversity of denitrifiers that are divergent from previously cultivated strains. The spatial and temporal heterogeneity of denitrifiers in sediments was demonstrated based on phylogenetic analysis of denitrification genes off the New Jersey shore (Scala and Kerkhof, 2000) and from Washington coast and Puget Sound sediments (Braker *et al.*, 2000). There appear to be similarities between communities in different layers of sediment cores even though steep redox gradients were present in the core (Braker *et al.*, 2001). The authors hypothesized that invertebrate bioturbation may be responsible for the relative homogeneity of denitrifiers along vertical gradients. In contrast, denitrifier diversity along vertical profiles of water columns show differences in community structure between depths as a function of oxygen concentration (Liu *et al.*, 2003). Principle component analysis showed that nitrate and oxygen levels may control denitrifier community structure off the Pacific coast of Mexico (Liu *et al.*, 2003). The denitrifier community

composition is influenced by O_2, NO_3^- and NO_2^- gradients and depth within the water column in the Chilean OMZ (Castro-Gonzalez *et al.*, 2005). Similarly, Jayakumar *et al.* (2004) observed the highest denitrifier diversity in Arabian Sea samples with high nitrate concentrations and the lowest diversity in a surface water sample with undetectable nitrate, implying a correlation between ecosystem chemistry and genetic diversity.

Although diversity studies reflect microbial community composition, they do not identify members of the community that may be actively denitrifying. Studies of cultivated denitrifiers show that expression of denitrification genes is induced in the presence of nitrogen oxides at low oxygen tensions. In estuaries with anthropogenic loading of nutrients, denitrifiers are often active in the sediments that have high levels of nitrate. Nogales *et al.* (2002) assayed the expression of *narG*, *napA*, *nirS*, *nirK*, and *nosZ* genes in two sediment samples taken from the River Colne estuary with high denitrification rates and found low expression of *nirS* genes and barely detectable expression of *nosZ* genes, even though all five genes were present in the samples. In a more recent study in the same estuary, Smith *et al.* (2007) found higher copy numbers of expressed denitrification genes at the estuary head where the rates of denitrification are highest. They also found higher copy numbers of the nitrate reductase genes (*narG* and *napA*) than for three *nirS* subgroups at each site sampled (Smith *et al.*, 2007). Although it is unclear at this time whether expression levels between different denitrification pathway genes are due to differences in transcript abundances at the time of sampling, or differences in detection limits between different genes, it seems that gene expression assays are progressing for studying marine denitrifiers.

It is also possible to use antibody based approaches to assay the accumulation of enzymes involved in denitrification pathways in environmental samples. Ward and Cockroft (1993) developed antisera to nitrite reductase from a marine *Pseudomonas stutzeri* isolate, and assayed sediment, water column and microbial mat samples. The antibody identified nitrite reductase in mat samples and was more specific than a DNA probe designed against the same species (Ward and Cockroft, 1993). More recently, other strains of denitrifiers have been isolated from both sediment and water column samples. Sequence information regarding the denitrifying genes should prove invaluable for future refinement of both sequence based approaches and the development of additional antibodies to denitrifiers important in the marine environment.

8.2. Anaerobic ammonia oxidation (anammox)

Although denitrification was thought to be the major sink of fixed N in the marine nitrogen budget, another process of converting fixed nitrogen to N_2 gas by anaerobic ammonium oxidation (anammox) has recently been shown to be important in marine environments (recently reviewed in Francis *et al.* (2007); Jetten *et al.*, 2003; Kuypers *et al.*, 2003) (see Devol, Chapter 6, this volume). Anammox bacteria are unusual chemolithoautotrophs first discovered in sewage treatment plants (Jetten *et al.*, 2003). They oxidize ammonia with nitrate as a terminal electron acceptor under anoxic conditions producing N_2 gas. Anammox bacteria (in the genera *Kuenenia, Brocadia, Scalindua,* and *Anammoxglobus*) form

a monophyletic cluster in the 16S rRNA tree that branches deeply in the order Planctomycetales (Kuypers *et al.*, 2003). Therefore, this monophyletic group can be targeted with 16S rRNA probes by PCR and FISH. Bacteria in this group also localize anammox reactions to a subcellular compartment surrounded by membranes with a unique ladderane lipid signature (van Niftrik *et al.*, 2004). Detection of these lipids in the environment can also be used to indicate the presence of anammox bacteria.

Anammox activity has been described in marine sediments (Amano *et al.*, 2007; Engstrom *et al.*, 2005; Hietanen, 2007; Penton *et al.*, 2006; Rich *et al.*, 2008; Risgaard-Petersen *et al.*, 2004; Rysgaard *et al.*, 2004; Schmid *et al.*, 2007; Thamdrup and Dalsgaard, 2002; Trimmer *et al.*, 2005) and in anoxic water columns (Dalsgaard *et al.*, 2003; Hamersley *et al.*, 2007; Jaeschke *et al.*, 2007; Kuypers *et al.*, 2003, 2005; Lam *et al.*, 2007; Thamdrup *et al.*, 2006) and is thought to account for 30–50% of total N_2 produced in oceans (Devol, 2003). Kuypers *et al.* (2003) identified Planctomycetes in the Black Sea on the basis of 16S rRNA sequences that corresponded to peaks of ladderane lipid profiles and nitrate concentrations. Using fluorescence *in situ* hybridization (FISH) they determined an anammox cell density of $\sim$1900 $\pm$ 800 cell ml^{-1}, enough to account for their observed ammonium oxidation rates (Kuypers *et al.*, 2003). An optimized set of PCR primers to the 16S gene from the *Candidatus* Scalindua group of annamox bacteria was developed recently and was used to show widespread distribution of these groups in marine and freshwater sediments (Penton *et al.*, 2006). Genomic approaches have proven fruitful for illuminating the physiology of anammox bacteria which have yet to be isolated in pure culture. Strous *et al.* (2006) used environmental genomics methods to assemble the genome of the uncultured anammox bacterium *Kuenenia stuttgartiensis* from a complex bioreactor community. The authors identified candidate genes responsible for ladderane biosynthesis and biological hydrazine metabolism which provide a blueprint for future physiological studies and could be good targets for anammox function in the environment.

8.3. Ammonia oxidation and nitrification

The oxidation of ammonia to nitrate is catalyzed by chemoautotrophs and is particularly important in the formation of ''new'' nitrate in the deep ocean (Ward, 2000). The major significance of nitrification is converting reduced N into an oxidized form, nitrate, that can lead to the removal of nitrogen from the system through denitrification (Ward, 2000 and Chapter 5, this volume). Ammonia oxidation is typically an aerobic process that occurs in aerobic or microaerophilic habitats or at interfaces between anaerobic and aerobic environments (Ward, 2000). The oxidation of ammonium to nitrate provides relatively little energy per mole of substrate oxidized. Therefore, ammonia-oxidizers and nitrifiers are slow growing microorganisms that depend on relatively large concentrations or fluxes of substrate. Cultivation of these microorganisms can be difficult and studying them *in situ* is limited by low abundances (<0.1% of total prokaryotes in marine water column) and low rates of activity typical of most environments. Thus, molecular approaches prove particularly useful for studying nitrification because they provide a sensitive means by which to assay organisms that are not abundant and have slow growth rates.

Molecular and immunological approaches have been used to characterize the distribution or diversity of nitrifiers. For a long time, there were only two known monophyletic lineages of aerobic ammonia-oxidizers found in the γ- and β-Proteobacteria (reviewed in Kowalchuk and Stephen, 2001). Recently, an exciting discovery was made; ammonia-oxidizer was isolated that belongs to the marine Crenarchaeota (Konneke *et al.*, 2005). Crenarchaeota are found in high numbers in cold oxic oceans (DeLong, 1992; Fuhrman *et al.*, 1992). Therefore, a numerous group of marine microbes have the potential to oxidize ammonia and may be major primary producers in environments deficient in organic nutrients and sunlight. For a more extensive discussion of marine nitrification we refer you to Ward, Chapter 5, this volume.

Non-marine ecosystems are dominated by β-Proteobacterial ammonia-oxidizers in the *Nitrospira* and *Nitrosomas* groups and, therefore, can be studied using phylogenetic (e.g. rRNA) approaches designed to target this subdivision. However, ammonia-oxidizers in the marine environment are found in both β- and γ- Proteobacteria subdivisions and, therefore, it is more difficult to use 16S rRNA directed studies to comprehensively study these organisms in marine systems. Therefore, many studies of ammonia-oxidizers in the marine environment focus on the β subclass of Proteobacteria and ignore the γ subclass. These studies have found that different populations occupy different niches in the marine environment. For example, distinct *Nitrosomas* groups correlated with gradients of salinity, ammonia, and oxygen in an estuary (de Bie *et al.*, 2001), *Nitrosomas* groups were shown to be associated with particulate matter in the Mediterranean Sea whereas *Nitrospira* groups were found in planktonic samples (Phillips *et al.*, 1999). *Nitrospira*-like 16S rRNA phylotypes were found to be widely distributed, even in polar oceans (Hollibaugh *et al.*, 2002). Nitrite oxidizers are found in several taxonomic groups, but they have not been studied much in any environment, including the marine environment.

The gene encoding the α-subunit of AMO (*amoA*) has been sequenced from many cultivated ammonia-oxidizers in the Proteobacteria and in general, *amoA* phylogenetic trees correspond well with those of 16S rRNA. The *amoA* gene also has greater sequence variation in comparison to 16S rRNA (Rotthauwe *et al.*, 1997) so it provides better phylogenetic resolution for the ammonia-oxidizers. The *amoA* gene is useful for studying ammonia-oxidizer diversity in the marine environment because it is possible to detect all Proteobacterial lineages simultaneously (Table 30.1). Nold *et al.* (2000) used *amoA* gene phylogeny to show that ammonia-oxidizers in Washington coast and Puget Sound sediments were dominated by β-Proteobacteria. Mortimer *et al.* (2004) measured nitrate concentrations and nitrification in vertical profiles of sediment samples from an organic-rich marine fjord and compared those profiles to microbial populations in the sediment cores by PCR and RT-PCR of 16S rRNA sequences. A shift in ammonia-oxidizing bacterial community composition was seen at the same depth in a sediment core where a major nitrate peak occurs at an anoxic depth, suggesting a correlation between bacterial community composition and nitrate generation (Mortimer *et al.*, 2004). Physiological studies on *Nitrosomonas europea* and *Nitrosomonas eutropha* suggest that anaerobic oxidation of ammonia may also be carried out by β-Proteobacterial

ammonia-oxidizing bacteria (Schmidt and Bock, 1997, 1998). Ammonia oxidation may be coupled to the reduction of manganese in continental shelf sediments (Mortimer *et al.*, 2004).

The archaeal *amoA* gene has also been targeted in the marine environment and distinct ammonia-oxidizing archaeal communities were found at the base of the euphotic zone, suboxic water columns, and in estuarine and coastal sediments (Francis *et al.*, 2005). A time series study in the North Sea showed the archaeal *amoA* correlates with a decline in ammonium concentrations and was 1–2 orders of magnitude higher than *amoA* from bacterial nitrifiers (Wuchter *et al.*, 2006). A similar patter was seen in Monterey Bay and the North Pacific Subtropical Gyre (Mincer *et al.*, 2007). Archaeal *amoA* is more abundant that bacterial *amoA* in estuarine sediments and shows a phylogentic patterning that changes with space across the estuary (Beman and Francis, 2006). Therefore, this recently discovered group of crenarchaeal nitrifiers may have a significant impact on the cycling of N and C in the ocean.

9. Summary and Perspective

The increasing application of molecular biological techniques to studies in marine nitrogen cycling demonstrates the feasibility of assigning functional roles in biogeochemical transformations to individual organisms. Molecular biological methods have been instrumental for identifying the presence of organisms for major nitrogen transformation pathways that may have long remained undetected otherwise. Gene based detection methods often uncover a vast diversity of uncultivated organisms which may in part explain missing N budget terms. For example, part of the oceanic fixed N deficit may be accounted for by the activity of new groups of N fixing organisms which are unaccounted for in current budgets (Codispoti, 2007). However it is also important to keep in mind that although functional gene diversity may be related to ecosystem biocomplexity and stability, genetic diversity is not necessarily related to the rate or extent of geochemical transformations encoded by those genes (Zehr and Ward, 2002). Measurements of the expression of specific genes make it possible to determine the distribution of individual genotypes that are physiologically active. It is now feasible to determine the correlations between the distributions of individual genotypes, expression of genes and physico-chemical factors in the marine environment. It may be years from now before this explosion of molecular and genetic data can inform predictive ecosystem models directly, but knowledge of the genetic potential and responses of organisms in the environment can provide a blueprint for refining considerations impacting ecosystem function. For example, Doney *et al.* (2004) suggest, ''Such an approach would be based on determining the environmental factors that regulate specific functions analogous to genetic regulation; that is models would start with a simulated ocean genotype, one much richer than presently resolved, and then predict, under a range of conditions the expression of a simulated phenotype, which could then be compared with genomic data''.

Isotope Tracer Methods for Studies of the Marine Nitrogen Cycle

Fredric Lipschultz

Contents

1. Introduction

The use of the stable nitrogen isotope, ^{15}N, as a tracer is central to the study of the nitrogen biogeochemistry of marine ecosystems and the physiology of marine organisms. Studies of ecosystem processes such as denitrification or nitrification would be extremely limited without direct rate measurements; although attempts are often made to infer rates from net changes in concentrations of various nitrogen species, through the use of inhibitors, and other indirect assessments. Similarly, the application of ^{15}N tracer methods has enhanced our understanding of organismal metabolism by allowing us to make

direct observations of transport, uptake, and assimilation of N compounds by organisms (see Mulholland and Lomas, this volume), and to identify and quantify transformations such as nitrification or nitrate reduction to ammonia (see Ward, this volume).

Advances in the use of ^{15}N in pelagic marine systems were initially compiled by Harrison (1983) over 20 years ago. At that time, the number of studies using ^{15}N was still quite small due to the difficulty of making the isotopic measurement itself, and the limited ability to isolate the various dissolved components of the nitrogen cycle. Most studies therefore focused on movement of ^{15}N from the dissolved to the particulate pool since particles are easily isolated by filtration. A decade later, Glibert and Capone (1993) described methods for studying nitrogen cycling in aquatic and sediment systems. Included in their discussion were issues such as isotope dilution; a problem that had become apparent as techniques were developed to isolate dissolved source pools such as nitrate or ammonium. Glibert *et al.* (1982), for instance, demonstrated that consumption and production of ammonium could be sufficiently large to dramatically change the ammonium isotopic ratio over the course of an incubation. These changes permitted the calculation of remineralization rates, which if not corrected for can introduce significant errors in calculations of uptake rates. Standard methods for uptake studies using ^{15}N were canonized for the JGOFS program (Knap *et al.*, 1996) and by Dugdale and Wilkerson (1986).

This review covers improvements in tracer methods as applied to pelagic marine over the past decade and attempts to point out promising new directions for the future. Applicable methods from the large literature on benthic nitrogen cycling studies are highlighted, but a complete review is beyond the scope of this effort. The focus is on the methods rather than on ecological or physiological applications of the methods, as the applications are covered in other chapters of this volume. However, salient applications of the methods will be mentioned to provide context as to why one might want to isolate and analyze the isotopic composition of a particular analyte. The review begins with major changes over the past years, discusses the basic experimental design of tracer experiments, then covers the analytical separation of the different constituents of the nitrogen cycle, and concludes with the ^{15}N analysis itself and interpretation of the resulting isotope data using various models.

Two major developments in analytical chemistry have greatly enhanced our ability to conduct nitrogen isotopic analyses in the ocean; improvements in the actual instrumentation for ^{15}N analysis, and advances in chemical detection that provide an ability to more accurately measure low concentrations of ammonium and nitrate (see also McCarthy and Bronk, this volume). Coupling of mass spectrometers to CHN (carbon, hydrogen, nitrogen) analyzers (e.g., Owens, 1988), combined with advances in computers that permitted extensive automation, has opened up the field to a far wider range of practitioners as well as permitted a vast expansion in the speed of analysis that can be completed. These advances have resulted in CF-IRMS (continuous flow isotope ratio mass spectrometry) essentially supplanting the alternative technology of emission spectroscopy for ^{15}N analysis.

The ability to measure low nanomolar concentrations of dissolved nutrients opened up the possibility of conducting true tracer experiments in the vast bulk of the oceans. Experiments using tracer level additions (typically considered to be 10% of the ambient source concentration) had been limited to high nutrient environments in coastal and estuarine habitats. In oligotrophic regimes, investigators commonly added a fixed tracer

addition (e.g., 30 to 100 nM) to all samples with concentrations near or below the detection limit, resulting in major perturbations to the resident microbial community. Precise detection of low nanomolar concentrations of ammonium progressed from concentrating methods, first by extraction (Brzezinski, 1987) and then by diffusion (Jones, 1991), to direct analysis by fluorescence (Holmes *et al.*, 1999). Most recently, long-pass capillary cells have permitted nanomolar analysis of ammonium using colorimetry (Li *et al.*, 2005). Parallel improvements occurred for nitrate/nitrite by increasing the sensitivity of colorimetric analysis (Adornato *et al.*, 2005; Oudot and Montel, 1988; Yao *et al.*, 1998; Zhang, 2000) and application of chemiluminescent detection (Garside, 1982; Braman and Hendrix, 1989). Improvements have continued with automation and the ability to analyze multiple chemical species at low concentrations (e.g., Hales *et al.*, 2004; Masserini and Fanning, 2000). Coupled with new techniques to isolate and extract dissolved nutrients for isotopic analysis, these improvements permitted measurements of uptake rates in the oligotrophic Pacific (McCarthy *et al.*, 1996) and Atlantic Ocean (Harrison *et al.*, 1996; Lipschultz, 2001; Rees *et al.*, 1999).

Another major improvement since the 1983 review is not analytical, but conceptual; there is an increasing awareness of the complexity of the nitrogen cycle. Our improved ability to study various fluxes means that investigators should assess not only movement of N compounds into the particulate pool, but also transformations among the dissolved pools such as ammonium regeneration and nitrification on a regular basis. Nitrogen fixation, routinely dismissed as insignificant prior to the mid-1990s, must now be considered in any study of new production (see Carpenter and Capone, this volume). The interplay between denitrification, anammox, dissimilatory nitrate reduction to ammonium (DNRA) and nitrification in suboxic systems is far more complex than imagined a few years ago, and new approaches are rapidly being developed (see Section 3.4; see also Devol, this volume and Naqvi, this volume). However, there is still no canonical set of rate measurements that must be made in every ecosystem, nor set of standard methods to be employed, and there remains sometimes sharp disagreement over the interpretation of tracer results (e.g., DON production).

2. EXPERIMENTAL DESIGN

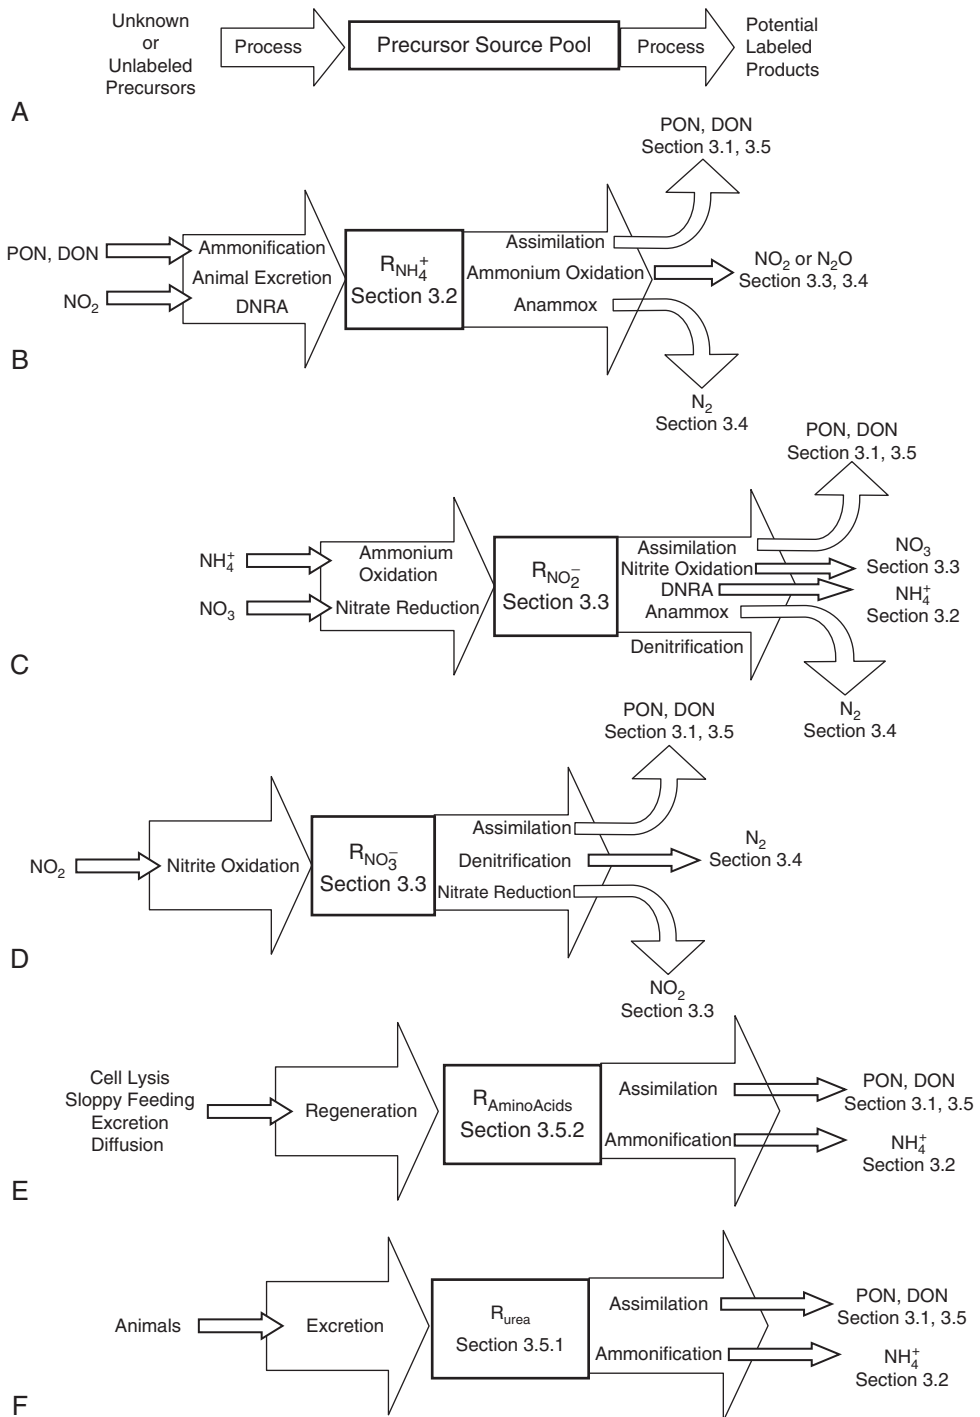
The basic terminology used in this review (Fig. 31.1A) includes the precursor and product, where the precursor can either be labeled or unlabeled. When labeled, the precursor will also be referred to as the ''source'' since it supplies tracer to the progressively ^{15}N enriched product pool. The process of isotope dilution refers to the addition of an unlabeled precursor to the source pool resulting in a decrease in the source isotopic ratio. The precursor could be known, such as for NO_3^- isotope dilution where NO_2^- is the only option, or unknown as with NO_2^- isotope dilution where NO_3^- or NH_4^+ could be the precursor. Isotopic equilibrium is achieved when the product pool has the same isotopic composition as the precursor pool and it is important to note that isotope dilution fosters this condition. At equilibrium, a rate can no longer be discerned by comparing the isotopic ratios of the pools. As suggested by the unidirectional arrows in Fig. 31.1, an assumption of the tracer method is that isotope recycling does not occur. However, we know this


Figure 31.1 Illustration of the different analytical pools, their potential inputs of unlabeled precursors, and losses of labeled analyte to potential product pools. The various metabolic processes affecting the central pool are listed, as well as the chapter section reference for information on the appropriate analytical separation techniques. (A) Cartoon of sources and sinks of a central pool, (B) Ammonium, (C) Nitrite, (D) Nitrate, (E) Amino acids, and (F) Urea.

in fact can occur for instance, when ammonium is assimilated but the organism is then eaten and ^{15}N is excreted from the animal back into the ammonium pool.

2.1. Initial planning

The initial planning of tracer studies using ^{15}N to measure nitrogen cycle rates requires consideration of several practical issues. Two aspects are inextricably linked to determine length of the incubation; turnover rate of the relevant pools and the detection limits for the analytical methods. The turnover rate (pool size^{-1} × uptake rate) needs to be estimated for both source and product pools to ensure that sufficient tracer can be detected in the product pool while dilution of the source pool is either insignificant or small enough so that isotopic equilibrium, isotopic recycling, or severe isotopic dilution does not become an issue (see Section 5.2.1) (Glibert *et al.*, 1982; Harrison and Harris, 1986). A balance therefore needs to be found between increasing the incubation time to enhance detection of tracer in the product pool and minimizing the incubation time to prevent potential issues affecting the source pool. Given the detection limit of mass spectrometers and a best-guess turnover rate for the product pool, one can estimate the relative trade-offs between incubation time and changes in isotopic labeling of the source and product pools at a given enrichment level.

Turnover rate × incubation time × source enrichment = change in enrichment, e.g., $0.1\ d^{-1} × 0.2\ d × 10\% = 0.2\%$.

Generally the shortest incubation possible would resolve this dichotomy for biogeochemical processes such as nitrification or denitrification. However, complications arise for uptake studies since short incubations have the potential to primarily detect transport (movement across the cell membrane) whereas longer incubations favor assimilation into organic compounds such as amino acids or proteins. This problem can be especially serious if the source isotopic enrichment increases the nutrient concentration sufficiently to significantly perturb the uptake kinetics of the resident microbial community. A sudden, large concentration increase can lead to "surge" transport during which transport and assimilation are uncoupled, that is a cell's internal pools swell rapidly and assimilation lags (Goldman and Glibert, 1982; Kanda *et al.*, 1988).

Another, more subtle, point to consider whenever the receiving pool is heterogeneous (e.g., PON or DON) is underestimating the turnover time due to achieving isotopic equilibrium between source and receiving pools. For instance, since the particulate pool typically includes detrital nitrogen, the isotopic difference between the two pools will never approach zero even when the live component is at equilibrium with the source pool. Hence, although no further flux between the compartments can be detected, the rate calculation will always yield a finite, albeit continuously declining apparent rate. This type of issue arises due to confusion of equating a pool, the operational entity actually measured, with a compartment, the well-mixed and kinetically homogeneous mathematical construct used in models (see Section 5).

Final points to consider include the degree of replication and treatment of the initial, or time zero, concentrations and enrichment of both the product and source pools. The ability to replicate analyses has been greatly enhanced by the advent of automated CF-IRMS so that there is no longer a reason not to measure duplicate samples as a minimum. However, given the high analytical precision of modern mass spectrometers, the replication should be from the field by incubating replicate bottles

from a single sample depth (a measure of natural variability) rather than from duplicate analyses from the same bottle (e.g., a measure of analytical error). Assumptions made concerning the initial time points can also greatly affect the calculated rates when product enrichments are small. Researchers will often assume that particles have constant natural abundance values, or only assess the natural abundance periodically during the study to account for small, natural (‰) level changes. Others add the tracer to the incubation bottle, deploy the incubation bottles and then immediately filter an initial time point for comparison with the final values. One then needs to decide how to interpret the initial time point given there is often a substantial time between tracer addition and filtration (often 30 min). During this interval, the population may experience abnormal conditions (e.g., high light exposure or surge uptake due to nutrient perturbation) prior to filtration. In oligotrophic samples from the base of the euphotic zone, this can be a significant fraction of the total uptake. Similarly, the initial source pool enrichment can simply be calculated from the initial concentration and the ^{15}N addition, or actually measured. Given the potential matrix effects on the final value, it is preferable to directly measure both the initial and final source enrichments with the same analytical procedure to reduce potential errors.

2.2. Incubation protocols

In addition to the aforementioned issues of the length of the incubation, there are a host of additional choices required during the planning of any incubation experiment, regardless of the involvement of ^{15}N. The primary production literature is replete with cautionary tales of bottle effects such as trace metal (Fitzwater *et al.*, 1982) or sampling (Williams and Robertson, 1989) contamination. Although these issues have not been directly tested for nitrogen cycling, there is no reason not to follow all the same precautions learned the hard way from other metabolic studies. One particular area of concern is potential trace metal contamination of the ^{15}N stock solution, an issue of major concern for ^{14}C work requiring passing the tracer stock solution through a Chelex column or diffusing gaseous CO_2 from the commercial source into a new container. As far as I am aware, such precautions are not routine in ^{15}N work (or at least not often reported). At a minimum, the stock solutions should be analyzed for trace metals to assess the potential for contaminating the incubation water. Another contamination concern is the actual material of the incubation vessel. Again as for primary production studies, incubations with ^{15}N should use polycarbonate or polystyrene bottles that can be adequately cleaned of trace metals and are transparent. Studies where UV is an important factor, such as nitrification, need to consider the wavelength transmission curves for the incubation vessel.

The decision whether to incubate on deck or to use an *in situ* deployment, such as a spar buoy, rests partially with the effects of light and temperature, but also with the issue of incubation length. Deck incubations generally use neutral density screens to adjust the light levels, and pump surface water through the incubator to control temperature. A potential concern with pumping surface water is whether there is a strong temperature gradient between the surface and the depth of one's deepest samples, as the organisms could become temperature-shocked due to the sudden temperature change. As with primary production studies, it is also possible to use

wavelength filters to adjust the light quality to better mimic the water column. Deck incubations have a significant advantage in that they permit time course analyses of uptake or sequential short-term incubations to study the effects of the diurnal light cycle or entrained rhythms on uptake. *In situ* deployments are often chosen to best capture the ambient light field experienced by the organisms. In addition, since primary production is often determined using an *in situ* spar buoy (e.g., JGOFS standard protocol (Knap *et al.*, 1996)), there are also advantages to parallel deployment of incubations for nitrogen cycling. The ability to conduct both ^{13}C and ^{15}N measurements simultaneously also has favored use of *in situ* incubations. However, such deployments typically last from dawn to dusk because exposure of incubation bottles from deeper, low light depths to surface light levels during deployment or retrieval in the middle of the day could bias the uptake rate. Since light period incubations can be as long as 18 h, issues raised earlier of pool turnover times potentially can be of concern.

2.3. Pathways

All pathways of the nitrogen cycle are now amenable to probing with ^{15}N, a capability reached over the past decade that continues to improve with the development of new methods such as for anaerobic ammonium oxidation (anammox) (see Devol, this volume). Although chapters are included in this volume covering individual pathways, it is worthwhile to review our current view of the entire nitrogen cycle from the viewpoint of tracking ^{15}N precursor additions to the different potential product pools (Fig. 31.1). The analytical techniques to separate the various pools are described in Section 3, the isotopic measurements of the pools in Section 4, and models for data analysis of the tracer movement between compartments in Section 5.

   Although it is rarely necessary, or desirable, to isolate all intermediate pools in the nitrogen cycle, it is important to consider their potential effect on rate calculations (see also Section 5). For instance, a study of denitrification rates might add $^{15}NO_3^-$ and extract the dinitrogen pool, but since nitrite and N_2O are intermediates, the tracer could become "trapped" in the intermediate forms until they reach a sufficient degree of labeling that the tracer becomes detectable in the subsequent, more reduced form. Clearly the true rate of dinitrogen formation would only be achieved once the intermediate pools are at isotopic equilibrium with the purported source pool, in this case nitrate. The salient point to consider is the turnover time of the intermediates and hence whether their isotopic ratio needs to be directly determined or whether they come into equilibrium rapidly enough to be considered homogeneous with the precursor pool. The issue of pools versus compartments is also central to the discussion concerning the rate of DON production (e.g., Slawyk and Raimbault, 1995; Flynn and Berry, 1999), which itself echoes the same, earlier debate over use of ^{14}C for studies of DOC production. The same issue affects the interpretation of attempts to measure the uptake of DO^{15}N (Bronk and Glibert, 1993) since the degree of labeling of each DON compound in the operational pool undoubtedly varies and one cannot discern which compound or compounds are actually being utilized. Additionally, the DON might simply be remineralized to ammonium and the tracer taken up from that pool, further aggravating the interpretation.

Another consideration while planning a tracer experiment is achieving mass balance, or accounting for the entire amount of added tracer. Although a common criterion for radioisotope experiments, it was not generally considered for ^{15}N work until an apparent loss of tracer during incubations was reported (Bronk and Glibert, 1994; Eppley and Renger, 1992; Laws, 1984; Slawyk et al., 1990a; Thybochristensen and Blackburn, 1993; Ward et al., 1989). Since the lost tracer was suspected to be in the DON pool, new methods were developed to study the nitrogen flux through the DON pool (see Section 3.5), although depending on the methodology, losses could also occur to other pools. For instance, achieving balance in $^{15}NO_3^-$ uptake experiments may require isolation of the nitrite pool in addition to PON due to phytoplankton excretion of nitrite, if the nitrate extraction protocol does not include nitrite. Such excretion can occur due to changes in light level or to poor coordination of nitrate and nitrite reduction within the cells, processes that appear to account for maintenance of the primary nitrite maximum in the ocean (Lomas and Lipschultz, 2006). Net nitrate uptake into PON would thus only equal gross uptake if all excreted nitrite was assimilated during the incubation. Filtration artifacts have also been suggested to cause loss of label, but direct analyses have not found it to be a significant problem (although see Wilkerson and Grunseich, 1990). Although mass balance should always be a goal as discovery of unaccounted losses stimulates new research, not all studies that have tested mass balance have found problems (Lipschultz et al., 1986; Slawyk et al., 1998).

3. ANALYTICAL SEPARATIONS

3.1. Particles

The simplest and most common method to remove particles from incubation water is by filtration (but see Slawyk et al., 1998 for an alternative approach). Glass–fiber filters, typically with 0.7 μm nominal cutoff (GF/F), are often the choice (Kanda et al., 1998) although other options have been explored such as Teflon, polycarbonate or silver filters. As has been shown for studies of primary production, care should be taken to minimize the pressure differential across the membrane to minimize cell rupture. For instance, Wilkerson and Grunseich (1990) reported 20–70% reduction in ^{15}N uptake with 13 cm Hg pressure differential compared to gravity filtration. Altabet (1990) tested aluminum oxide filters for natural abundance measurements since they are available in precisely defined pore size that would facilitate size fractionation studies. Raimbault et al. (2000) compared the two filter types for $^{15}NO_3^-$ uptake and found that while the GF/F filter failed to capture up to 60% of the PON, uptake rates were similar on both filters, implying that the small particles escaping filtration were not utilizing nitrate. Interestingly, although Altabet (1990) noted that the polycarbonate ring around the filter had to be removed via combustion before use, Raimbault et al. (2000) did not pre-combust the aluminum oxide filters but did not state how they dealt with it. Libby and Wheeler (1997) compared 0.2 μm teflon filters against GF/F filters for PON analysis and also found 60% higher PON on the teflon. Prior to analysis, one would either need to remove

the particles from the filter or to digest the material on the filter by persulfate oxidation (Raimbault and Slawyk, 1991). One could also use Ag filters that have known pore sizes and can be directly combusted, but they are obviously expensive. GF/F filters have been found to retain only ~50% of bacteria (Taguchi and Laws, 1988) which could partially account for the discrepancy between the 0.2 and 0.7 μm filter sizes (for more on PON analysis, see Chapter 28 by Bronk and McCarthy, this volume).

In addition to incomplete retention of particles, glass–fiber filters adsorb dissolved organics on the high surface area of the filter (Maske and Garcia-Mendoza, 1994). For ^{15}N studies, although mass retention of DON is not a major issue, retention of the highly labeled incubation water on the filter has the potential to affect the isotopic ratio of the retained particulates so that wetting the filter prior to filtration and rinsing afterwards with filtered seawater is a common practice. Filtered seawater is used to prevent osmotic shock of the living particles.

Regardless of the type of filter, the particle load needs to be preserved prior to mass spectroscopic analysis. Common options include drying or freezing the filter, with storage of the filter in Whirlpak bags, microcentrifuge tubes, alumninum or tin foil, or plastic Petri dishes. Lorrain et al. (2003) assessed the effects of removing inorganic carbonates and of preservation on suspended particulate samples for natural abundance ^{13}C and ^{15}N analysis. They observed that fuming with HCl vapors followed by drying resulted in no change, whereas dilute acid wash or freezing were capable of altering the signal. Since any changes were at natural abundance levels, either freezing or drying should be effective for tracer experiments. If fuming with HCl is used, note that filters should not be wrapped in tin or aluminum since the fumes are corrosive.

Determination of the size class of active consumers of nitrogen is a common objective and the typical approach is sequential filtration through different pore size filters. A filter with precise filtration characteristics, such as a 5 μm Nuclepore filter, is often used to remove large particles after incubation with ^{15}N, followed by removal of smaller particles onto a GF/F filter (Probyn, 1985; Probyn et al., 1990; Glibert et al., 1992; Hasegawa et al., 2000; Ward and Bronk, 2001). Uptake by the larger particles can be assessed either by removal of the large particles from the Nuclepore filter and capture onto a glass–fiber filter for analysis, or a parallel sample can be filtered onto a GF/F to determine uptake by the entire size spectrum from which is subtracted the uptake of the <5 μm particles. Alternatively, the wet oxidation method of Raimbault and Slawyk (1991) can be employed directly with the Nuclepore filter. An alternative to size fractionation is density fractionation, recently employed by Hamilton et al. (2005) who used gradient centrifugation to separate benthic algae from detritus.

Flow cytometry, where various properties of individual particles can be interrogated as a basis for cell sorting, can also be used for size fractionation. Lipschultz (1995) for instance, found that phytoplankton >10 μm preferentially used nitrate over ammonium compared to cells <10 μm. Flow cytometry also has the distinct advantage over all other particle analysis methods by permitting fractionations based on pigment content that allows isolation of phytoplankton from bacteria, or separation by pigment type to permit isolation of cyanobacteria from algal cells. Current flow cytometry (FCM) and CF-IRMS technology now permits dual ^{13}C and ^{15}N

analysis on cells as small as *Prochlorococcus* spp. (Casey *et al.*, 2007). Flow cytometry has also been applied for studies using other tracers such as ^{35}S (Zubkov and Tarran, 2005; Zubkov *et al.*, 2001) and ^{13}C (Li, 1994; Pel *et al.*, 2003). It is surprising that flow cytometry has not been more widely applied, but hopefully the continuing advances in instrumentation and availability of molecular probes will attract more researchers to this versatile tool.

Size fractioned particles can also include individual macroscopic particles ranging from large phytoplankton to seagrasses to zooplankton that have sufficient mass for analysis. Villareal and Lipschultz (1995) analyzed the internal nitrogen pool of individual cells of large, solitary phytoplankton such as the giant diatom *Ethmodiscus rex*, and Villareal *et al.* (1993) isolated visible aggregations of *Rhizosolenia* spp. for isotopic analysis. Nitrogen fixation by individual colonies of the cyanobacteria, *Trichodesmium*, has also been amenable to stable isotopic analysis (Orcutt *et al.*, 2001) using the low mass protocol of Owens and Rees (1989). Larger organisms such as seagrasses or zooplankton (Hasegawa *et al.*, 2001) can also readily be isolated, although care is required to prevent exceeding the mass limit of the CF-IRMS instrument or to adequately homogenize the sample to ensure analysis of a representative fraction.

3.2. Ammonium

As the primary inorganic nitrogenous nutrient in most marine ecosystems, tracing the fate of ammonium is critically important. Initial approaches to isolating ammonium for isotopic analysis by steam distillation were derived from the soil literature. Difficulties distilling samples with the typically low ammonium concentrations present in marine waters has led to development of a range of alternative techniques, with few researchers still utilizing distillation. In all methods involving ammonium, great care is required to minimize ammonium contamination from the atmosphere (e.g., cleaning compounds such as Windex), from sample/reaction containers and from reagents.

3.2.1. Organic extractions

Since the typical analysis of ammonium concentration relies on formation of a colored compound, indophenol, investigators have extended the analysis to extract and concentrate the dye for isotopic analysis, either by solvent extraction (Dudek *et al.*, 1986), or by solid phase extraction (Selmer and Sorensson, 1986; Wheeler *et al.*, 1989). In any such method, inadvertent extraction of dissolved organic nitrogen is a crucial concern that can strongly affect the blank and that can vary by depth or location. To overcome this problem, Preston *et al.* (1996b) further developed the extraction by derivatizing the indophenol dye after solid phase extraction and then analyzing the derivatized dye by gas chromatography–mass spectrometry (GC–MS). Even if compounds other than indophenol are derivatized, the GC separation, as well as monitoring the specific molecular ions for the derivatized indophenol, greatly reduces the potential interference from unknown compounds. Additionally, the GC–MS requires far less mass than typical CF-IRMS analysis, so that analysis of 50 nM ammonium in 50 ml samples becomes possible rather than extracting several liters or adding carrier ammonium to reach sample masses of

~1–4 μmol. The precision is also more than sufficient for studies of isotopic dilution (~0.05–0.22 at.% excess at 7% atom percent abundance). The main drawback is the multiple steps required for the analysis: dye formation, extraction, derivatization and isotopic analysis. Clark *et al.* (2006) recently extended the Preston *et al.* (1996b) approach by addition of a deuterated internal standard that minimizes the accumulated errors arising during the extensive sample processing, presenting results for ammonium regeneration rates from the North Atlantic at ammonium concentrations as low as 10 nmol kg^{-1}.

A recent improvement builds on the fluorometric analysis of ammonium concentration (Holmes *et al.*, 1999) with OPA (ortho–phthalaldehyde). Johnston *et al.* (2003) extracted the OPA-NH$_4^+$ derivative (1-sulfonato-iso–indole) by solid phase extraction and found that derivatized amino acids were not retained along with the indole on the column so that the method was specific. Since they developed the method for natural abundance work, the requisite high precision obliged analysis by CF-IRMS and its attendant high mass requirement (7.14 μmol N for a standard deviation of 0.5‰) that is difficult to achieve in oligotrophic waters. Since tracer experiments do not require such high precision, a lower mass could likely be used with the inherently lower precision GC–MS.

Another derivatization approach was developed by Gardner *et al.* (1991, 1993, 1995) based on high performance liquid chromatography. Ammonium is directly separated from the sample using cation exchange and then detected fluorometrically by post–column derivatization with OPA. Although not completely separated from ^{14}NH$_4^+$, increasing proportions of ^{15}NH$_4^+$ increased the retention time of the single peak, hence permitting construction of a calibration curve. The method has the advantage of using small sample size (<5 ml but high concentration) and not requiring extensive chemistry prior to the HPLC analysis, but does require careful matching of standards to sample salinity. It also requires large tracer additions to achieve a reasonable precision (standard error of 2 at.%), which limits its utility to habitats such as high nutrient coastal regimes where turnover times are fast and the perturbation is not thought to greatly affect the experimental interpretation.

3.2.2. Gaseous extraction

The second class of methods for isolating ammonium from samples relies on conversion of the ionic to gaseous form at high pH, with differences arising from the techniques used to remove the ammonia. As noted earlier, initial protocols were adopted from the extensive soil science literature on steam distillation (e.g., Glibert, 1982). However, this approach suffered from sample carryover effects and a high blank, both of which were partially responsible for the extensive literature as various approaches were taken to resolve the problems. Rather than actively forcing the gas from solution by heating, a range of methods have been developed that rely on passive diffusion into an acidic solution (Blackburn, 1979; Holmes *et al.*, 1998; Kristiansen and Paasche, 1989; Laima, 1993; Risgaard–Petersen *et al.*, 1995). Although these techniques generally require long periods of time to transfer the gas from the solution to the acidic trap, they do not require active intervention. For instance, Holmes *et al.* (1998) sandwiched a glass–fiber filter saturated with acid between two Teflon filters and floated it on the high pH sample while oscillating the

solution to breakdown the diffusion boundary layer and gently heating (40°C). Ammonia slowly diffused through the Teflon filters to the acidic filter over 14 days, whereupon the filter was recovered, dried and directly analyzed by CF-IRMS. A variant of this approach was employed by Lipschultz and Cook (2002) who extracted $^{15}NH_4^+$ from the cytoplasm of a sea anemone by pumping the samples through Teflon tubing surrounded by a static solution of acid that was then assayed for isotopic composition. As noted below, the diffusion methods also are often employed for sequential removal of ammonium, nitrate and DON after conversion of the additional components to ammonium (e.g., Slawyk and Raimbault, 1995).

3.3. Nitrite and nitrate

Isotopic analysis of these oxidized species requires conversion to forms amenable for entry into the mass spectrometer. The methods can be loosely grouped by the level of reduction, with the simplest being conversion of nitrate to nitrite, followed by conversion to dinitrogen, or complete reduction to ammonium. A range of methods exists for the separation of nitrite via organic extraction (Section 3.3.1). The analysis of ammonium has been discussed above (Section 3.1), so this section focuses only on the actual conversion of oxidized nitrogen to ammonium (e.g., Devarda's alloy, mossy Cd (Jones, 1978), or Zn dust (Gardner *et al.*, 1995)). Conversion to N_2 or N_2O will be mentioned, but direct analysis of these gases for denitrification studies will be covered in Section 3.4.

A common practice is to reduce NO_3^- to NO_2^- via cadmium reduction prior to isotopic analysis so that both species are combined for analysis. Although NO_2^- concentrations in many marine systems are very small compared to NO_3^-, there are instances where one is interested in both separately or in just NO_3^-. One approach is to measure the concentrations of both species and then, by assuming no tracer is present in NO_2^-, one can back calculate the actual $^{15}NO_3^-$. Alternatively, removal of NO_2^- prior to reduction of NO_3^- can be achieved by several approaches. Olson (1981) used sulfamic acid, however since the destructive action of the strong acid is reactivated during the subsequent diazotization reaction with NO_3^- after its reduction to NO_2^-, the yield of the final azo dye can be low and variable (Lipschultz, 1984). Yakushiji and Kanda (1998) took advantage of the reaction of sulfanilic acid with NO_2^- (see below). Rather than forming the final azo dye, the diazonium ion can be destroyed by heating which effectively destroys the initial NO_2^- present in the sample. Two new techniques remove nitrite by reaction with sodium azide in acetic acid buffer to produce N_2O (McIlvin and Altabet, 2005) or via reaction with ascorbic acid to produce NO which is then removed bubbling (Granger *et al.*, 2006).

3.3.1. Organic extractions

The earliest approaches to measuring the concentration of nitrate and nitrite relied on the conversion to a highly colored azo dye. Initial approaches to analysis of the isotopic content of nitrate and nitrite relied on similar conversion followed by extraction of the dye into an organic solvent in a separatory funnel. The organic phase was then removed, evaporated and the extracted dye analyzed for isotopic content (Olson, 1981; Schell, 1978; Wada and Hattori, 1972). The extraction was

improved by Kator *et al.* (1992), who employed the same basic solid phase technique as had been applied to analysis of ammonium (Section 3.2.1). Yakushiji and Kanda (1998) suggested use of sulfanilic acid as the initial coupling reagent rather than aniline that had been used by prior workers, as they found the aniline derivative was difficult to effectively extract. As with ammonium, the same issues of large, variable blanks are present with these methods since other organic compounds are extracted that can co-elute with the dye. Yakushiji and Kanda (1998) found that the blank can be greatly reduced by passing the effluent from the NO_3^- reduction step through the solid phase column prior to formation of any dye, hence removing adventitious organic nitrogen contamination prior to derivatization. This approach also worked sufficiently well for Johnston *et al.* (2003) that they were able to make natural abundance measurements. One still has to consider contamination from the aniline reagent used for the derivatization, but this should be far more constant than unknown DON compounds.

As for ammonium, Preston *et al.* (1998) resolved the blank issue for nitrate by derivatization of the eluted azo dye to a compound that was amenable to GC–MS analysis. An additional advantage was the ability to analyze very small amounts of nitrate or nitrite, which meant that low concentrations could be analyzed without addition of carrier nitrogen. Recently, Clark *et al.* (2007) modified the GC–MS approach (Preston *et al.*, 1998) by addition of an HPLC preconditioning step to maintain sensitivity of the mass spectrometer and use of a deuterated internal standard to increase accuracy. An extension of this type of approach eliminates the entire dye formation and extraction step by directly reacting nitrate with penta-fluorobenzyl bromide (PFB) to form an ester that can be analyzed by GC–MS (Miyajima *et al.*, 2005). Although developed for DON analysis after oxidation to nitrate (see Section 3.5.3), it could be adapted to $^{15}NO_3^-$ analysis itself. Interestingly, as well as reacting with NO_3^-, PFB will also directly react with NO_2^-, so that each analyte can be measured independently and simultaneously as the products have different masses. However, the method does suffer from poor derivatization of NO_3^- in the presence of Cl^-, which is clearly an issue for seawater samples! Miyajima *et al.* (2005) note that strict care is required to calibrate the procedure with standards at the same salinity as the samples.

3.3.2. Conversion to gaseous forms

An alternative approach for analysis of NO_3^- or NO_2^- is conversion to a gaseous form such as N_2O, N_2, or NH_3. Conversion to ammonia commonly employs Devarda's alloy combined with moderate heating. Sigman *et al.* (1997) observed that the alloy can add a significant blank that varies with the batch, and note that combustion of the alloy failed to reduce the blank while also reducing the reduction efficiency. They also suggest that Devarda's alloy may cause breakdown of some components of the DON pool in seawater, resulting in contamination of the $^{15}NO_3^-$ isotopic signal. Tanaka and Saino (2002) replaced Devarda's alloy with an aluminum reagent that reduced the blank and permitted analysis of nitrate at low concentrations. Once ammonia is formed, it can be analyzed by any of the methods described in Section 3.2.

Several investigators have used biological reduction of NO_3^- or NO_2^- to gaseous forms amenable for direct analysis via mass spectrometry. Risgaard-Petersen *et al.* (1993) and Jensen *et al.* (1996) used cultures of denitrifying bacteria to respire NO_3^- and NO_2^- to N_2 which was then stored for analysis by mass spectrometry. Given the large atmospheric burden of N_2 that represents a constant threat of massive contamination, Sigman *et al.* (2001), building on earlier efforts (Hojberg *et al.*, 1994), chose to work with N_2O by employing a mutant strain of a denitrifying bacteria that only produced N_2O. This approach had several advantages over chemical reduction to N_2 such as a 100-fold reduction in the sample size requirement, a reduction in the blank size, and a reduced time requirement of the analysis. A chemical method using sodium azide in acetic acid buffer to produce N_2O from NO_2^- has been successfully employed by McIlvin and Atlabet (2005) for natural abundance measurements in aquatic systems, and could thus been useful for tracer work.

3.4. Gaseous nitrogen—N_2O and N_2

In addition to the previously discussed methods where production of N_2 or N_2O from other forms of nitrogen is an analytical step, there are related methods for analysis of the gases where the gas itself is the form of interest. For instance, studies of denitrification have been transformed by the application of the isotope pairing technique (IPT) (Nielsen, 1992) that requires analysis of all three isotopic variants of N_2 ($^{28}N_2$, $^{29}N_2$, $^{30}N_2$). An excellent review of the IPT approach, including compilation of studies, and a comparison and discussion of various approaches to using IPT such as batch mode versus flow-through systems, was provided by Steingruber *et al.* (2001). The technique accounts for the two potential pathways for the appearance of the ^{15}N: either denitrification or coupled denitrification–nitrification where the source of some of the N is from nitrification (see Chapter 6 by Devol, this volume). The critical difference between direct analysis of the gas, and gas produced by various reduction techniques (Section 3.3), is that no information is retained in the isotopic forms of N_2 after reduction and one can simply employ standard mass spectroscopic analysis where the ion current in all three collectors is considered together. Although emission spectroscopy is no longer often used, it is capable of analysis of only the total isotopic ratio rather than all of the isotopic combinations. The comprehensive review of all extant denitrification methods for both terrestrial and aquatic systems by Groffman *et al.* (2006) should be consulted before embarking on an assessment of denitrification.

Recent work has demonstrated that denitrification is not the only pathway producing N_2. The anaerobic ammonium oxidation (anammox) pathway has received considerable attention and appears to account for the lack of ammonium in some denitrifying regimes (e.g., Dalsgaard *et al.*, 2003; Kuypers *et al.*, 2003). In addition to $^{15}NO_3^-$ to trace denitrification, parallel incubations with $^{15}NH_4^+$ are used to track the anammox pathway, $NH_4^+ + NO_2^- = N_2 + 2H_2O$ (Dalsgaard and Thamdrup, 2002; Risgaard-Petersen *et al.*, 2003, 2004; Rysgaard and Glud, 2004; Thamdrup and Dalsgaard, 2002;). Risgaard-Petersen *et al.* (2003) provide details on the calculations for the IPT (N.B. erratum by Risgaard-Petersen *et al.*, 2004) when both denitrification and anammox occur simultaneously because anammox alters the expected distribution of the N_2 isotopomers produced solely from denitrification.

An additional complication is the observation of DNRA in culture and the field by anammox bacteria (Kartal *et al.*, 2007). They reported production of ^{15}N:^{15}N from *Kuenenia stuttgartiensis* provided $^{15}NO_3^-$–with production of $^{15}NH_4^+$ that then fed the anammox pathway and thus masqueraded as denitrification.

Extraction of N_2 from water samples, generally stored in a gas–tight container sealed with a septum (e.g., Exetainer), involves partitioning of the gas into a suitable headspace such as helium. The gas is allowed to equilibrate and the headspace is sampled for introduction of the gas phase into the mass spectrometer (Capone and Montoya, 2001). Hamilton and Ostrom (2007) provide a detailed exploration of the use of exetainers and demonstrated high fidelity with the classic, large-volume extraction protocol. Rather than extraction into a headspace, several investigators have employed membrane inlet mass spectrometers (MIMS) to directly sample N_2 for denitrification and nitrogen fixation studies (An *et al.*, 2001; Jensen *et al.*, 1996). MIMS can also be used directly to measure denitrification by monitoring changes in the N_2/Ar ratio over time since the Ar composition reflects changes in temperature and other physical factors while change in the N_2 concentration reflects the balance between nitrogen fixation and denitrification (Kana *et al.*, 1998). An advantage of combining MIMS with the isotopes is the ability to separate the two contributions to the net flux. MIMS also obviates the need for the generally slow, separate extraction step. The membrane inlet configuration varies but always features a gas–permeable membrane that separates the mass spectrometer from the solution (Hartnett and Seitzinger, 2003; Kana *et al.*, 1994). A probe inlet (Hartnett and Seitzinger, 2003) permits analysis of depth zonation of rate processes in sediments but has only been employed for N_2/Ar measurements. Either a quadrupole or magnetic sector mass spectrometer can be used for the isotope pairing analysis, but the quadrupole can also simultaneously determine the N_2/Ar ratio.

Special mention goes to Sameshima-Saito *et al.* (2004) who developed a gas chromatographic method for $^{15}N_2$ analysis. Interestingly, they found that using a N_2 carrier gas of natural abundance with a thermal conductivity detector (TCD) permits detection of the enriched $^{29}N_2$ and $^{30}N_2$ species due to slight differences in their respective thermal conductivity from the $^{28}N_2$ carrier. However, although the method only requires the commonly available TCD-GC, does not suffer from atmospheric N_2 contamination problems, and is fairly precise, it is incapable of separating the varying contributions of $^{29}N_2$ and $^{30}N_2$ as both peak elute simultaneously. Thus, as with the MIMS approach, it is only suitable to screen for total N_2 production.

Analysis of $^{15}N_2O$ during nitrification and denitrification rate studies has been limited. Punshon and Moore (2004) further developed the method of Barnes and Owens (1998) to extract $^{15}N_2O$ produced from either $^{15}NH_4^+$ or $^{15}NO_3^-$ by natural samples. Using purge-trap gas chromatography with a quadrupole mass spectrometer, they were able to determine production rates for N_2O from nitrification. No production was observed with $^{15}NO_3^-$, which was not surprising since denitrification is not expected in the oxic water samples. The IPT for $^{15}N_2$ production from two different precursor pools has been extended to N_2O analysis by Bergsma *et al.* (2001) for production of N_2O from soils, and Master *et al.* (2005) explored the theory of isotopic pairing in IPT to include N_2O production in sediments. Nicholls *et al.* (2007) have recently applied a suite of ^{15}N additions to identify the pathways and rates of N_2O production in the suboxic regime of the

Arabian Sea. After extracting the gases by equilibration, they utilized cryofocusing of N_2O with separation from CO_2 on a capillary column before isotopic analysis by CF-IRMS of the N_2O. They found the vast bulk of N_2O was produced from NO_2^- reduction, with little contribution from nitrification at any depth within the suboxic waters. Their results also suggested an alternate source of nitrogen for dentrification, such as DON or DNRA via internal coupling to N_2 production.

Nitrogen fixation studies do not require analysis of the precursor N_2 isotopic composition, but rather the particulate receiving pool of prokaryotes and possibly DON or ammonium if there is significant leakage of the tracer to those pools during the course of the incubation (e.g., Glibert and Bronk, 1994). Tracer methods for nitrogen fixation have not been popular due to the ease of applying the acetylene reduction method (for a discussion, see Chapter 4 by Carpenter and Capone, this volume). However, as clearly analyzed by Montoya *et al.* (1996), use of $^{15}N_2$ has some significant advantages that have led to increased use in recent years. Among the advantages are increased sensitivity, ability to partition the total fixation rate into different pools (i.e., DON) or different organisms, and increased certainty since the acetylene reduction method always requires a potentially variable conversion factor. An example of these advantages is the recent batch culture study of Mulholland *et al.* (2004) that quantified the appearance of $^{15}N_2$ as NH_4^+ and DON, finding about 93% of the tracer was retained within *Trichodesmium* in 2 h incubations over the first 11 days of the experiment with little production of DON. They also found that a 4:1 conversion factor for the acetylene based rate best approximated the gross $^{15}N_2$ fixation rate. Capone and Montoya (2001) provide methodological details on both denitrification and nitrification using ^{15}N and acetylene approaches.

3.5. Dissolved organic nitrogen

Development of methods for analysis of the bulk DON pool have accelerated due to increased interest in the cycling of dissolved organic carbon (DOC). Analysis of this pool generally requires considerable processing to remove dissolved inorganic nitrogen (DIN) that would affect the DON isotopic ratio and to remove salts that are deleterious to the mass spectrometer. Additionally, in contrast to most other tracer applications, the interpretation of the experimental results is still open to discussion due to uncertainty in both the identity of the precursor pool and the huge heterogeneity of the DON pool. For instance, Bronk and Glibert (1993) isolated phytoplankton derived $DO^{15}N$ and employed it as a tracer for DON uptake, forcing the assumption that the pool was uniformly labeled and wasn't simply remineralized to ammonium prior to uptake by the particulate pool. Improvements in the ability to isolate specific fractions for analysis (Nunn and Timperman, 2007) will certainly help improve our understanding of the role of DON in the marine nitrogen cycle (see Section 6).

3.5.1. Urea
The basic approach for analysis of ^{15}N–urea is to use the enzyme urease to convert urea to ammonium. The few available methods differ primarily in handling the removal of pre-existing ammonium and the extraction of newly produced ammonium (see Section 3.2 for options). Hansell and Goering (1989) used ^{15}N–urea as a

precursor, but did not isolate the urea for isotopic analysis, using the breakdown rate for ^{14}C-urea to estimate the turnover time for urea and so correct for isotope dilution. Slawyk et al. (1990b) tested both simple diffusion and a combined distillation followed by diffusion approach to remove the ab initio ammonium and then the ammonium produced by the urease enzyme. The ammonia diffusion was clearly superior and they reported high precision despite only removing ~90% of the initial ammonium. They found extremely rapid turnover of urea with an 80% recovery of their tracer, proposing the missing tracer might be found as ^{15}NH$_4$$^+$, which suggests the need to monitor that pool rather than simply discard the pre-existing NH$_4$$^+$. Indeed, Lipschultz (2001) found rapid appearance of ^{15}N in ammonium during incubations with ^{15}N-urea in the Sargasso Sea. Rysgaard and Risgaard-Petersen (1997) used cation exchange to remove ammonium from seawater samples prior to enzymatic hydrolysis, followed by their micro-diffusion method (Risgaard-Petersen et al., 1995) to remove the ammonium and convert it to N$_2$ for mass spectrometry. Impressively, the cation exchange removed all of the 20 μM ^{15}NH$_4$$^+$ from a solution so that no residual tracer could be detected by mass spectrometry. Although only 10 nmol of urea was required, the 2 ml sample used in their protocol would require addition of carrier or rescaling of the volumes to handle the typically 10–100× lower concentrations found in natural waters. Lomas et al. (2002) modified Slawyk et al.'s (1990a,b) protocol to be able to use their normal distillation procedure and were able to remove 95% of the NH$_4$$^+$ with little urea loss and subsequently recover 95% of the NH$_4$$^+$ produced from the urease step.

Another approach (Patterson et al., 1993), that has not been attempted in aquatic systems, uses the same basic derivatization scheme for both amino acids and for urea that was employed by Preston et al. (1996a) for amino acids in seawater. Using N-methyl-N-(tert-butyldimethysilyl)trifluoroacetamide (MTBSTFA), they quantified the isotopic composition of doubly and singly labeled ^{15}N-urea in blood plasma, which suggests the method should be transferable to marine systems.

3.5.2. Amino acids

Two similar methods for isotopic analysis of amino acids in marine systems permit calculation of the turnover time of many of the individual amino acids (Preston et al., 1996a). In the earlier work, free amino acids were first extracted onto a Chelex 100 column, then eluted and derivatized for GC–MS analysis. The same derivatizing agent and GC column is used as Preston et al. (1998) used for their nitrate procedure (Section 3.3.1), making experience with one protocol readily applicable to the other. Most of the common amino acids can be simultaneously determined in the resulting ion chromatogram, but some such as Tyr, Glu and His suffer from low derivatization yield and are not detected. Sommerville and Preston (2001) extended the earlier work by an initial derivatization with IsoBOC (isobutylcarbonyl) to permit extraction with solid phase chromatography (rather than Chelex 100) before the same derivatization and GC–MS analysis as used by Preston et al. (1996a). By selective ultrafiltration and hydrolysis to free amino acids, they were also able to analyze the isotopic composition of amino acids in dissolved combined amino acids, dissolved peptides and dissolved proteins. These methods also permit measurement

of the production of amino acids from $^{15}NH_4^+$ or $^{15}NO_3^-$ rather than taking a black-box approach of extracting the entire DON pool.

One can also extract and analyze the amino acids within an organism, either as dissolved free or combined amino acids, as well as from proteins after hydrolysis with strong acid. Dohler and Hagmeier (1997) used 80% ethanol to extract amino acids from field populations of phytoplankton for ^{15}N analysis. Kanda (1988) used hot water, and Lipschultz and Cook (2002) used trichloroacetic acid (TCA) to extract the low molecular weight (LMW) pool, which includes the amino acids, for ^{15}N analysis. McClelland *et al.* (2002) measured the natural abundance of amino acids in proteins of zooplankton after hydrolysis by forming *N*-pivaloyl-*i*-propyl (NPP)–amino acid esters. Rather than analyzing the derivatized compounds by GC–MS, they separated the compounds by GC, then combusted the compounds exiting the GC for analysis by CF-IRMS as N_2 gas (GC-c-IRMS). Piniak *et al.* (2003) used the same derivatization to measure the production of free amino acids within an anthozoan after exposure to $^{15}NH_4^+$. Recently, Veuger *et al.* (2005) developed an analytical protocol similar to McClelland *et al.* (2002) using GC-c-IRMS to trace assimilation of ^{15}N into either D- or L-alanine. This provides a measure of bacterial versus algal uptake since only the bacteria synthesize D-Ala. Veuger *et al.* (2007) have presented an update to address potential artifacts such as racemization and varying bacterial D/L ratios. In addition, either method can be used for analysis of the full suite of amino acids. Extraction of internal pools is mentioned again in Section 3.6, and compartmental analysis of such data is discussed in Section 5.2.2.

3.5.3. Bulk DON

Separation of the overall DON pool from samples presents a wealth of sequential analytical choices that has fostered considerable disagreement over the reliability of the final results (Bronk and Ward, 2000). In general, the protocols require initial removal of PON, followed by removal of DIN, and finally conversion of the remaining DON using wet oxidation procedures based on standard methods for measuring DON concentrations. The resulting NO_3^- can then either be converted to a form amenable for mass spectrometric analysis (Section 3.3), or be reduced to ammonium before analysis (Section 3.2). Taking an historical approach in the next section, I summarize the two core methods in common use and the disagreements between their advocates. However, in addition to extant issues over the quality of the data, there are disagreements over the proper interpretation of the tracer during uptake of DI^{15}N that will be discussed in Section 5.2.2.

Bronk and Glibert (1991) initially employed an ion retardation column to remove DIN after filtration of particles, leaving only the DO^{15}N for mass spectrometric analysis. With this simple procedure, the DON was ready for isotopic analysis after evaporating the water. Unfortunately, the manufacturer no longer makes an adequate resin (Bronk, personal communication) and so this procedure is defunct. In addition, they analyzed the internal, LMW pool of the particulates using TCA to precipitate the higher molecular weight compounds. This step was motivated by a desire to directly analyze the presumptive precursor for the external DON rather than to assume the precursor was the DI^{15}N, since the tracer would be diluted within the cells when the newly synthesized, labeled organic compounds mixed with pre-existing ones or with ones created via catabolic processes. To overcome

the precursor problem, Bronk *et al.* (1994) combined the separated particulate and dissolved organic pools to calculate the ''gross'' uptake of $DI^{15}N$.

Slawyk and Raimbault (1995) developed a different approach, based on the methods of Axler and Reuter (1987), that employed standard methods for DON concentration measurements. Again beginning with filtration of particles, they tested both distillation and diffusion to remove the DIN before oxidizing the DON with persulfate to NO_3^-, which was then reduced to NH_4^+ using Devarda's alloy. The resulting NH_4^+ was finally captured for analysis by either distillation or diffusion. They recommended diffusion to remove NH_4^+ due to better recovery. Subsequently, and for the same reasons as Bronk *et al.* (1994), they retained the particulates with the DON so that the oxidation step included both pools, permitting calculation of gross uptake of $DI^{15}N$ (Slawyk *et al.*, 1998). By comparing gross uptake (they used the term WOPMC for ''without particulate material collection'') to the standard uptake measurement into just the particles, they were able to estimate DON uptake.

Without access to the ion resin, Bronk and Ward (1999) switched to vacuum distillation to remove NH_4^+, followed by peroxide oxidation under UV radiation to convert DON to NO_3^-. The nitrate was then reduced to nitrite and isolated by solvent extraction using tricholoroethanol (Olson, 1981) (Section 3.3). As noted above, Miyajima *et al.* (2005) have recently also analyzed DON by conversion to nitrate but employed GC–MS analysis of the PFB derivative. Their approach has the advantage of requiring small sample sizes, which also permits simply drying the sample to remove NH_4^+ during the DIN removal step. Clearly, any of the methods for $^{15}NO_3^-$ analysis (Section 3.3) would be suitable for this purpose too.

The positives and negatives of the different approaches to removal of DIN (vacuum distillation vs diffusion) and to convert DON to an extractable form are still a matter of disagreement (Bronk and Ward, 2000). Primary issues of concern include premature conversion of DON to DIN during the initial removal of DIN, and poor oxidation efficiency of DON to nitrate. Under the warm basic conditions used to remove DIN, DON can be lost as a result of basic hydrolysis of amino groups and subsequent volatilization of NH_3 (Bronk and Ward, 2000; Sigman *et al.*, 1997). With respect to poor oxidation efficiency for DON, a large community-wide comparison of DON oxidation methods indicates that proper use of the persulfate oxidation, UV oxidation, and high temperature combustion methods all yield similar results (Bronk *et al.*, 2000). Care should be taken, however, to monitor the performance of UV lamps over time when using the UV oxidation method and to take extreme care in keeping blanks low when using the persulfate oxidation method (e.g., Knapp *et al.*, 2005). The best approach to removing DIN prior to this step though remains unresolved at this point and should be evaluated by each investigator for their particular circumstances.

3.6. Internal pools

The isotopic composition of the internal constituents of cells has occasionally been determined to understand metabolic pathways. Separation of ^{15}N-labeled cellular constituents based on solubility in TCA was used by Wheeler *et al.* (1982) and Glibert and McCarthy (1984). Bronk and Glibert (1991) also used TCA extraction, followed by ultrafiltration to extract the soluble LMW component of field samples.

Kanda *et al.* (1988) similarly used solubility, but employed hot ethanol rather than TCA. Both approaches separate LMW compounds into the soluble fraction, and macromolecular compounds into the insoluble fraction. However, care should be taken comparing these different approaches, not just due to differential solubilities, but also the operational definition of "soluble" since filtration with micron pore size filters (e.g., GF/F) will produce a sharply different molecular weight cutoff compared to ultrafiltration or centrifugation. Although not using ^{15}N, Dortch and coworkers (Clayton *et al.*, 1988; Dortch *et al.*, 1984; Thoresen *et al.*, 1982) examined a range of techniques for such separations, including hot water rather than ethanol. Although it is not clear exactly where the molecular weight cut-off actually lies with these techniques, the soluble fraction is assumed to be primarily dissolved free amino acids and some portion of the dissolved combined amino acid pool. Kanda *et al.* (1988) used a simple compartmental model (see Section 5) of time course data to calculate the assimilation of $^{15}NH_4^+$ into the LMW pool and the movement of ^{15}N into, and out of, the macromolecular fraction. They found that exponentially growing diatom cells maintained a small internal LMW pool that rapidly (1–2 h) came into isotopic equilibrium with the external source and subsequent assimilation reflected macromolecular synthesis rates.

Appearance of ^{15}N into specific components of the heterogeneous and ill-defined LMW DON pool, such as individual amino acids within cells, either free or as components of proteins, has occasionally been determined (e.g., Dohler and Hagmeier, 1997). Piniak *et al.* (2003) measured the appearance of $^{15}NH_4^+$ into individual free amino acids in the sea anemone, *Aiptasia pallida*, but were not able to quantify rates since the isotopic composition of the precursor $^{15}NH_4^+$ inside the cells was not determined. The appearance of $^{15}NH_4^+$ inside cells was determined by Lipschultz and Cook (2002) in the anemone *Condylactis* using a teflon membrane to separate NH_4^+ from the remainder of the LMW compartment, trapping the NH_3 into an acidic solution on the other side of the membrane. Mulholland and Bernhardt (2005) extracted intracellular NH_4^+ from *Trichodesmium* IMS101 using boiling, Milli-Q water and then isolated NH_4^+ in the extract using solid phase extraction after creating indophenol dye (Section 3.2.1). Application of Preston *et al.*'s (1996a) method would permit analysis of the turnover of internal amino acids in a manner similar to that employed by Hama *et al.* (1987) using ^{13}C. Both McClelland and Montoya's (2002) or Veuger *et al.*'s (2005) approaches for ^{15}N-amino acid analysis of proteins also opens access to study of amino acid metabolism of marine organisms ranging from bacteria to zooplankton.

4. ^{15}N Measurement

Detailed reviews of the theory and practical aspects of the instrumentation for ^{15}N measurements are available in Preston (1993) for emission and Mulvaney (1993) for mass spectrometry.

4.1. Emission spectrometers

Emission spectrometers use the difference in optical properties of N_2 that arise from the increased mass of the different isotopomers to calculate the isotope ratio. The equipment is less expensive than mass spectrometers due to the lower complexity of

the equipment. The simplicity and low cost of the instrument, along with greater reliability, led to its initial popularity. Although the technique lacks precision compared to mass spectrometry, it is generally sufficient for tracer experiments (Preston, 1993). Greatly improved precision was achieved using diode array imaging technology (Lipschultz, 1993), but inherent limitations of the optical technique have stymied further improvements. Although it is possible to couple emission spectrometry to combustion systems and to automate the analysis (Therion *et al.*, 1986), rapid developments in mass spectrometry have resulted in this approach losing favor so that emission spectrometry currently is rarely employed.

4.2. Mass spectrometers

As noted above, major improvements in the design of mass spectrometers (e.g., Preston and Owens, 1983) have led to far wider use of the technology. Additional advances include the ability to take the instrument to sea (Owens, 1988), allowing feedback on experiments during the expedition. In contrast to most users of mass spectrometers, ocean scientists are often limited by the amount of mass available for analysis. A major problem with analysis of small masses is correcting for the blank and the differential amplification of the isotope beam currents in the mass spectrometer. Although a solution is simply to add sufficient ''carrier'' nitrogen of known isotopic content to each sample, care must be taken to ensure accurate, precise, and consistent additions to be able to retrieve the true sample values. Owens and Rees (1989) were able to analyze samples as small as 10 nmol N with sufficient precision for tracer studies by shifting the timing of the oxygen pulse used to combust the samples later in the analysis cycle. Since the oxygen pulse was a major contributor to the blank, the shift removed its contribution from the sample peak while still allowing complete combustion. Fry *et al.* (1992) presented a correction method for the blank using a mass series of known isotopic composition. Later, Fry *et al.* (1996) used cyrofocusing for small samples to improve the signal to noise ratio of the sample peak and enable analysis at natural abundance levels. Pearson *et al.* (2004) make note of their implementation of a ''nano-combustion'' interface to their CF–IRMS that permitted use of $\sim$1 nmol C rather than the typical 1 µmol C for stable isotope precision measurements. Such an interface would obviously be tremendously useful in a range of applications. In addition to improvements in the basic equipment, there are a host of alternatives to magnetic sector mass spectrometers that have not been explored by ocean scientists such as time-of-flight mass spectrometry that could permit analysis of spatial patterns or of individual cells (see Section 6).

Mass spectrometers are also now capable of simultaneously measuring the ^{13}C isotopic ratio and investigators have increasingly conduced dual ^{13}C and ^{15}N experiments. Slawyk and coworkers (Slawyk, 1979; Slawyk *et al.*, 1977) conducted the earliest studies that predated the advent of CF–IRMS. Subsequent applications include Collos and Slawyk (1984), and more recently Dauchez *et al.* (1995), Kudela and Cochlan (2000), Mousseau *et al.* (2000), Marba et al. (2002), Fan and Glibert (2005). As discussed below, one uses the same equation for ^{13}C uptake as for ^{15}N uptake studies (Legendre and Gosselin, 1996).

By far the most common type of marine sample analyzed by mass spectrometry is particulate, which means the analyst must cope with the filter used for separation (see Section 3.1). The most commonly used filter, the glass fiber GF/F, presents several challenges. First is reducing the blank, which is accomplished by pre-combustion of the filter (generally 2–4 h at 450°C) prior to use and storage so that the filters do not become recontaminated via adsorption of atmospheric nitrogen compounds. A second challenge is preparing the filter for introduction into the combustion system, as too large a filter package will result in jamming of the automated sample introduction apparatus. Artisanal solutions abound for folding and compressing the filter to fit into the tin foil cup used to contain the sample. Beside the obvious solution of using the smallest possible filter (typically 25 mm) that still permits adequate filtration time, compression can be achieved with lever-arm pill machines or simply smashing a rod down on the filter with a hammer (e.g., www.stableisotopefacility.ucdavis.edu/sampleprep.htm). Kanda *et al.* (1998) present a diagram for a custom-made tablet press capable of compressing 47 mm filters for use with automated sample trays on CHN analyzers coupled to mass spectrometers.

The actual combustion of the glass filter presents additional problems. The filters melt and potentially clog the combustion tube, and attempting to analyze too many samples in one run can fill the tube so that the final samples are no longer adequately combusted. The filters can also chemically interact with the quartz combustion tube and greatly shorten its life, resulting in leaks and high operating costs. The simplest approach is to replace the tube and its chemicals after each run, absorbing the cost as part of the analysis. However, many analysts use various types of sacrificial ''liners'' that are placed inside the combustion tube. These include quartz glass tubing that is discarded after each run or ceramic tubes (Kanda *et al.*, 1998) that last ~20 samples before discarding. Steel liners (SAE-J405–30310) can be obtained that will withstand multiple runs (>100) of ~50 filters with removal of the glass slag from each run accomplished using a hammer (pers. obs.).

Finally, glass fiber filters are commonly used as a solid support for other forms of nitrogen such as organics (Sections 3.2.1 and 3.3.1) or ammonium (Section 3.2.2). As there is no need for a small pore size to capture particles, a GF/C can be used as the reduced amount of glass is less a problem in the combustion system. It is possible to place the organic nitrogen compound in its solvent directly into a tin cup for drying, but some manufacturer's cups permit the solvent to leak through minute holes with resultant loss of sample.

5. Data Analysis

5.1. Basic equations

Once the appropriate isotopic measurements have been completed, there remains the need to choose the correct model to calculate the rate. Although typically denoted ''the rate equation'', in reality it is a model that bears with it assumptions that should be understood and appreciated. Sheppard (1962) set forth the basis for

interpretation of any tracer, stable or radioactive, and detailed the mathematics for compartmental analysis. His essential equation for transfer of a tracer from a source compartment to a sink compartment

$$\frac{dR_{sink}}{dt} = V(R_{source} - R_{sink}) \tag{31.1}$$

holds regardless of whether one considers DIN uptake into particles or ammonium oxidation to nitrite. R_{sink} is the isotopic ratio of the product or sink compartment, R_{source} is the isotopic ratio of the ^{15}N source compartment, and V is the transfer coefficient (AKA turnover rate with units T^{-1}). There are several important considerations that are often overlooked, but become apparent when the typical equation that is actually employed by most investigators Eq. (31.2) is compared to the above.

$$\frac{R(t)_{sink} - R(t-1)_{sink}}{\left(R_{source} - R(t-1)_{sink}\right)\Delta t} = V \tag{31.2}$$

The derivative is now approximated by a difference equation based on the single final measurement often conducted on the sink pool, $R(t)_{sink}$, and $R(t-1)$ is $R(t=0)$ which is assumed to be the natural abundance of N_2. The derivative makes clear that as the two compartments approach isotopic equilibrium, the rate of change of R_{sink} also asymptotically declines so that V remains constant.

However, when measuring nitrogen uptake by particles in the marine system, the presence of detrital nitrogen on the filter along with the living pool causes two problems. First, in the denominator, $R(t)_{sink}$ can never reach equilibrium with the ^{15}N source even though the active component (phytoplankton + bacteria) within the operational pool (PON) may actually be at equilibrium. Considering potential growth rates of the active pool on the order of 1 day, a long incubation may in fact permit substantial progress towards equilibrium, especially when R_{source} is declining due to dilution (e.g., Glibert et al., 1982). As a concrete example, if the living PON is 10% of the total and reaches 99% of equilibrium with an $R_{source} = 10\%$, the denominator will be 9% rather than 0.1%, resulting in a major underestimate of the true rate. Another issue arises from approximating the derivative by the difference since the trajectory of $R(t)_{sink}$ is curved whereas it is linear with the assumptions of Eq. (31.2). Finally, if $R(0)_{source}$ is used, then again the result can be an underestimate if isotope dilution is significant (Section 5.2.1). Many of these problems can be minimized by restricting the incubation period (see Section 2.1) or by ensuring that the operational pool is really a compartment (i.e., kinetically homogeneous and well-mixed).

Dugdale and Wilkerson (1986) discussed the equations and experimental considerations for determining uptake rates into particles (ρ) in marine applications, clearly pointing out that the turnover rate, V (Eq. (31.2)), should not be used since $R(t)_{sink}$ included the detrital component. They recommended using a 2–6 h incubation and the following equation:

$$\rho = \frac{R(t)_{\text{sink}} - R(0)_{\text{sink}}}{\left(R_{\text{source}} - R(0)_{\text{sink}}\right)\Delta t} \times \text{PON}(t) = V \times \text{PON}(t) \qquad (31.3)$$

where the numerator is the at.% ^{15}N excess in the sink pool (particulates) and $R(0)_{\text{sink}}$ is the initial at.% of the sink pool. They noted that multiplying V by the total PON gave the uptake rate, ρ, into the active pool. The turnover rate would only have well-defined meaning if the detritus was not present as during a bloom, or the living component was isolated (e.g., Lipschultz, 1995). Dugdale and Wilkerson (1986) also recommended that PON(t), the value for the particulates at the end of the incubation, be used rather than an alternative approach using PON(0). Legendre and Gosselin (1996) revisited the computation of rates to compare equations for ^{13}C and ^{15}N uptake, showing that by making some approximations (i.e., that the at.% ^{15}N initially was zero rather than 0.366 and hence that the at.% ^{14}N was 100%, and that R_{source} was about 9% greater than a nominal 10% addition), that Eq. (31.3) was identical to the standard equation for ^{14}CO$_2$ or ^{13}CO$_2$ uptake

$$\rho = \frac{R(t)_{\text{sink}} - R(0)_{\text{sink}}}{(R_{\text{DIC}})\Delta t} \times [\text{DIC}] \qquad (31.4)$$

where DIC is the concentration of dissolved inorganic carbon in seawater. One then need only substitute [DIN] for [DIC] and R_{DIN} for R_{DIC}. These assumptions make sense for radiotracers since the tracer additions are typically miniscule compared to the standard 10% stable isotope addition. Cobelli et al. (1987, 1992) earlier discussed the same issue at length. Several considerations of the effects of uptake of a single labeled DIN source in the presence of uptake of multiple other nitrogen sources have led to the conclusion that Eq. (31.3) is accurate (Collos, 1987; Legendre and Gosselin, 1996).

5.2. Specific models

5.2.1. Isotope dilution
Models for calculating isotope dilution are based on the assumption of a single, well–mixed compartment losing uniformly labeled material while simultaneously gaining unlabeled material. Although assessment of just the isotopic content over time permits calculation of the turnover time of the compartment, when combined with concentration measurements one can also calculate transport rates into, and out of, the compartment. Application to marine systems originated with Blackburn (1979) and Caperon et al. (1979), and was then extended by Glibert et al. (1982, 1985) and Laws (1984). The extent of dilution was tested in a range of environments over the ensuing years (Glibert et al., 1992; Harrison and Harris, 1986; Kanda et al., 1987; Lipschultz and Cook, 2002; Lipschultz et al., 1986) with the extent ranging from considerable to limited, suggesting that each investigator should assess this likelihood independently. Although attention has primarily focused on ammonium,

there have also been reports of isotope dilution for nitrate (Lipschultz, 2001), urea (Slawyk *et al.*, 1990b), and amino acids (Preston *et al.*, 1996a).

As with the equations for transfer between two compartments Eqs. (31.1–31.4), the same equation for isotope dilution (Glibert *et al.*, 1982) applies to any single compartment that can be measured (see Section 2).

$$P(t) = P(0) + (d - u) \times t \qquad (31.5)$$

and

$$\ln[R(t) - R(0)] = \ln[R(0) - \text{NA}] - [d/(d - u)] \\ \times [\ln(P(t) - P(0))] \qquad (31.6)$$

where d is the dilution or input of unlabeled material to the compartment, u is the loss from the compartment with the same isotopic composition (R) as the compartment, and NA is the natural abundance value prior to the addition of the tracer. The concentration of the material (P) at any time, t, is the sum of the net change over time, $(d-u) \times t$, from the initial amount $P(0)$. Glibert *et al.* (1982, 1985) discuss the various permutations when the concentration doesn't change or the concentrations are undetectable. They pointed out that R_{source} in Eqs. (31.1–31.4) needs to reflect any isotope dilution and that u is not equivalent to particulate uptake (ρ in Eq. 31.3) unless there are no other losses from the dissolved pool such as nitrification in the case of ammonium isotope dilution. Practically, isotope dilution can be calculated using the equations outlined in Mulholland and Bernhardt (2005).

It is worth noting that the term isotope dilution has also been applied to applications where the concentration of a compound is determined isotopically rather than by direct chemical determination. The most familiar application is the determination of the magnitude of a blank (pre-existing ^{14}N in an analysis) by adding a known amount of ^{15}N to a sample and determining the decrease from the expected isotopic value of the tracer addition. This concept can also be used in field samples, such as for determining the concentrations of dissolved and combined amino acids.

5.2.2. Compartmental analysis

Compartmental analysis is an extension of the simple, single compartment models (Sections 5.1 and 5.2.1) to include multiple compartments. It is far more commonly applied in medical studies or in other ecosystems than the marine environment. Even for ^{15}N, the soil, plant, and limnological communities have applied the technique with great success (e.g., Tank *et al.*, 2000). It also has a long history of use in conjunction with radioisotopes such as carbon (Smith and Geider, 1985; Smith *et al.*, 1979) or phosphorus (Perez-Martinez *et al.*, 1995; Smith *et al.*, 1985). However, to implement such an approach requires analysis of the mass and isotopic composition of nearly all compartments, as well as over multiple times, which represents a major analytical undertaking for stable isotopes. However, a more

complete analysis of the nitrogen cycle not only ensures that there is mass balance of the tracer (or at least identifies clearly identifies a problem if some tracer is missing), but also ensures that rates of individual processes are placed in their biogeochemical context. One also gains more confidence in the calculated rates due to the additional constraints of multiple assessments of the same processes. For instance, measuring the $^{15}NH_4^+$ loss via isotope dilution and ^{15}N appearance in particles as well as NO_2^- means that the sum of uptake and ammonium oxidation are constrained to equal (in a statistical least–squares sense) the net NH_4^+ loss term. The most complete example of compartmental analysis of the aquatic nitrogen cycle provides an example of the power of the technique (Lipschultz et al., 1986).

   A simple example is that of Kanda et al. (1988) who coupled the internal LMW and macromolecular compartments together to calculate uptake of external $^{15}NH_4^+$ into the LMW, as well as rates of macromolecular catabolism and anabolism. Bronk (1999) isolated the intracellular DON pool and calculated an intracellular transformation rate, which quantifies the flow of nitrogen from the intracellular NH_4^+ pool to the intracellular organic N pool. LaRoche and Harrison (1987) explored a range of three compartment models to explain the observed exchange of ^{15}N between particulate and ammonium pools. The third compartment, DON, was not directly measured but was tested as a sink for the missing ^{15}N that initially disappeared and then reappeared from the mass balance calculation (see Section 2.3). The best model was one lacking in biological veracity as the tracer could move from NH_4^+ directly to DON without passing through a living cell (PON), although this is the same conceptual model underlying some estimates of phytoplankton DON loss. This model would work operationally if the DON precursor pool within the cells rapidly came to isotopic equilibrium with the external DIN pool during the incubation. Here, defining ''rapid'' is the key issue and likely a contributor to some of the differences between estimates of DON release since a long (relative to the precursor reaching equilibrium) incubation would result in a very different result than a shorter incubation. Without direct measurements of all precursor compartments (including actually knowing the appropriate precursor's identity), as was attempted by Bronk and Glibert (1991), it is best to take a step back and combine both DON and PON, as is done in the calculation of gross nitrogen uptake rates (Bronk et al., 1994; Slawyk et al., 1998). Flynn and Berry (1999) should also be consulted. It should, however, be possible to better understand the mechanisms of DON loss by measuring ammonium and amino acid isotope dilution of both internal and external compartments now that improved methods are available (e.g., Mulholland and Bernhardt, 2005; Mulholland et al., 2004).

5.3. Comparisons between ^{15}N rates and other methods

Confidence in rates of nitrogen cycling can be gained not only by redundant ^{15}N measurements such as described above (Section 5.2.2), but also by comparison to other analytical approaches. Comparison of rates measured by tracer with those measured by net changes in concentration is the most common approach, but requires the assumption that net concentration change is really due to only a single

input or output. For instance, comparing $^{15}NO_3^-$ uptake into particles to $\Delta[NO_3^-]$ requires assuming no nitrification.

5.3.1. Nitrification

There have been very few comparisons of different methods for determination of nitrification rates. Enoksson (1986) compared three isotopic methods, ^{15}N, $^{14}CO_2$ incorporation with N-serve to inhibit nitrification, and NO_3^- isotope dilution. She found ammonium oxidation measured with ^{15}N was 2–7 times greater than determined by the other methods, but pointed out that both different incubation times (from 1 to 12 days) and different substrate additions were used which would greatly alter the measured rates. Jones (1992) found a good relationship between a ^{14}CO method and ^{15}N for measuring ammonium oxidation. Although most researchers have switched to direct assessment using ^{15}N, there is still usage of the $^{14}CO_2$ method (e.g., Brion et al., 2000).

5.3.2. Denitrification

By far the majority of denitrification studies have been in sediments, with limited successful direct measurements in anoxic water columns (see Chapter 6 by Devol, this volume). There have been several comparisons between the most commonly used denitrification assay, the acetylene block technique, and ^{15}N based measurements (reviewed in Cornwell et al., 1999). The acetylene block has generally been found to underestimate denitrification since it also blocks nitrification within the sediments that acts as a major source of oxidized nitrogen in a process termed coupled nitrification–denitrification (Seitzinger et al., 1993). Incomplete blockage of reduction of N_2O to N_2 is also a potential issue. ^{15}N based methods initially suffered from inability to resolve the sedimentary from water column contribution due to lack of labeling in the sedimentary $^{14}NO_3^-$ precursor. The IPT method (Section 3.4, Nielsen, 1992) resolved this issue. Welsh et al. (2001) compared the IPT with acetylene block in sediments from a seagrass bed where assumptions of the IPT approach might not be met. Rates were similar in the dark, but rates in the light were twice as high with acetylene blockage. Assuming the IPT was correct, they suggested the excess N_2O arose from dissimilatory nitrate reduction to ammonium (DNRA) activity. Bernot et al. (2003) compared the ^{15}N-MIMS IPT (Section 3.4) with acetylene block rates in estuarine sediments, finding that addition of chloramphenicol was need during the acetylene block incubations to limit changes in the microbial community's response to the ideal conditions created during the assay. They recommended the use of short-term acetylene block assays as a cost-effective substitute for ^{15}N based analysis.

The early approach to denitrification rates of direct measurement of net N_2 fluxes resulted in rates that were often too high due to long incubation times (Seitzinger et al., 1993). However, Hamersley and Howes (2005) have recently optimized the protocol for direct measurements after carefully considering a range of variables. Rather than a batch or closed incubation, Risgaard-Petersen et al. (1993) used a continuous flow system and found excellent agreement with the IPT approach. A variation of the direct measurement technique employs the N_2/Ar

ratio measured using MIMS (Hartnett and Seitzinger, 2003; Kana *et al.*, 1998) that doesn't require long incubations. However, these direct measurements of net N_2 flux cannot resolve any losses of N_2 due to nitrogen fixation. As noted above (Section 3.4), An *et al.* (2001) have developed a ^{15}N method to resolve both coupled nitrification–denitrification as well as N_2 fixation. Eyre *et al.* (2002) found that N_2/Ar could be affected by interaction of O_2 with N_2 in the mass spectrometer, resulting in artificially higher rates. Removing oxygen prior to MIMS analysis resulted in comparable rates with the IPT method. Along with suggested improvements, they present a detailed analysis of the assumptions of both techniques. Kana and Weiss (2004) noted that their particular instrument did not suffer the same oxygen effect and so their rates and technique were valid. Eyre *et al.* (2004) retorted that indeed their instrument had the effect and each investigator should test the magnitude on their equipment. They noted that they consistently found slightly lower rates with N_2:Ar and suggested that nitrogen fixation was the cause.

5.3.3. Uptake

After a spate of findings that ^{15}N uptake did not match the net loss of nutrient during incubations (e.g., Eppley and Koeve, 1990; Eppley and Renger, 1992; Slawyk *et al.*, 1990a; Ward *et al.*, 1989), more recent comparisons have found far better agreement. Boyd *et al.* (1995) reported a 1:1 correspondence between net nitrate loss and $^{15}NO_3^-$ uptake into particles over a range of NO_3^- concentrations, without the need to invoke loss to DON or filter losses. Raimbault *et al.* (2000) concluded that large discrepancies between net losses and uptake were likely erroneous since their results were in agreement once a small DON loss (∼10%) was included. They also found little loss of $^{15}NO_3^-$ to submicron particles passing the standard GF/F filter (see Section 3.1). There was also no detectable isotope dilution of nitrate during their 12 or 24 h incubations, although it is important to note that at the lowest concentrations (as low as 3 nM), ^{15}N additions were 42 nM so that isotope dilution would likely only have been detectable if true tracer additions were utilized. For instance, Lipschultz (2001) observed significant isotope dilution of a 1 nM $^{15}NO_3^-$ addition with constant 10 nM concentrations during incubations in the Sargasso Sea. In such a case, there was no net concentration change so that ^{15}N would be the only way to measure a rate.

Besides phytoplankton, the only comparison for other autotrophic systems is that of Naldi and Wheeler (2002) and O'Brien and Wheeler (1987) who both found good agreement between uptake by macroalgae and ^{15}N-based uptake rates, with little loss of DON or ammonium.

6. Future Directions

The past two decades since Harrison's review in 1983 has seen good progress in techniques to isolate and analyze the isotopic composition of the dissolved inorganic pools. Progress has been far slower for the dissolved organic, and particularly the

particulate, nitrogen fractions, with both DON and PON essentially still dealt with as a black box. For PON, flow cytometry holds great promise as a tool to study different size fractions or pigment classes (Lipschultz, 1995; Casey *et al.*, 2007 submitted for publication), but has not been widely adopted for metabolic studies. Use of ^{13}C rather than ^{14}C removes the concern of contaminating the instrument and permits dual isotope (^{13}C and ^{15}N) experiments. Vital stains open the window for a range of metabolic studies of living cells, and molecular techniques now permit exploration of a wide range of taxonomic or even metabolic groupings. For instance, Pel *et al.* (2003) used pyrolysis GC–MS to analyze for ^{13}C labeled fatty acids in very small amounts of filamentous cyanobacteria isolated by fluorescence-activated cell sorting. Such a technique might be applicable to marine species such as *Trichodesmium* and analysis of ^{15}N. Chen *et al.* (2000) developed an *in situ* PCR method for prokaryotes that permitted flow cytometric analysis of the expression of a specific gene inside bacterial cells. This type of approach could also be coupled to isotopic analysis to truly relate enzyme activity to rates.

A range of molecular techniques that have been coupled to stable isotopes are poised to make important contributions such as permitting attribution of rates to the responsible organisms. Radajewski and coworkers (Hutchens *et al.*, 2004; Radajewski *et al.*, 2000) developed stable isotope probing (SIP) which uses ^{13}C labeled growth substrates to selectively recover "heavy" ^{13}C-labeled DNA by density gradient ultracentrifugation. Radajewski *et al.* (2003) provides an excellent review of the advantages and disadvantages of the different SIP approaches. The labeled DNA can then be amplified, cloned, and sequenced to identify which organisms are actively growing on the substrate. Unfortunately, this approach requires long incubations and very high substrate labeling to achieve sufficient separation of the labeled DNA. MacGregor *et al.* (2002) recovered rRNA using biotinylated oligonucleotide probes to bind the RNA to streptadivin-coated magnetic beads on a column. Although the application involved determining the natural abundance ratio of the RNA, they note potential application in tracer studies. More recently, Pearson *et al.* (2004) replaced the biotinylation step with oligo-dT paramagnetic beads to separate rRNA for isotopic analysis. To overcome the significant amount of material previously required, they developed a "nano–combustion" interface to the CF-IRMS so that ~3 nmol C was required for 0.3‰ precision. For nitrogen, Cadish *et al.* (2005) recently explored protocols for ^{15}N-DNA SIP, finding an 40 at.% labeling of the DNA was required which would limit the application of this approach. A major limitation of this approach is the co-mingling of heavy, isotopically labeled DNA with unlabeled DNA with high G+C content causing smearing of the signal. This was overcome by Buckley *et al.* (2007) who employed sequential CsCI density gradient centrifugation, with the second gradient including bis–benzimide.

Another interesting suite of approaches that undoubtedly will be further developed employs SIMS—secondary isotope mass spectrometry (also know as multiple-isotope imaging mass spectrometry (MIMS)). Orphan *et al.* (2001) applied FISH–SIMS or fluorescent *in situ* hybridization SIMS to detect isotopically light carbon in archaeal cells, identifying the Archaea by FISH and using SIMS to quantify the isotopic composition of individual cells by ion microprobe. Finzi *et al.* (2006) applied nanoSIMS to visualize uptake of $^{15}N_2$ and $^{13}CO_2$ by individual cells of a

single filament of *Trichodesmium*. Lechene *et al*. (2007) demonstrated the power of this new technology by imaging isotopically labeled, individual nitrogen-fixing bacteria within shipworms, and the transfer of ^{15}N to adjacent tissues. Rather than FISH to visualize the cells, TEM sections allowed precise registration of the two images of intact shipworms. Note that these approaches identify particular organisms involved in a particular process rather than the rate of an entire population of organisms, for which flow cytometry is far better suited.

Although beyond the scope of this review, it is worth mentioning two other areas where ^{15}N tracers could be applied to studies of marine organisms. There is burgeoning interest in a subset of proteomics that employs stable isotopes such as ^{15}N. Of particular interest is the potential to conduct $DI^{15}N$ incubations and then separate the proteome to detect appearance of the tracer into specific proteins using a wide range of techniques reviewed recently by Tao and Aebersold (2003). Application of electrospray ionization – fourier transform ion cyclotron resonance – mass spectrometry (ESI-FTICR–MS) to analysis of DON (Nunn and Timperman, 2007) could also be used to identify $DO^{15}N$ produced by phytoplankton after exposure to $DI^{15}N$. Nuclear magnetic resonance (NMR) can also be employed with ^{15}N to study metabolism of a wide range of organisms (Mesnard and Ratcliffe, 2005). Applications have included cytoplasmic storage of NH_4^+ or NO_3^- in cells as well as assimilation pathways.

ENZYMES AND NITROGEN CYCLING

Contents

1. PRINCIPLES AND PRACTICE

1.1. Importance of enzyme-mediated reactions

Enzyme–mediated reactions are responsible for most of the transformations of nitrogen (N) that occur in the marine environment, thus measurements of enzymes have figured prominently in oceanographic work for some time, especially in terms of N assimilation (see Falkowski, 1983).

Many different measurements of enzymes are undertaken to acquire different types of information. For example, the presence of genes for an enzyme has been used to infer whether organisms are capable of performing particular functions, the expression of those genes or the appearance of the enzyme protein is used to indicate if and under what conditions the gene is functioning, while assay of the activity of the enzyme has been used to infer rates of particular processes (see Section 2). In fact, virtually all measurements classified as ''molecular'' and most rate measurements of ''uptake'' are, in fact, measurements of enzymes. Because strictly molecular methods (i.e., the capacity to perform a reaction; see Chapter 30 by Zehr and Jenkins, this volume) and N uptake (i.e., the net result of enzymatically mediated processes; see Chapter 6 by Mulholland and Lomas, this volume) are discussed elsewhere in this book; in this chapter, we will focus primarily on measurements of enzyme activities.

Conceptually, measurements of enzyme activity are easier to interpret than measurements of the presence or absence of particular enzymes, genes, or transcripts or rates of transcription and translation, and are more likely to be related to physiological rates. Measurements of enzyme activity have often been proposed as quantitative indices/estimators of biological rate reactions. Moreover, enzyme activity can often be measured quickly and using conventional ocean-going equipment, so that these measurements are more easily incorporated into oceanographic studies. That said, assays of enzyme activity are subject to different biases than molecular methods, and the interpretation of enzyme activity relies on specific knowledge of reaction pathways and their regulation (see Section 1.3.5). Interpretation of enzyme activity is often complicated when pathways are branched, cyclic, or reversible; when different enzymes produce similar products or compete for similar substrates; or when different pools of the same enzyme are regulated differently.

Paradoxically, as we have gained more information about enzymes from the molecular perspective, the interpretation of enzyme activity measurements and the classification of enzymes have actually become more complicated. First, there are different classification schemes for gene or protein sequences (derived from molecular biology) and biochemical function (derived from classic enzymology). For example, enzyme genes and proteins are classified in term of homologous structures and sequences. In contrast, in biochemical classification schemes, enzyme nomenclature is based in the reaction that is mediated (the International Union of Biochemistry and Molecular Biology (IUMB) uses Enzyme Commission (EC) numbers for this purpose; Table 32.1). Thus, two evolutionary divergent enzymes that catalyze the same reaction would fall into the same EC category, while their functional proteins might be quite distant based on genetic analysis. In addition, enzymes that catalyze processes such as membrane transport, where there is no actual chemical change, cannot easily be accommodated in the biochemical classification scheme. For example, because they mediate no chemical transformation ''permeases'' or ''translocases'' are generally not included in enzymological classifications, yet are frequently adopted in the molecular biology literature.[1] In this discussion, we will generally classify enzymes according to activity (i.e., EC numbers) but we will also consider pathways that mediate no chemical transformation.

In 1983, Falkowski observed, ''there is little information on the N enzymology of marine organisms'' and also noted that there was ''scanty'' information about transporters (Falkowski, 1983). At that time, most of the information available for enzymes was based on activity assays with relatively few attempts to purify enzymes and characterize their structural and functional diversity, and very few attempts to use molecular or other techniques to probe the full range of enzymes mediating

reactions affecting the marine N cycle. Much of the information regarding N assimilation was based on analogies with processes in higher plants and freshwater green algae. Remarkably, much of this information has proven to be correct.

Since 1983, the technical aspects of enzyme measurements have changed radically. For perspective, the first monoclonal antibodies were produced less than a decade before (Köhler and Milstein, 1975), practical DNA sequencing methods were in their infancy (Maxam and Gilbert, 1977; Sanger et al., 1977), mainstays such as the polymerase chain reaction had yet to be put forward (Saiki et al., 1988), and automated DNA sequencers were still the stuff of science fiction (Smith et al., 1986). A remarkable suite of molecular measurements are now considered routine (see Chapter 30 by Jenkins and Zehr, this volume). While the principles of enzyme activity measurements remain largely the same, technical innovations such as improved spectrophotometers (including diode array detectors), compact scanning fluorometers, more sophisticated optics for fluorescence microscopes, and multiwell plate readers (e.g., Butler et al., 1988), as well as the development of highly fluorescent enzyme substrates (e.g., Molecular Probes, Bachem) have now revolutionized the practice. We contend that in order to understand how genetic capacity is expressed in the environment, it is critical to couple molecular measurements with rate estimates of activity in the environment.

In this chapter, our goal is to review the practical aspects of enzyme activity measurements and their interpretation and to illustrate how such measurements have advanced our knowledge of marine N cycling. While our main focus will be the assimilatory pathways found in marine photoautotrophs, we will also consider degradation pathways and secondary metabolism, and will point out other groups of marine organisms where enzyme activity has proven useful in examining aspects of the N cycle.

1.2. Overview of enzymes involved in marine nitrogen cycling

There are an enormous number of enzymes that are relevant to the marine N cycle and we still know little about many of them. Indeed, since all enzymes are proteins, all enzymes are intrinsically part of the N cycle. We can broadly divide enzymes into: (1) those involved in inorganic N acquisition (including uptake, reduction, and assimilation, and acquisition of organic N), (2) those involved in using N compounds as electron sources or sinks (i.e., dissimilatory enzymes), (3) those involved in incorporating N into macromolecules or synthesizing secondary compounds that contain N, (4) those responsible for turnover and maintenance of internal N, and (5) those involved in pathways strongly coupled to N metabolism. Table 32.1 provides a summary of relevant enzymes and enzyme classes, including prokaryotic and eukaryotic autotrophs and heterotrophs.

1.2.1. Nitrogen acquisition
Mulholland and Lomas (this volume, Chapter 7) have reviewed the general uptake and assimilation pathways for photoautotrophs (summarized in Fig. 7.2). Transporter proteins are not enzymes in the strictest sense because they do not catalyze particular chemical transformations, but facilitate entry of specific compounds into

cells. A distinct Transporter Classification (TC) system exists that is analogous to the EC system (http://www.tcdb.org), although there remain areas of overlap (e.g., ATPases are in TC 2. 2.2.1, but also fall under EC 3.6.3.x; Table 32.1). Although it is possible to make measurements of nutrient transport and infer ''activities'' of transporters using techniques that measure membrane potential such a patch-clamping (Boyd and Gradmann, 1999a,b; Taylor and Brownlee, 2003), it is not possible to unambiguously measure such activities using traditional enzyme assays. Immunochemical and gene sequencing methods have been most useful for isolating transporters (Hildebrand and Dahlin, 2000; Lara *et al.*, 1993; Tischner *et al.*, 1989; Chapter 30 by Jenkins and Zehr's review, this volume).

Reduction of nitrogen compounds to NH_4^+ may be viewed as a committing step on the way to assimilation. Enzymes mediating these reactions are attractive targets for study because they generally represent linear pathways relating enzyme activity to metabolic flux of particular compounds: nitrogenase (N_2), nitrate reductase (NO_3^-), and nitrite reductase (NO_2^-) (Table 32.1). Assimilation of nitrogen generally refers to the synthesis of small organic molecules, such as amino acids, from inorganic N and some cellular C compound, and enzymes responsible for this process include glutamine synthetase (GS), glutamate synthase, and glutamate dehydrogenase (Table 32.1).

There are also a number of enzymes that degrade organic N compounds, inside or outside the cell, thereby making N available for assimilation or uptake, respectively. Examples we will consider include urease, amino acid oxidases, and extracellular peptidases (Mulholland *et al.*, 2002; Mulholland and Lee, in revision, Chapter 7 by Mulholland and Lomas, Fig. 2, this volume; Table 32.1). In addition, for heterotrophic organisms, digestive enzymes, especially proteases, are important for internal N cycling, recouping cellular N, and excretion.

1.2.2. Nitrogen compounds as electron sources or sinks

In addition to N assimilation, nitrogen compounds in nature can also be used as electron sources or sinks, especially by prokaryotes (but not exclusively, see Zvyagil'skaya *et al.*, 1996). The enzymes that mediate these dissimilatory reactions have been studied extensively in the context of inputs and losses of fixed N in the marine N budget. Many of these measurements have been based on enzyme activities (e.g., dissimilatory nitrate reductase). Since dissimilatory reactions have been reviewed elsewhere in this volume (Chapter 5 by Ward and Chapter 6 by Devol, this volume), these will not be discussed further and we refer the reader to these chapters.

1.2.3. Incorporation of nitrogen into macromolecules and secondary compounds

Incorporation of nitrogen is typically viewed as flux of inorganic N into macromolecules such as proteins and nucleic acids. Pathways of protein and nucleic acid synthesis are complex, and highly regulated so that single enzyme activities are unlikely to provide useful information regarding their production and turnover. In addition to what we think of as ''conventional'' metabolites, marine organisms contain a bewildering array of N-containing secondary compounds, many of which are responsible for

toxic effects, cell–cell communication, and other processes we still know little about. In particular, enzymes of EC classes 4.3 (C–N lyases), 6.3 (forming C–N bonds), and 3.5 (acting on C–N bonds, other than peptide bonds) are likely to be important in cells, as are transaminases and carboxylases (Table 32.1). Few of these enzymes have been measured in marine organisms, especially with respect to N cycling. However, there is increasing recognition of the importance of these enzymes, for understanding toxic secondary metabolites such as domoic acid (Pan *et al.*, 1998; Shimizu, 1996), and there have been recent advances in appreciating the importance of such enzymes including the role of *N*-sulfotransferase in saxitoxin production (Sako *et al.*, 2001).

1.2.4. Turnover and maintenance of internal nitrogen

Intracellular nitrogen turnover is poorly understood in marine species despite the fact that N turnover is often used to estimate productivity. In addition, N turnover is often estimated based on C turnover and Redfield stoichiometry but these may not be in balance in natural systems (Mulholland *et al.*, 2006). Since the major pool of cellular N in organisms is in protein, understanding protein turnover is likely to shed light on cellular N turnover in general. Based on our understanding of eubacteria, plants, and animals (e.g., Bond and Butler, 1987; Gottesman and Maurizi, 1992; Vierstra, 1993), it seems likely that the major catabolic pathways for proteins are conserved amongst all of these groups (Fig. 32.1).

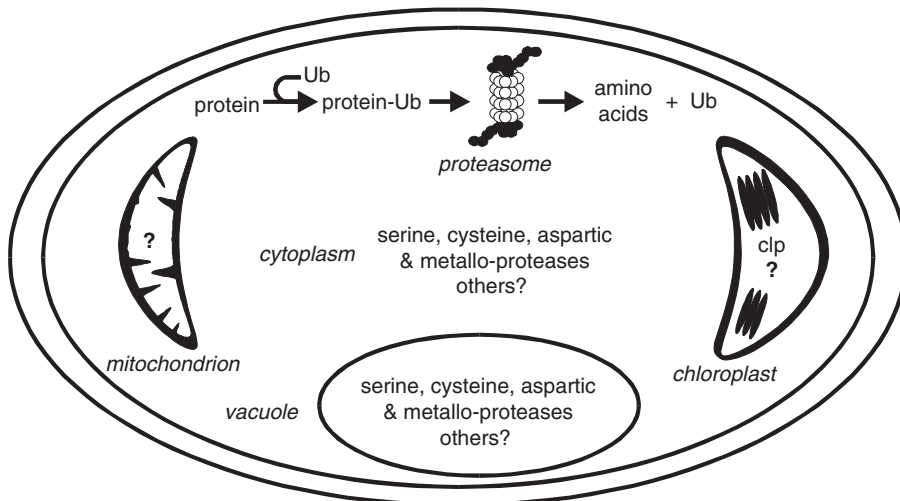
Protein turnover is essential for acclimation to changes in the external environment (e.g., irradiance or N supply), release of stored nitrogen during N-limited periods, removal of damaged or mis-synthesized N-containing compounds, reorganization of cell morphology to generate resting stages, production of specialized structures such as


Figure 32.1 Pathways of protein turnover and maintenance in a hypothetical unicellular eukaryotic photoautotroph (after Collos and Berges, 2002). Ub represents ubiquitin and polyubiquitin. Question marks indicate current uncertainties about proteases present in different cell compartments.

heterocysts, cell cycle functions, cellular defense mechanisms, and the creation and removal of intra- and intercellular signaling compounds. Within cells, degradation of protein is accomplished by the activity of hydrolytic enzymes and is regulated by cellular compartmentalization, selectively activating or inactivating particular groups of proteases, or other energy dependent pathways (see Vierstra, 1993). In some cases, the degradation products are then removed from cells or cellular compartments through specific pathways, e.g., urea cycle enzymes, or glutamate dehydrogenase in the case of heterotrophs (e.g., Mayzaud, 1987).

Proteases are traditionally divided into four classes, based on the key amino acids found in the active site of the enzyme: serine proteases, cysteine proteases, aspartic proteases, and metalloproteases (Bond and Butler, 1987), although more recently a number of enzymes have been characterized that defy such a classification systems because they exhibit mixed characteristics and have multiple activities (Liu *et al.*, 2003). Protease activities are also classified by the nature of the cleavage they catalyze: endoproteases (i.e., cleaves within a peptide chain; also called proteinases) versus exoproteases (cleave at the ends of peptide chains) such as aminopeptidases or carboxypeptidases. Proteases are sensitive to pH and as such, their location in cellular compartments may vary (Berges and Falkowski, 1998). In eukaryotic cells large (600–900 kDa), multisubunit proteases with multiple activities (proteasomes) are present. Many details of proteasomes remain unclear (Liu *et al.*, 2003), but this protease complex is involved in the ubiquitin–dependent proteolytic pathway. Ubiquitin (Ub) is a highly-conserved 76-amino-acid peptide that is covalently coupled to proteins targeted for degradation (Kerscher *et al.*, 2006). Proteins labeled with multiple Ub molecules (polyubiquitinated proteins) are rapidly degraded by proteasomes. It has also become clear that there are several other polypeptides found in cells that share similarities with Ub and function in protein modification, e.g., SUMO, ISG15, Nedd8, and Atg8 (Kerscher *et al.*, 2006). For example, SUMO is a 100-amino-acid peptide with 20% homology to Ub. While some of these polypeptide-tagging systems may have proteolytic functions (e.g., SUMO, Colby *et al.*, 2006), others may function to regulate transcription, signal transduction, and the cell cycle (Kerscher *et al.*, 2006).

There is evidence that the majority of protein turnover within higher plant cells may occur via the Ub/proteasome pathway (Rock *et al.*, 1994; Vierstra, 2003); the few data available from marine organisms suggest that the pathway is very well conserved (e.g., Moriyasu and Malek, 2004; Tonon *et al.*, 2003; Berges, unpublished annotation from *Thalassiosira pseudonana* genome sequencing project). Within pro-karoytes and organelles of eukaryotic cells that have evolutionary roots in the prokaryotic domain, Ub and proteasomes are not found, but ATP-dependent proteases such as the Clp, Lon, and Ftsh proteases are thought to have similar functions (Clarke *et al.*, 2005; Sakamoto, 2006).

Beyond proteases, there is virtually nothing known about other enzymes mediating N turnover, e.g., the nucleases that degrade RNA and DNA (cf., Falkowski and La Roche, 1991), or about the degradation of complex molecules like toxins and phytochelatins. Some details are available for chlorophyllases from marine diatoms and they may be compartmentally regulated, because degradation proceeds very rapidly when cells are homogenized (Owens and Falkowski, 1982).

1.2.5. Other enzymes connected with nitrogen cycling

A number of other enzymes deserve consideration because they are involved in pathways that are closely linked to nitrogen metabolism, such as Rubisco and other carboxylases that are critical to the coupling of C and N metabolism (Huppe and Turpin, 1994), or electron transport system (ETS) enzymes such as isocitrate dehydrogenase that are involved in respiratory metabolism (Roy and Packard, 2001). Others are relevant to N losses (e.g., esterases that are used as indices of cell lysis; Agusti *et al.*, 1998 or proteases associated with active cell death processes, e.g., Berman–Frank *et al.*, 2004) (Table 32.1).

1.3. Measuring enzyme activity

What we generally want to know is the rate at which enzymes are catalyzing reactions in nature. True *in situ* assays of enzymes are not yet practical outside of the laboratory, although technological developments may make these sorts of observations possible in the future. In practice, enzyme-specific assays are developed based on the chemical reaction catalyzed (Table 32.2). Because all EC enzymes consume substrates to generate products, the chemical reaction and its energetics are examined to determine logical, and chemically measurable, endpoints for evaluating enzyme activity. Commonly endpoints are selected based on: disappearance of a substrate, production of an end-product, consumption of cellular energy, production of byproducts, or oxidation of a reducing equivalent (Table 32.2).

Unfortunately, enzyme activity measurements are considerably more complex than simply quantifying enzyme proteins or the production of metabolites. Achieving efficient extraction of proteins of interest can be challenging and the cellular environment or environments in which the enzyme operates may be difficult to simulate *in vitro*. In this section we consider general approaches to activity assays (e.g., strategies and types of assays), practical considerations (e.g., precautions and controls), kinetic measurements, and interpretation (e.g., deciding whether an enzyme activity can serve as an index of a metabolic rate).

1.3.1. Approaches to enzyme activity measurements

Assaying enzyme activity is often a trade off between the desire to measure activity in living cells under natural environmental conditions (a strict *in vivo* assay) and extracting and purifying the enzyme and making measurements under precisely controlled conditions (a strict *in vitro* assay). While maintaining natural, and thus relevant, conditions is often important in understanding rate reactions *in situ*, it is often difficult to measure the reaction in a way that is satisfactory. Therefore, in practice, all assays fall somewhere in between the two extremes: even the gentlest *in vivo* assay involves some perturbation to the natural environment, and even the most rigorous *in vitro* assay involves assumptions (see Kornberg, 1990).

In general, the best candidates for *in vivo* assays are extracellular or cell surface associated enzymes because there are a variety of fluorescent or fluorogenic substrates that can be added to intact cells in natural seawater whose disappearance or products can be measured (e.g., leucine aminopeptidases (LAPs), cell surface amino

Table 32.2 Overview of N assimilatory enzymes, their chemical reactions, and assay endpoints

N Assimilation	Reaction catalyzed	Energy	Reductant	Cofactors	Inhibitors	Assays
Nitrate reductase	$NO_3^- + 2e^- + 2H^+ \rightarrow NO_2^- + H_2O$	ATP	NAD(P)H; NADH; NADPH; ferredoxin		NH_4^+, CN^-, hydroxylamine, vanadate CN^-	NO_2^- production, NADH oxidation
Nitrite reductase	$NO_2^- + 6e^- + 8H^+ \rightarrow NH_4^+ + 2H_2O$		Ferredoxin; NAD(P)H			Disappearance of NO_2^-, NH_4^+ production
Nitrogenase	$N_2 + 8H_2 \rightarrow 2NH_4^+$	ATP	Ferredoxin or flavodoxins	Mg^{2+}		Acetylene reduction, $^{15}N_2$ uptake
Urease	$CO[NH_2]_2 + 2H_2O \rightarrow 2NH_4^+ + CO_2$		Ferredoxin or flavodoxins		High urea	NH_4^+ production
Urea carboxylase/ allophanate hydrolase	$CO[NH_2]_2 + 3H_2O + HCO_3^- \rightarrow 2CO_2 + 2NH_4^+$	ATP		Biotin	Avidin	$^{14}CO_2$ production
Glutamate dehydrogenase	$NH_4^+ + \alpha\text{-ketoglutarate} \rightarrow$ glutamate		NAD(P)H; NADH; NADPH		Methionine sulfoxamine azaserine, albizziine	NAD(P)H oxidation or NAD(P)$^+$ production
Glutamine synthetase	$Glu + NH_4^+ \leftrightarrow Gln$	ATP		Mg^{2+}; Mn^{2+}		Hydroxylamine, P_i formation, ATP hydrolysis and NADH oxidation, glutamine production

(Continued)

Table 32.2 Overview of N assimilatory enzymes, their chemical reactions, and assay endpoints (*continued*)

N Assimilation	Reaction catalyzed	Energy	Reductant	Cofactors	Inhibitors	Assays
Glutamate synthase	Gln + α-kg → 2Glu					^{14}C glu production; NADH oxidation
Extracellular proteases	Various		NADH; NADPH; ferredoxin			Fluorogenic and fluorescent substrates; substrate disappearance; product formation
Amino acid oxidases	Amino acid + H_2O + O_2 → NH_4^+ + keto or other acid + H_2O_2					H_2O_2 production; fluorescent substrates; substrate disappearance; product formation

acid oxidases, and peptide hydrolysis; Hoppe, 1983; Mulholland *et al.*, 1998, 2002, 2003; Pantoja and Lee, 1994, 1999; Pantoja *et al.*, 1997). Because enzymes catalyzing similar or even identical reactions can be located both intracellularly and on the cell surface, for assays of cell surface enzymes, it is best to disturb the sample as little as possible to keep cells from bursting and mixing intracellular and extracellular enzyme pools. If truly extracellular enzymes are the assay target, then it is also important to do filtered controls to distinguish enzymes released to the environment (exoenzymes) from those associated with cells (ectoenzymes).

Intracellular enzymes are usually measured in chemically defined homogenates *in vitro* (e.g., nitrate reductase, Berges *et al.*, 1995). Recently, novel noninvasive assays have been developed using magnetic resonance techniques (e.g., Callies *et al.*, 1992; Mesnard and Ratcliffe, 2005), and some of these may be applicable to natural plankton assemblages (see Feuillade *et al.*, 1995). There are also a number of hybrid assays, where intracellular enzymes are measured by permeablizing cell membranes without extraction (sometimes referred to as ''*in situ*'' assays, see Corzo and Niell, 1991). In some respects, hybrid assays represent the worst of both worlds: permeablization (typically with alcohols) alters the local environment of the enzyme so *in vivo* conditions are not realized, yet the substrate concentrations are not controlled as in *in vitro* assays (see Berges, 1997). The availability of membrane-permeable substrates and the ability to monitor changes in them on a single-cell basis using flow cytometry has also led to the development of new enzymological methods, and though these have yet to be applied to enzymes of the N cycle, there is enormous potential for a growing number of reactions for which fluorescent substrates are available (Collier, 2000; Jellett *et al.*, 1996; Jochem, 1999).

The vast majority of *in vitro* enzyme assays measure activity in a reaction vessel to which reductant, substrates, and cofactors are supplied in excess (so-called V_{max} assays, see Section 1.3.3). Under these conditions, one assumes that enzyme activity is not limited by any chemical factor so the enzyme-mediated reaction proceeds at its optimal rate. Consequently, V_{max} assays are sometimes referred to as measuring ''potential'' activity, even though this term can be deceptive (see Section 1.3.5). *In vivo* assays, on the other hand are thought to better estimate ''actual'' physiological rates *in situ* because reductant, substrates, and cofactors are not augmented. However, it is conceivable that energy supply or substrates may limit activity, at least over time in a closed reaction vessel, and so care must be taken to select appropriate time scales over which to measure activity. As a further complication, there may be more than one enzyme catalyzing the same reaction in an organism or extract, or multiple organisms with different forms of the same enzyme in a given samples. In this case, kinetic parameters at subsaturated substrate concentrations may well be impossible to interpret.

1.3.2. Assays

Several considerations are common for both *in vivo* and *in vitro* assays. For example, many enzymes can be assayed using artificial rather than physiological substrates. This may simplify detection and quantification of substrate or product pools, but rates measured are not necessarily equivalent to those achieved using natural substrates. Enzyme assays are usually either stop-time (i.e., a substrate is added, the

reaction is allowed to proceed, and is then stopped at a precise time; comparing initial and final time points, depletion of substrate or increase in product can be calculated), or continuous (i.e., a variable such as absorbance or fluorescence is continuously monitored over time, and changes in these properties can be related to changes in substrate or product) (see Rossomando, 1990). Absorbance measurements have traditionally been used, based on specific peaks (e.g., NADH absorbs strongly at 340 nm), but fluorescence measurements are more precise (since two wavelengths are specified, e.g., fluorescein isothiocyanate (FITC)-labeled substrates have absorption peaks near 480 nm and fluorescence peaks close to 530 nm), and generally offer detection limits over an order of magnitude lower. Care must be taken in selecting fluorescent compounds because many substrates developed for medical use have red fluorescence (e.g., Texas Red), and are almost useless in organisms that have chlorophylls; green fluorescing substrates (e.g., FITC) are generally more adaptable.

1.3.2.1. *Storage and extraction* Because enzymes are highly labile, care must be taken during sample collection, storage, and handling to preserve enzyme activity. Appropriate holding times for preserved samples, holding temperature, and selection of preservatives or preservation methods all need to be considered on an enzyme-specific basis. For example, algal nitrate reductases are extremely labile and require immediate storage at liquid N_2 temperatures (e.g., $-196^{\circ}C$) to maintain activity (see Berges and Harrison, 1995a, Young *et al.*, 2005), while many algal proteases retain activity at room temperatures for many hours (e.g., Berges and Falkowski, 1998). Enzymes must be protected during sample handling and homogenization to avoid pH fluctuations, oxidation of cellular material, and other compounds such as phenolics or exogenous heavy metals (Gegenheimer, 1990; Volkin and Klibanov, 1989). In addition, selection of extraction buffers is important because, in addition to controlling the pH, activities of different enzymes are enhanced or depressed by different buffers (Berges and Harrison, 1995a; Stoll and Blanchard, 1990). Finally, intracellular proteases can degrade enzymes, either specifically or nonspecifically. A number of protease inhibitors can be used to prevent this (unless of course proteolytic enzymes are the target of assays) (Gegenheimer, 1990; Volkin and Klibanov, 1989); however, in phytoplankton and macroalgae, there is evidence that commonly-used protease inhibitors are not effective (see Berges and Falkowski, 1996; Perez-Llorens *et al.*, 2003).

1.3.2.2. *Assay conditions* To measure realistic enzyme activities, pH, temperature, and ionic strength should be kept as close to physiological conditions as possible, but in many cases we may not know the conditions that are relevant to a particular enzyme within a cell or cellular compartment. One strategy is to assume that the conditions that produce maximum activity are those for which the enzyme is adapted. However, while changing pH and temperature may produce higher rates of activity in a test tube, the resulting measurements often become further distanced from reality. For example, raising the assay temperature generally increases reaction rates up to a point. However, high temperatures can also denature enzymes and result in lower enzyme activity (e.g., Berges *et al.*, 2001). Rather than ''maximizing''

activity, a better process might be "optimization," wherein temperature, pH, and ionic strength are kept close to what are believed to be physiological conditions, and substrate and cofactor concentrations are adjusted so as to be nonlimiting for a given assay duration (see also Newsholme and Crabtree, 1986).

In the case of *in vivo* assays, there are tradeoffs in selecting the concentrations of substrates (including fluorescent or fluorogenic compounds being used as tracers) to add to incubations. Concentrations of substrates are ideally adjusted to levels found in the environment. However, sometimes these concentrations are not known or ambient concentrations are so low that substrates are rapidly depleted in bottle incubations, precluding an accurate rate measurement. It is therefore paramount that enzyme assays are conducted on appropriate time scales (and these may vary temporally, spatially and depending on the enzyme and organism) so that substrates are not significantly depleted in incubation bottles. Conversely, if substrate additions are too high relative to ambient environmental concentrations, enzyme activity can be stimulated over natural conditions (e.g., see Chapter 7 by Mulholland and Lomas, this volume). A common strategy is to add substrates at saturating levels. This allows for stable measurements, and can be an indication of maximal rates of activity under the environmental conditions. These so-called "potential" rates should be used cautiously because rate processes in organisms often depend on nutrient and environmental "prehistory," and because other elements and factors also in short supply in nature may become limiting over time in incubation bottles.

For intracellular enzymes, the picture is complicated because we do not have a clear idea of physiological substrate concentrations and turnover times inside cells; indeed, compartmentalization, metabolic channeling, and tight coupling of reactions make it difficult to estimate intracellular concentrations even under ideal conditions (Albe *et al.*, 1990; Srere, 1987). For these reasons, intracellular enzyme assays are typically run at saturating substrate concentrations (i.e., V_{max} assays); the reaction rate should then depend only on the quantity of active enzyme (see Section 1.3.3).

1.3.2.3. Quality-control measures

There are a number of basic quality-control steps that need to be taken to ensure that rate measurements are not biased by assay artifacts. First, it must be demonstrated that the rate reaction is linear over time for the period of the assay. If this is not the case, then either the enzyme is not stable, the substrates are being depleted over the course of the assay, or there is some sort of inhibition of the reaction over time, perhaps by a reaction product. Second, the activity should vary directly with the amount of enzyme (or homogenate) added. If this is not true, it suggests a problem with the assay such as degradation of enzyme or exhaustion of substrates. Third, for a V_{max} assay, all reaction substrates must be saturating. Typically, this is evaluated by running parallel reactions varying the concentration of each substrate independently; however, even this is not simple because reactions can also be inhibited by high substrate concentrations.

1.3.2.4. Scaling activity

Once activity measurements have been made, they must be scaled to something ecologically or physiologically relevant. *In vitro* enzyme activity is typically scaled to cell protein because it is straightforward to make protein

determinations in the same homogenate that is used for assays, but this may not always be appropriate (see Berges and Harrison, 1995b). In many studies of N cycling, it is relevant to simply express enzyme activity as the amount of nitrogenous product generated or substrate consumed per unit time per unit biomass. Alternative scaling variables include cell number, cellular N and C, or chlorophyll *a* biomass; the choice of scaling factors depends largely on the process being measured and the context in which the measurement was made. Enzyme activity is typically expressed as units (U) (or, less commonly, International Units, IU), where one unit is the amount of enzyme needed to catalyze the conversion of one micromole substrate to product in one minute. Since minutes and micromoles are not SI units, some investigators prefer to use moles per second, although this results in small values. The katal (kat), a derived SI unit representing the catalytic activity that will raise the rate of reaction by one mole per second in a specified assay system is technically correct, but is not often used (see Dybkaer, 2000).

1.3.3. Enzyme kinetic measurements

Beyond the instantaneous rate measurements described above, determining how enzyme activity varies with substrate concentration can provide useful information about enzyme capacity and the rates that are likely to be observed under different environmental conditions. These kinetic measurements probably work best in *in vivo* assays of exo- and ectoenzymes where substrate concentrations can be measured directly from the external environment and there are no metabolic intermediary pools or reactions to complicate the picture. Kinetic measurements also have limitations as there can be bottle effects, diffusion boundary layers around organisms can be important, and it is often difficult to make measurements at the "low" substrate end-members in all but the most oligotrophic environments. Further, kinetic parameters are physiological variables themselves, dependent on the preconditioning of cells and so can vary widely even in the same organism, across environments (see Chapter 7 by Mulholland and Lomas, this volume).

For *in vitro* assays, it is extremely difficult to determine the relevant intracellular concentrations of substrates due to compartmentalization of particular reactions, competing reactions that produce and consume common substrates, and metabolic channeling (Albe *et al.*, 1990; Srere, 1987). Consequently, *in vitro* kinetic measurements may not be very useful for assessing *in situ* or *in vivo* reaction rates. However, provided assays conditions are carefully controlled, kinetic parameters may be very useful for characterizing enzyme isoforms and enzymes from different metabolic pools, different organisms, or from organisms collected from different environments.

In most cases where enzyme kinetics have been measured in marine settings, simple Michaelis–Menten models have been used to characterize enzyme activity. This is sensible, because such rectangular hyperbolic models suit many biological processes (e.g., Berges *et al.*, 1994). Aquatic biogeochemical models use a "classical" kinetics formulation to describe N uptake (e.g., Fasham *et al.*, 1990; Moore *et al.*, 2002). Similarly, physiological models use enzyme kinetic principles to formulate mathematical equations describing enzymatically mediated N assimilation (Packard *et al.*, 2004). However, it is still unclear whether such kinetic descriptions are ecologically meaningful for the reasons described earlier. In addition, many enzymes

display non-Michaelis–Menten kinetics due to regulatory pathways, and multiple enzymes or enzyme isoforms accomplishing the same reaction but with different substrate affinities. For example, allosteric enzymes have multiple subunits, regulatory sites that bind modulators other than the substrate, and/or multiple binding sites for substrate. Michaelis–Menten kinetics assume that there is no interaction among binding sites when in fact, binding of a modulator can cause activation/inhibition of enzyme activity, while binding of a substrate on another subunit may increase or decrease binding at another subunit (cooperativity) (Cornish-Bowden, 2004; Ottaway, 1988). Such mechanisms make it difficult to interpret enzyme activity, especially in the context of the commonly used kinetic models (see also Section 1.3.5).

1.3.4. Enzyme inhibitors

Enzyme inhibitors represent powerful tools for isolating specific enzyme activities in crude homogenates (e.g., proteases; Berges and Falkowski, 1996), verifying assays, and determining whether alternative metabolic pathways exist. They can also provide a means to differentiate the roles of different taxa that perform identical reactions. For example, cyanobacterial assimilatory nitrate reductases are quite distinct from eukaryotic forms and so the relative contributions of the two groups to total nitrate assimilation might be distinguished using a carefully selected inhibitor. Very few specific inhibitors are known (e.g., vanadate for nitrate reductase, methionine sulfoximine [MSX] for GS, and azaserine for glutamate synthase), and so their use has been limited.

To be used effectively, the mechanisms through which inhibitors exert their effects need to be understood. For example, competitive inhibitors compete with physiological substrates for binding sites. Their effect depends on the relative concentrations of substrates and the inhibitor and the degree of inhibition depends on the number of active sites occupied by the inhibitor versus the metabolic substrate. In contrast, noncompetitive inhibitors bind to parts of the enzyme other than the substrate binding site, so the degree of inhibition depends only on the inhibitor and not the substrate concentration. This type of inhibition is typically irreversible and reduces the amount of total enzyme available to catalyze a particular reaction. Uncompetitive inhibition occurs when the inhibitor binds to the enzyme–substrate complex and prevents the reaction from being catalyzed.

There are also inhibitors that affect enzyme synthesis. Inhibitors of transcription (e.g., dibromothymoquinone [DBMIB]) and inhibitors of translation (e.g., cycloheximide [CHX]) are available but these are not specific to particular enzymes. In addition, because protein synthesis takes place within the chloroplast and mitochondrion in eukaryotes, prokaryotic protein synthesis inhibitors (e.g., chloramphenicol [CAP]) may be necessary to distinguish prokaryotic versus eukaryotic activity (e.g., Segovia and Berges, 2005).

1.3.5. Interpreting enzyme measurements

There are many factors that can affect enzymes *in vivo* that are not simulated in *in vitro* assays. Consequently, *in vitro* enzyme activities may or may not reflect actual *in situ* rates. In nature enzymes may not be substrate-saturated as they are in *in vitro* assays;

N is often limiting in the marine environment. Further, many enzymes are sensitive to cellular substrate concentrations rather than extracellular concentrations and it is difficult to measure the relevant intracellular metabolite pools. *In vitro* assays may affect the conformation of enzymes and the degree to which they are modified. For example, allosteric effects (see Section 1.3.3) may be modified under *in vitro* conditions. Many enzymes undergo posttranslational regulation wherein enzyme activity is affected by binding of activator/inactivator proteins and covalent modification of the enzyme (e.g., adenylylation, phosphorylation or carbamylation) (Ottaway, 1988). When there is posttranslational modification of enzymes, enzyme activity measured in assays may be unrelated to *in vivo* activity (see Section 2.2.1) and there are few ways to determine the extent of enzyme modification in nature.

To understand why it is often difficult to interpret *in vitro* enzymes assays, it is useful to consider the principles of metabolic control theory, derived from engineering control theory (Raven, 1981). Consider a series of enzyme catalyzed reactions, where *a, b, c*, and *d* represent substrates and or products of reactions catalyzed by enzymes represented by A, B, and C:

$$a \xrightarrow{A} b \xrightarrow{B} c \xrightarrow{C} d$$
Control of the whole series of reactions generally rests at one point (the rate-limiting step), which is often the first step (Newsholme and Crabtree, 1986), catalyzed in this case by enzyme A. Further, it has been argued that it is advantageous that control of a metabolic pathway not shift between steps as conditions change, otherwise regulation would be unreasonably complex, i.e., in this example, the step catalyzed by A should continue to be rate-limiting. For this to be true, the concentration of *b* and substrates downstream must always be below saturation for the enzymes catalyzing their transformations, such that they do not accumulate and enzymes B and C do not become rate limiting. It follows that enzyme A is always functioning at close to its capacity, an thus V_{max} assays for A would give information about the rate of flux through the whole pathway, but that V_{max} assays for enzymes B and C would not. Another way cells could maintain a single rate-limiting step in a metabolic pathway is for downstream enzymes (e.g., B and C) to have K_m values that are close to the steady state concentrations of *b* and *c*, respectively, when the pathway is functioning at its maximum rate (see Heinrich and Hoffmann, 1991). In this way, even small changes in *b* or *c* will result in relatively large changes in the rates of enzymes B and C (respectively) and thus prevent these enzymes from becoming rate limiting. Although this example is theoretical, there are considerable empirical data supporting such relationships (see Albe *et al.*, 1990; Pettersson, 1991). Moreover, if conditions change so that fluxes through a pathway increase or decrease, parallel adjustments in concentration occur in all the enzymes along the particular metabolic pathway (see discussion in Fell, 2005), opening the possibility that even nonrate-limiting enzymes (e.g., B or C) could provide information about prevailing metabolic fluxes (see Newsholme and Crabtree, 1986).

In addition to determining where metabolic pathways are regulated it is also essential to understand how particular enzymes are regulated in order to interpret

enzyme activity assays. In the case where an enzyme or enzyme pathway is controlled by an enzyme whose concentration or activity is regulated at the level of synthesis and degradation, an *in vitro* enzyme activity is likely to be a good reflection of *in situ* rate. It is much more difficult to interpret enzyme activity for enzymes that are regulated allosterically or posttranslationally because simple V_{max} measurements may not reflect enzyme availability or potential.

Analysis of metabolic networks may help us properly interpret enzyme activities from enzyme abundance, and ultimately extrapolate to the whole organism using models. Application of such computational modeling to enzyme systems is still limited but promising. For example, Su *et al.* (2006) were able to develop computational models of N assimilation in *Synechococcus* sp. WH 8102 that closely corresponded to results from microarray analyses of gene expression.

Ultimately, if enzyme activity measurements are to be useful we need to be able to validate them in cultures under controlled laboratory conditions, and then in controlled field settings where there is basic understanding of the important processes, resident organisms, and their metabolic pathways. In natural samples, it is often difficult to specifically target organisms of interest using bulk collection methods. As a result, it is not always clear to whom enzyme activities can be attributed (e.g., cooccurring organisms or endosymbionts). Unfortunately, the field-oriented focus of aquatic sciences, lack of appropriate cultured organisms, and the time-pressures of most project funding cycles mean that such validations are seldom done.

2. Case Studies of Specific Enzymes

2.1. Inorganic nitrogen acquisition

Inorganic N is taken up by microbes and marine plants in a variety of forms and uptake is facilitated through a variety of transporters (see Chapter 7 by Mulholland and Lomas, this volume). Inorganic N compounds must first be reduced to ammonium prior to their assimilation into organic compounds and these reduction steps are enzymatically mediated and are described here.

2.1.1. Nitrogenase
2.1.1.1. Overview Nitrogenase, the enzyme complex catalyzing N_2 fixation, is found in phylogenetically diverse prokaryotes (archaea and bacteria, including cyanobacteria), ranging from aerobic heterotrophs, aerobic and anaerobic phototrophs to strict anaerobes (see Chapter 4 by Carpenter and Capone, this volume). The enzyme is extremely sensitive to O_2 and N_2 fixation is energetically expensive, "costing" a cell up to 16 molecules of ATP per molecule N_2 reduced (Postgate, 1998). Nitrogenase enzymes are numerous but biochemically similar and so the whole family of enzymes is referred to as "nitrogenase" even though the name does not conform to systematic enzyme nomenclature (Postgate, 1998). The enzyme complex nitrogenase consists of two proteins, a molybdenum iron protein (Protein 1) that binds N_2 (dinitrogenase reductase) and a smaller iron protein (Protein 2) that acts

as an electron donor to Protein 1 (nitrogenase reductase), although alternative nitrogenases that contain vanadium or only iron in the larger subunit have been identified. As well as catalyzing the reduction of N_2 to NH_3, nitrogenase can reduce other small triply bonded molecules, including acetylene, azide, and cyanide, and nitrogenase reduces hydrogen ions to gaseous hydrogen, even when N_2 is present. Many assays of nitrogenase activity take advantage of these competing reactions. Although N_2 consumption or H_2 production theoretically can be used to estimate N_2 fixation rates, N_2 concentrations in aquatic systems are high (and generally saturated in seawater) and simultaneous production and consumption of H_2 both intracellularly and extracellularly through a variety of processes confounds interpretation of this measurement.

2.1.1.2. Assay techniques   Because robust *in vitro* assays have not been developed, nitrogenase activity has been estimated based the use of isotopic tracers and substrate analogs. Nitrogen fixation rates have been estimated based on $^{15}N_2$ uptake using tracer techniques (e.g., see Chapter 31 by Lipschultz, this volume). This method is a sensitive measure of net $^{15}N_2$ uptake into particulate organic nitrogen (PON) (Montoya *et al.*, 1996; Mulholland *et al.*, 2004a,b, 2006), however, because diazotrophs can release fixed N_2 prior to its assimilation into biomass (e.g., Capone *et al.*, 1994; Glibert and Bronk, 1994; Mulholland *et al.*, 2004a,b, 2006), $^{15}N_2$ uptake can underestimate total or gross N_2 fixation (Gallon *et al.*, 2002; Mulholland *et al.*, 2004a,b, 2006). Other assays of nitrogenase activity rely on reduction of other triply bound compounds that serve as N_2 analogs.

Most often, assays of nitrogenase take advantage of the enzymes' ability to reduce acetylene (C_2H_2) (Capone, 1993). The acetylene reduction method is convenient, very sensitive and relatively simple. However, acetylene reduction assays should not be excessively long because nitrogenase preferentially reduces C_2H_2 as opposed to its natural substrate N_2 and thus ''starves'' cells for N. Because C_2H_2 reduction measures just the reduction step, it is a measure of gross N_2 fixation, while movement of $^{15}N_2$ from the dissolved to the particulate pool measures net N assimilation (see Gallon *et al.*, 2002; Mulholland and Bernhardt, 2005; Mulholland *et al.*, 2004a,b). In addition, the stoichiometry of these two reactions is different and a conversion factor is needed to estimate N_2 fixation rates; theoretically a ratio of 3:1 mol C_2H_2:N_2 are reduced (Montoya *et al.*, 1996; Postgate, 1998). However, because nitrogenase reduces H^+ along with N_2, ratios >3:1 are often assumed and observed; for example, if 1 mole of H_2 is also produced for each mole of N_2 reduced, the ratio of C_2H_2:N_2 fixation increases to 4:1. Despite this potential bias, for the marine diazotroph *Trichodesmium*, little net H_2 production has been observed under environmental conditions (Scranton, 1984; Scranton *et al.*, 1987) suggesting either: (1) that hydrogen production from nitrogenase is low in nature (and so a 3:1 conversion factor is justified), or (2) that cells efficiently recoup H_2 produced during N_2 fixation, arguing for higher ratios and the need for a thorough evaluation of hydrogen cycling within cells.

Estimates of acetylene reduction are usually calibrated against $^{15}N_2$ to determine the appropriate ratio extrapolating N_2 fixation from C_2H_2 reduction. However, release of recently reduced N_2 and the difficulty in chemically recovering all possible

dissolved pools into which products of N_2 fixation might be released, may make intercalibration between the two methods impossible (Mulholland, 2007). In numerous paired comparisons, ratios of C_2H_2 reduced to N_2 taken up varied by at least an order of magnitude (see Mulholland, 2007; Mulholland et al., 2006). Even though it may be impossible to intercalibrate the two methods, the difference between N_2 reduction (gross N_2 fixation) and net N_2 assimilation may provide an excellent index of the release of recently fixed N_2 that has proven promising in culture systems (Mulholland, 2007; Mulholland and Bernhardt, 2005; Mulholland et al., 2004a,b, 2006).

More recently, the capacity for N_2 fixation has been evaluated by amplifying *nif* genes (which encode nitrogenase enzymes), from natural samples using appropriate primers (see Chapter 30 by Jenkins and Zehr, this volume). DNA macro- and microarrays have been used to explore the diversity of N_2 fixing organisms (Jenkins et al., 2004) and quantitative PCR approaches have been used to determine the abundance of particular groups of diazotrophs (Church et al., 2005). These molecular methods have high sensitivity but they cannot determine if there is actually nitrogenase activity. Recent studies have coupled gene expression assays with uptake experiments to demonstrate active N_2 fixation in open ocean unicellular diazotroph populations (Montoya et al., 2004).

2.1.1.3. Enzyme regulation and interpretation of activity assays For *Trichodesmium*, probably the best studied marine N_2 fixer, nitrogenase is regulated both at the level of transcription and activity and so gene presence and even the presence of gene products, are not quantitative measures of nitrogenase activity (Zehr and Capone, 1996; Zehr et al., 1993; and see Chapter 30 by Jenkins and Zehr and Chapter 7 by Mulholland and Lomas, this volume). Nitrogenase, like many enzymes involved in N reduction and metabolism, appears to be regulated through negative feedback from intracellular NH_4^+, other downstream metabolites (amino acids), and cellular N:C status (Flores and Herrero, 1994; Guerrero and Lara, 1987; Mulholland et al., 1999). N_2 fixation also appears to be sensitive to or inhibited by other forms of N in the growth medium (Flores and Herrero, 1994; Guerrero and Lara, 1987; Smith and Gallon, 1993). Though it was previously thought that virtually any NH_4^+ or NO_3^- in the growth medium inhibited the synthesis and activity of nitrogenase, recent studies suggest that environmentally-relevant concentrations (e.g., 1 or 2 μM) of these compounds do not inhibit N_2 fixation in the oligotrophic or coastal ocean (Mulholland et al.1999, 2001). In addition to N, nitrogenase activity is dependent on the provision of ATP (and so is tied in with the light cycle in photoautotrophs) and Mg^{2+} and the absence of O_2. As for other N assimilation pathways, further metabolism of NH_4^+ produced through N_2 fixation can also be limited by the provision of carbon skeletons.

In addition to regulation at the level of transcription, at least some nitrogenases can be regulated by covalent modification (inactivation) of the Fe protein (Capone et al., 1990; Gallon, 1992; Zehr et al., 1993). However, regulation of nitrogenase appears to be complex since nitrogenase is also subject to circadian rhythms and may be related to heterocyst formation in heterocystous species (Chen et al., 1996, 1998; Herrero et al., 2001).

2.1.1.4. *Information gained from assays and future potential* Nitrogenase activity assays remain the most important means to estimate rates of N₂ fixation and acetylene reduction assay is a good example of an *in vivo* assay that does not require much manipulation of natural samples. Thus, there should be a good relationship between what the assay measures and the actual rate of N₂ fixation *in situ*. Finding means to convert measures of acetylene reduction to N₂ reduction remains a critical issue, and H₂ production is an important part of the problem. Physiological studies of N₂ fixation and H₂ production catalyzed by nitrogenase in *Trichodesmium* are hampered by the lack of *in vitro* assays.

2.1.2. Nitrate reductase

2.1.2.1. *Overview* Because nitrogen is thought to limit primary productivity in much of the world ocean, and nitrate thought to be the primary form of new N available in most systems (Dugdale and Goering, 1967), nitrate reductase (NR) activity was one of first enzyme measurements to be broadly applied in an oceanographic context (Eppley, 1978; Eppley *et al.*, 1969). Features of the enzyme that made it suitable for assay included high specific activity, relatively easy extraction, and a straightforward, sensitive assay.

In eukaryotes, NR is a complex enzyme containing molybdenum, iron–heme, and flavin adenine dinucleotide that uses NADH, NADPH, or both as a reductant (the basis for division of the enzyme into subclasses: EC 1.7.1.1, 1.7.1.2, or 1.7.1.3). The eukaryotic enzyme is best characterized from higher plants (Campbell, 1999; Fischer *et al.*, 2005), but generalizations hold well in the green algae (Solomonson and Barber, 1990; Song and Ward, 2004; Wang *et al.*, 2003) and diatoms (NR's in *T. pseudonana* and *P. tricornutum* are 50–60% identical to higher plant and green algal gene sequences; Allen *et al.*, 2005) where the genes and proteins have been examined. In most cases, the enzyme appears to be dimeric, with subunits of about 100 kDa in size, however, Iwamoto and Shirawa (2003) have suggested that NR from *Emiliania huxleyi* is different, possibly a hexamer with 85 kDa subunits, and there are reports that NR from dinoflagellates may differ as well (Ramalho *et al.*, 1995). Assimilatory nitrate reductases are quite distinct enzymes in prokaryotes where they are ferredoxin-dependent and contain iron–sulfur clusters (Flores *et al.*, 2005).

2.1.2.2. *Assay techniques* One of the major problems in assaying NR activity has been the stability of the enzyme. Consequently, it has been difficult to measure any NR activity in some field samples (e.g., Hochman *et al.*, 1986), and measured NR activity has often been insufficient to account for observed rates of nitrate incorporation (e.g., Blasco *et al.*, 1984). Attempts to overcome this problem have included: assaying the parts of the enzyme catalyzed reaction that are less affected such as NADH oxidizing (diaphorase) activity, assaying NO_3^- reducing activity in the presence of artificial reducing compounds such as methyl viologen, or developing ''in vivo'' assays (Corzo and Niell, 1991; Hochman *et al.*, 1986). Problems extracting enzyme may be related to the high proteolytic activities observed in phytoplankton, which appear resistant to classical protease inhibitors (see Berges and Falkowski, 1998). Some success in countering this problem has been achieved by adding

''carrier'' proteins like BSA to provide abundant alternative targets for proteases, thereby protecting NR (Berges and Harrison, 1995a). NR activity is also very sensitive to storage conditions. In many cases, there are significant losses of activity when samples are stored frozen at $-80°C$, and preservation at liquid N_2 temperature is essential (Berges and Harrison, 1995a; Vergara et al., 1998; Young et al., 2005).

Typically, NR assays measure production of nitrite, using the sulphanilamide/N-(1-naphyl) ethylenediamine dihydrochloride reaction after a timed incubation period, and correcting for any nitrite present initially in extracts. Continuous spectrophotometric assays that measure NADH oxidation over time are feasible when cell biomass is high (e.g., in cultures), but corrections must be applied because enzymes other than NR present in cell homogenates can also oxidize NADH (Berges and Harrison, 1995a). Complicating things further, high levels of NADH and nitrate inhibit NR activities in some species and so assays need to be optimized on a species–specific basis (Berges and Harrison, 1995a,b). It is equally important to optimize assays for all types of NR because some NR enzymes require flavin adenine nucleotide (FAD) as a cofactor and this is also variable among species (Berges et al., 1995a; Everest et al., 1984).

2.1.2.3. Enzyme regulation and interpretation of activity assays

A diverse range of regulatory mechanisms have been described for NR in higher plants, green algae, and cyanobacteria, and these include induction by nitrate, repression by NH_4^+ or other products of N metabolism, and modulation by light (Campbell, 1999; Herrero et al., 1984; Solomonson and Barber, 1990; Song and Ward, 2004). In addition to feedback inhibition of NR, NH_4^+ can interfere with NO_3^- transport, thereby inhibiting NO_3^- uptake and reduction. The effect of NH_4^+ on NR is rapid in diatoms, indicating a relatively fast turnover of the enzyme (Berges et al., 1995; Vergara et al., 1998). In contrast, in some intertidal macroalgae, additions of ammonium have little effect on NR activity (Young et al., 2007b).

In eukaryotic algae (at least in diatoms), the primary mode of regulation of NR appears to be at the level of synthesis and degradation (Berges, 1997; Vergara et al., 1998). Consequently, the interpretation of NR activity measurements is relatively straightforward, and NR activity and NO_3^- incorporation rates are correlated (Berges and Harrison, 1995a,b; Berges et al., 1995). While posttranslational modification of NR by phosphorylation in response to changes in irradiance is well-described in higher plants (Huber et al., 1992), it has not been demonstrated for algae, and in diatoms, the NR protein appears to lack the key phosphorylation site found in higher plants (Allen et al., 2005) making it unlikely that this is a viable regulatory pathway.

Diel variability in NR activity, and NO_3^- uptake, has been observed in a variety of N–replete marine phytoplankton communities (e.g., Packard et al., 1971). Patterns vary among species (e.g., Lopes et al., 1997; Ramalho et al., 1995). In diatoms, NR activity typically has a peak near the middle of the light period, but there is also an increase in activity just prior to the beginning of the light period (Berges et al., 1995). This periodicity does not appear to be under the control of a circadian oscillator (cf., Chow et al., 2004; Vergara et al., 1998), but is more likely to be

linked to changes in internal carbon pools. The diel variability of NR activity is also affected by N status and N-deplete or starved cells will take up NO_3^- even during the dark (e.g., Cochlan *et al.*, 1991). Interestingly, while macroalgae in the lower intertidal zone show diel variations in NR activity, this is not observed in *Fucus* species in the upper intertidal (Young *et al.* 2007b).

NR activity is also sensitive to temperature, at least in diatom species. (Gao *et al.*, 2000) demonstrated that NR activity in diatoms such as *Skeletonema costatum* tended to lose activity above 16°C, while other eukaryotic enzymes were stable at over 30°C. Lomas and Glibert (1999) combined laboratory and field data to argue that this temperature sensitivity effectively limited diatoms to particular environments. Berges *et al.* (2002) speculated that features of the N-terminus of the NR protein might be responsible for temperature sensitivity, and these appear to be borne out in data from recent sequencing projects (Allen *et al.*, 2005).

In cyanobacteria, transcription of NR seems to be triggered by a high intracellular C:N ratio, as for nitrogenase (see Section 2.1.1.3). Further, regulations of NR and nitrogenase appear to share common features in a variety of organisms (e.g., Flores and Herrero, 1994). We are just beginning to understand many of the complex regulatory systems that control total N acquisition by aquatic microbes.

2.1.2.4. Information gained from assays and future potential   NR activity measurements have not been all that useful in predicting NO_3^- incorporation rates or new production as once hoped (see Blasco *et al.*, 1984), though these earlier assays may have underestimated true NR activities. However, NR assays have proven useful in examining the effects of iron limitation on nitrate metabolism (e.g., Boyd *et al.*, 1998; Timmermans *et al.*, 1994; see also NiR section below). In addition, NR activity measurements have been used extensively to examine patterns of nitrate incorporation in macroalgae (e.g., Corzo and Niell, 1991; Davison and Stewart, 1984; Davison *et al.*, 1984; Hurd *et al.*, 1995; Young *et al.*, 2007a,b) and to assess the contribution of epiphytes to N cycling in seagrass meadows (Young *et al.*, 2005).

Differences among NR enzymes might be exploited to provide taxon–specific information. For example, since cyanobacterial and eukaryotic enzymes differ markedly, there may be potential for using different assays to distinguish eukaryotic and prokaryotic NO_3^- uptake in natural communities (see Berges, 1997). At the protein level, NR from diatom species is remarkably variable in the N-terminal region, so that targeting NR genes could provide community information at a functional level (Allen *et al.*, 2005).

Interestingly, despite the fact that nitrate is one of the largest pools of inorganic N in many marine systems, not all species of phytoplankton can use NO_3^-. For example, some ''brown tide'' organisms are unable to grow on nitrate (DeYoe and Suttle, 1994), and at least some marine *Prochlorococcus* apparently lack nitrate assimilation gene clusters (Rocap *et al.*, 2003). NR activity assays could confirm such findings.

Finally, in addition to playing a key role in nitrate acquisition, NR may play a role in cell signaling. Desikan *et al.* (2002) found that NR mediates nitric oxide (NO) synthesis in *Arabidopsis* guard cells. NO signaling has also been established in *Chlamydomonas* (Sakihama *et al.*, 2002) and quite recently in diatoms (Vardi *et al.*, 2006).

2.1.3. Nitrite reductase

2.1.3.1. Overview   Despite early interest in nitrite reductase (NiR), relatively fewer measurements of the enzyme have been made, compared to NR (e.g., Eppley and Rogers, 1970; Eppley *et al.*, 1971). Traditionally, it has been considered that algae and cyanobacteria have only the ferredoxin-dependent form of the enzyme (Campbell and Kinghorn, 1990; Flores *et al.*, 2005; Luque *et al.*, 1993), but annotation of the *T. pseudonana* genome indicates the presence of both a nuclear-encoded ferredoxin-dependent enzyme, targeted to the chloroplast (homologous to vascular plant/cyanobacterial forms), and a second NiR with homology to a NAD(P)H dependent form found only in heterotrophic bacteria and some fungi (Allen, unpublished data).

2.1.3.2. Assay techniques   NiR is typically measured by following the disappearance of NO_2^- in cell homogenates, when provided with either reduced ferredoxin or alternative electron acceptors such as methyl viologen (Vega *et al.*, 1980). The assay is somewhat more complicated than that for NR. If methyl viologen is used, then sodium dithionite is typically used to reduce it and to maintain reducing conditions throughout the assays, though strictly anaerobic conditions may not be necessary (Milligan and Harrison, 2000; Vega *et al.*, 1980). It seems from the genome annotation data that diatoms, like yeast, may also have NAD(P)H-dependent NiR, but this has not been reported on in the literature.

2.1.3.3. Enzyme regulation and interpretation of activity assays   Available evidence suggests that there is a tight coregulation between NR and NiR in both eukaryotes and prokaryotes. Indeed, in cyanobacteria, N assimilation genes show gene clusters of NiR–permease gene-NaR (nitrate reductase genes) with an operon structure (Flores *et al.*, 2005). In prokaryotes, the two enzymes are very closely linked (Faure *et al.*, 1991), and both probably respond to the presence of NO_3^- (e.g., Galvan *et al.*, 1992; Wray, 1993). Such a regulatory system would presumably prevent the build-up of pools of nitrite that could prove toxic to cells. In many cases, NiR activity is greater than NR activity, which provides additional support that NR is the rate limiting enzyme of the pair (see above). Carbon limitation may also affect NiR, as in the case of NR (Suzuki *et al.*, 1993, 1995).

2.1.3.4. Information gained from assays and future potential   NiR assays have much more seldom been applied in the field, perhaps because of the more complicated assay, but also because it is not the rate limiting step of the NiR–NR pair. However, there may be special cases where NiR does become limiting for NO_3^- acquisition. (Kessler and Czygan1968) provided evidence that because NiR in green algae contains more iron than NR, iron limitation more strongly affects NiR. This also appears to be the case for at least one species of diatom; (Milligan and Harrison, 2000) demonstrated that under iron limitation, NiR was more strongly affected than NR, and speculated that control of nitrate acquisition might shift from NR to NiR under these circumstances.

2.2. Ammonium assimilation pathways

Ammonium is the common denominator in inorganic N assimilation and most forms of N taken up by cells are first reduced to NH_4^+ prior to their assimilation into cellular material. Ammonium assimilation also metabolically links the C and N cycles because C skeletons are required for amino acid synthesis. Consequently, the enzymes involved in N assimilation are extensively regulated in response to a variety of intracellular cues (N and C) and environmental variables. The regulatory mechanisms for NH_4^+ assimilation in microorganisms generally build upon detecting the presence or absence of NH_4^+ in the environment or in the cell or feedback from other downstream metabolites. The regulatory networks of well-studied microorganisms, including bacteria and cyanobacteria, include a transcriptional factor, the global N regulator, *NtcA*, that is involved in regulating transcription of co-regulated genes, and the signal transduction protein P_{II}, which broadcasts and amplifies cellular N status within cells; together, these coordinate N (and to some extent C) metabolism in cells (García-Fernández *et al.*, 2004; Herrero *et al.*, 2001; Tandeau de Marsac *et al.*, 2001). Recently, (Su *et al.* 2006) demonstrated that models of the N assimilation network agreed well with gene expression data from microarray studies for a cyanobacterial system, offering hope that even quite complex metabolic systems may prove tractable to this type of modeling analysis.

The assimilation of NH_4^+ in most marine phytoplankton and bacteria is via a cyclic pathway involving the enzyme pair GS and glutamate synthase (glutamine oxoglutarate aminotransferase [GOGAT]). GS first assimilates ammonium into the amide group of glutamine (gln) and then, GOGAT transfers the amide group to a molecule of α-ketoglutarate (α-kg) to form two molecules of glutamate (glu), one of which is recycled to GS to synthesize another glutamine (gln). While the reaction is fully reversible, in cells it is thought that GS/GOGAT works primarily in the forward or assimilatory direction. However, it does so at the expense of cellular energy since the GS reaction requires one ATP for each molecule of gln produced. More is known about GS because that is generally considered the rate-limiting enzyme in the pair (see above).

Glutamate dehydrogenase offers an alternative pathway by which ammonium can be incorporated through the reductive amination of α-kg. Because of its higher K_m for ammonium (millimolar range for GDH versus micromolar range for GS; Ahmed *et al.*, 1977; Bressler and Ahmed, 1984), GDH is thought to play a minor role in N assimilation in marine microbes (see Muro-Pastor *et al.*, 2005). However, GDH may offer a competitive advantage for cells when energy supplies are limited because it does not require ATP (see below). GDH activity is also common in marine animals, where it appears to operate primarily in the reverse direction resulting in the excretion of NH_4^+ (see Chapter 8 by Steinberg and Bronk, this volume). GS, GOGAT, and GDH are all fully reversible; many assays of their activity take advantage of this and as well as the hydrolysis of an ATP, the oxidation of reduced forms of specific coenzymes such as NADH or NADPH, or the consumption of substrates or production of products, or their analogs, over time.

In addition to their central role in amino acid biosynthesis, as primary products of N assimilation, gln and glu are thought to play an important role in regulating cellular N metabolism and determining cellular N status (Flynn and Gallon, 1990; Flynn et al., 1989, 1994; Mulholland and Capone, 1999; Mulholland et al., 1999). In enteric bacteria, the global N regulatory system (Ntr) is sensitive to intracellular C:N ratios (e.g., α-kg/gln) (Guerrero and Lara, 1987; Magasanik, 1993; Muro-Pastor et al., 2001; Reitzer and Magasanik, 1987). Global N control has also been observed in cyanobacteria but the cellular cues resulting in the expression of the transcriptional activator, NtcA, are unknown (Flores and Herrero, 1994; Lindell et al., 1998).

2.2.1. Glutamine synthetase

2.2.1.1. *Overview* GS (EC 6.3.1.2) catalyzes the condensation of glutamate and ammonium to form glutamine at the expense of ATP. There are three families of GS enzymes that have been identified. GS I, encoded by the glnA gene, is the typical eubacterial GS found in bacteria and archaea (Robertson et al., 1999, 2001), but also occurs in cyanobacteria (Herrero et al., 2001), and possibly some vascular plants (Mathis et al., 2000). It has 12 equally sized subunits. Type II GS, encoded by glnII, is found in eukaryotes and a few bacteria (Robertson et al., 2001). It has eight equally sized subunits. Type III GS, encoded by glnT and glnN, was thought to occur only in limited numbers of bacteria and in nondiazotrophic cyanobacteria (Herrero et al., 2001), but now appears to be more broadly distributed among the algae, e.g., diatoms and haptophytes (Robertson et al., 2001). In cyanobacteria, type III GS (glnN) consists of six identical subunits that are much larger than those of GSI or GSII (Merrick and Edwards, 1995).

The three classes of GSs are structurally related but their sequence similarities vary. Isoenzymes of GS are expressed in different cellular compartments, in microalgae, the cytoplasm and chloroplasts. The evolutionary origin of isoenzymes is the subject of research as are the relationships between different forms of GS (e.g., Robertson et al., 1999, 2001). Recent sequencing projects have provided data that indicate even greater complexities. For example, all of the genomes sequenced for *Prochlorococcus* have glnA and the amino acid sequence, molecular size and kinetic parameters are similar to those of other cyanobacteria (García-Fernández et al., 2004). Unexpectedly, the *T. pseudonana* genome contained all three forms of GS including the prokaryotic GSI type. The function of the different isoenzymes is also unclear. In higher plants, GS1 (cytosolic form) is thought to catalyze an N-recovery pathway and is typically used as a stress marker (e.g., Pageau et al., 2006).

2.2.1.2. *Assay techniques* GS is an excellent example of a reversible enzyme that is highly regulated and modified at multiple levels. GS is assayed in both the forward and reverse directions. In the forward direction, GS assays the biosynthesis of gln in the presence of the divalent cation Mg^{2+} (biosynthetic activity). Because Mg^{2+} appears to inhibit the activity of modified enzyme in the forward reaction, biosynthetic assay is thought to represent *in vivo* potential for gln synthesis via GS (Lee et al., 1988). In the reverse direction, GS assays measure total potential GS activity of both active and inactive enzyme in the presence of Mn^{2+} as the divalent cation (transferase activity) (Lee et al., 1988; Stadtman et al., 1979). In both of these

assays, hydroxylamine can be substituted for NH_4^+ and provides a stable product, γ-glutamylhydroxamate, which is easily measured and does not undergo further metabolism *in vitro* (Mulholland and Capone, 1999). The ratio between the forward and reverse direction assays may also provide an index of enzyme modification and the proportion of the total enzyme that is biosynthetically active in cells (Lee *et al.*, 1988; Mulholland *et al.*, 1999).

A variety of endpoints have been used to estimate GS activity in *in vitro* assays run in both the forward and reverse directions. Colorimetric assays for glutamyl hydroxamate and inorganic phosphate production and the release of NH_4^+ associated with the hydrolysis of gln (Bressler and Ahmed, 1984; Clayton and Ahmed, 1987; Falkowski and Rivkin, 1976; Shapiro and Stadtman, 1970; Stadtman *et al.*, 1979) are commonly employed, as are radioactive assays employing ^{14}C-glutamate (Pahuja and Reid, 1982; Prusiner and Milner, 1970; Rhee *et al.*, 1976; Thomas *et al.*, 1977). The GS/GOGAT pathway was first identified as the primary pathway of N metabolism in cyanobacteria using radioactive $^{13}NH_4^+$ (Meeks *et al.*, 1978); however, this method is impractical for routine assays given the short half life of ^{13}N.

Although this seems to paint a bright picture for GS assays, there are different forms of GS doing different things in different places within cells. *In vitro* assays using cell homogenates mixes these enzyme pools and confounds results measuring total activity in either direction. Currently, it is impossible to distinguish activity among isoforms in bulk enzyme assays. For example, in the diatom, *S. costatum*, GSII appears to play a role in assimilating NH_4^+ derived specifically from NO_3^- reduction (Takabayashi *et al.*, 2005).

Inhibitors have been used not only to identify pathways of N metabolism but also to distinguish between uptake and assimilation of inorganic N. For example, MSX is an irreversible inhibitor of GS and has been used to explore the role of N assimilation products (e.g., gln) and intracellular NH_4^+ on the feedback inhibition of processes such as nitrogenase activity and NO_3^- uptake (Arp and Zumft, 1983). In addition, the protonophore carbonyl cyanide *m*-chlorophenylhydrazone (CCCP) has been used to distinguish between uptake and assimilation of NH_4^+ in marine algae (Rees *et al.*, 1998).

2.2.1.3. Enzyme regulation and interpretation of activity assays

GS is a highly regulated enzyme and its regulation may preclude the ability to use simple activity assays to derive estimates of N assimilation in marine microbes. Different families of GS are regulated and modified differently. As with many enzymes, GS has characteristics that make interpretation of assay results difficult (e.g., sensitivities to feedback inhibition and divalent cation specificity), regulation occurs at both the level of synthesis and activity, and activity varies with growth conditions. In addition, subunits of GS are differentially and reversibly modified; by adenylylation in bacteria (Silman *et al.*, 1995), covalent modification by ADP-ribosylation (Merrick and Edwards, 1995), phosphorylation (Miflin and Habash, 2002), and by interaction of two inhibitory polypeptides in cyanobacteria (García-Domínguez *et al.*, 1999). The degree of inhibition appears to be governed by the number of modified subunits.

GS is regulated in response to cumulative feedback inhibition by multiple end products of glutamine metabolism (Stadtman, 2001) and the different families of GS are sensitive to different cellular cues (Shatters *et al.*, 1993). Nitrogen regulation of GS occurs under all growth conditions. Under N-replete conditions, nitrogen assimilatory capacity is controlled to coordinate nitrogen and carbon assimilation (balance). Under nitrogen-depleted conditions the cell's assimilatory capacity is modified. Severe starvation can result in expression of alternative N acquisition pathways (Ninfa and Atkinson, 2000).

Modification of GS is mediated through regulatory proteins (e.g., P_{II}) that are themselves highly regulated and reversibly modified (Arcondéguy *et al.*, 2001; Lee *et al.*, 2000; Magasanik, 2000). P_{II} proteins serve as signal processing proteins that integrate cellular carbon and nitrogen status and signal the control of N assimilation via GS in enteric bacteria, archaea, and some cyanobacteria (Arcondéguy *et al.*, 2001). The complexities of these regulatory pathways are beyond the scope of this review but regulation appears to occur in response to environmental factors such as dissolved inorganic nitrogen concentrations and feedback from intracellular metabolites. A *glnB* gene encoding for P_{II} protein has also been identified in marine cyanobacteria including, *Trichodesmium erythraeum, Prochlorococcus, Synechococcus* (García-Fernández *et al.*, 2004) as well as *Synechocystis* sp. and *Synechococcus* sp. (Forchhammer and Tandeau de Marsac, 1995; García-Domínguez and Florencio, 1997; Wyman, 1999).

As for GS, activation of the P_{II} protein is regulated by nitrogen availability and is dependent on photosynthetic electron transport (García-Domínguez and Florencio, 1997; Reyes and Florencio, 1995). P_{II} proteins have been reported so far only for red algae (Reith and Munholland, 1993), and marine cyanobacteria (García-Fernández *et al.*, 2004). However, it has been suggested that the P_{II} protein in *Prochlorococcus marinus*, like that of *Synechocystis* may serve more as a sensor for C acquisition than for N control (Palinska *et al.*, 2002). In addition to P_{II} signal transducer proteins, GlnK and GlnK-like proteins may also contribute to N regulation and signal sensing in bacteria and archaea. These proteins are structurally similar but functionally distinct (Ninfa and Atkinson, 2000).

Transcription of both the GS gene (*glnA*) and the P_{II} gene (*glnB*) are regulated by the transcription activator *NtcA* in enteric bacteria (Magasanik, 2000). However, there appear to be simpler regulatory pathways in some cyanobacteria such as *Prochlorococcus* (Gómez-Baena *et al.*, 2001). We still know little about the regulatory pathways affecting GS across algal taxa or among different GS pools. GS is not the only enzyme that is under N control in cyanobacteria (e.g., nitrogenase and NR above). Other enzymes involved in N uptake and assimilation are also regulated in response to N through common regulatory pathways. Because GS is needed to assimilate all N, GS activity must be maintained for cellular N acquisition. However, it appears that not only are there different GS pools but that they may be regulated differently and are transcribed from different promoters during growth on different forms of N (e.g., N_2; Tumer *et al.*, 1983). For example, nonheterocystous N_2 fixing bacteria and cyanobacteria have been shown to have elevated GS activity when fixing N_2 (Meeks *et al.*, 1987; Rai *et al.*, 1992; Smith and Gallon, 1993). For *Trichodesmium* spp., *glnA* transcript abundance was elevated both during the

pre-dawn period corresponding with the peak *nifH* transcript abundance and another peak late in the afternoon that was not correlated with nitrogenase-associated gene products (e.g., constitutive; Kramer *et al.*, 1996; Mulholland *et al.*, 1999; Wyman *et al.*, 1996). Consistently, the ratio of GS transferase/biosynthetic activity, or the proportion of the enzyme that was biosynthetically active, changed in response to the daily pattern of N_2 fixation in *Trichodesmium* IMS101, consistent with the idea of two separate pools of GS regulated differently, at the level of enzyme synthesis (Mulholland *et al.*, 1999).

2.2.1.4. *Information gained from assays and future potential*   GS activity is critical to our understanding of N assimilation in marine organisms but, is clearly a very complicated enzyme both from the standpoint of activity and regulation. Understanding GS activity and its regulation might offer insights into the marine N cycle but, in practice, it may be beyond our abilities to measure it effectively and to gain useful information from the interpretation of bulk enzyme assays at this time.

2.2.2. Glutamate synthase

2.2.2.1. *Overview*   Glutamate synthase (GOGAT; formerly glutamine: 2-oxogl-utarate amidotransferase) is a complex iron–sulfur flavoprotein that catalyzes the synthesis of two glu molecules from a molecule each of gln and α-kg. The eubacter-ial version of the enzyme is composed of two subunits. The small subunit is a flavin adenine dinucleotide-dependent NADPH oxidoreductase which shows sequence similarity to several other protein domains and enzyme subunits. Indeed, the small subunit of eubacterial glutamate synthase has been proposed to be a prototype of protein domains or enzyme subunits used in many different contexts to transfer electrons from NAD(P)H to an acceptor protein or protein domain. In the case of glutamate synthase, the small subunit provides electrons to the large subunit, which binds L-glutamine and 2-oxoglutarate and forms L-glutamate.

There appear to be three classes of GOGAT based on the source of the electron donor used for the conversion of glutamine and α-kg to glutamate: NADPH-GOGAT (EC 1.4.1.13) found primarily in bacteria and archaea, both NADH-GOGAT (EC 1.4.1.14) and Fd-GOGAT (EC 1.4.7.1) are found in eukaryotes (higher plants and algae), cyanobacteria, and animal cells. Different forms of the enzyme have distinct genes (Suzuki and Knaff, 2005). However, distribution of various forms of the enzyme appear to be complex. All three types of GOGAT were found in the *T. pseudonana* genome; *glsF*, the cyanobacterial ferredoxin dependent version, and two NAD(P) H dependent forms, *gltB* and *glt D*. It had been previously speculated that these two genes were typically fused to form *glnN* in eukaryotes; however, this is clearly not the case in *T. pseudonana* where these genes are separate (Armbrust *et al.*, 2004; Berges, unpublished data).

2.2.2.2. *Assay techniques*   Assays of GOGAT rely on measuring fluorometrically or spectrophotometrically the oxidation of reductant (Ahmed *et al.*, 1977; Avila *et al.*, 1987; Clayton and Ahmed, 1986; Inokuchi *et al.*, 1999), or measuring products of enzyme activity (e.g., ^{14}C-glutamate production; Cullimore and Sims, 1981; Prusiner and Milner, 1970). As for other enzyme assays, these assays are

sensitive to pH, temperature and substrate concentrations. Azaserine, a glutamine analog, inhibits GOGAT and has been used to probe GOGAT activity in nature.

2.2.2.3. Enzyme regulation and interpretation of activity assays

GOGAT activity does not appear to be as heavily regulated as GS activity, or perhaps it is just less studied (Florencio et al., 1987; Muro-Pastor et al., 2005). However, GOGAT does appear to be regulated by light and metabolite sensing systems in higher plants (Suzuki and Knaff, 2005). Cyanobacterial systems are well studied compared to other marine phytoplankton, but no regulation of GOGAT expression by N source has been observed for this group (Herrero et al., 2001). Interestingly, in heterocystous cyanobacteria, GS is present but GOGAT is absent from the heterocysts suggesting that gln or some other amino acid has to be transported from the heterocysts to vegetative cells to be further metabolized (Muro-Pastor et al., 2005).

2.2.2.4. Information gained from assays and future potential

GOGAT may be an excellent example of an enzyme that plays a secondary role in a cyclic enzyme pathway. However, if this is the case, it is unclear why it is so highly regulated in some cases. Additional functions for this enzyme in N metabolism may yet be identified.

2.2.3. Glutamate dehydrogenase

2.2.3.1. Overview

Glutamate dehydrogenase (EC 1.4.1.3) is an alternative pathway for NH_4^+ assimilation and glutamate synthesis in some species of algae, such as green microalgae and macroalgae, but it does not appear to be the dominant pathway of N assimilation in most marine phytoplankton. GDH is thought to function primarily in a catabolic role and likely only plays a role in ammonium assimilation when intracellular ammonium concentrations are very high (Melo-Oliveira et al., 1996; Moorhead and Smith, 2003).

As for GS and GOGAT, there appear to be several families of GDH with many isoenzymes in each family. NADP-GDHs have been found in the chloroplasts of green algae as well as in the mitochondria and cytosol of other species including macroalgae (Inokuchi et al., 1999). Organelle-specific GDH isozymes (chloroplastic, mitochondrial, and cytosolic) and two distinct GDH genes were isolated in the green macroalgae Bryopsis maxima (Inokuchi et al., 1999). NADP-dependent GDH activities were found in all three cellular compartments while NAD-dependent GDH was observed only in the chloroplasts.

Genes encoding GDH are not present in most cyanobacteria; however, they are present in one Prochlorococcus genome and in T. erythraeum (García-Fernández et al., 2004; Muro-Pastor et al., 2005). Interestingly, Trichodesmium appear to release NH_4^+ during active N_2 fixation (Mulholland et al., 2004a,b) and destroy and resynthesize much of their nitrogenase daily (Zehr et al., 1993), suggesting a catabolic role. Both NADH- and NADPH- specific forms of GDH are present in the diatom. T. pseudonana (Armbrust et al., 2004).

In heterotrophs, GDH is involved in the production of NH_4^+ during catabolism of protein (Park et al., 1986). Indeed, zooplankton often account for the majority of

GDH activity in marine systems (Bidigare *et al.*, 1982; Park *et al.*, 1986). Assays of the enzyme in the reverse direction are virtually identical to those discussed below.

2.2.3.2. Assay techniques   GDH utilizes both nicotinamide nucleotide cofactors; NAD^+ in the direction of N liberation (catabolic) and $NADP^+$ for N incorporation (assimilatory). In the forward reaction, GDH catalyzes the synthesis of amino acids from free ammonium and α-kg. The reverse reaction links amino acid metabolism with TCA cycle activity. In the reverse reaction, GDH provides an oxidizable carbon source used for the production of energy as well as a reduced electron carrier, NADH, and production of NH_4^+. As for other enzymes, spectrophotmetric methods have been developed for measuring oxoglutarate and aminotransferase activities by assaying substrates and products of the GDH catalyzed reaction (Ahmad and Hellebust, 1989).

2.2.3.3. Enzyme regulation and interpretation of activity assays   GDH is ubiquitous in both higher and lower organisms where it serves in both biosynthetic and catabolic capacities. Little is known about its regulation in marine microbes because it is not thought to be biosynthetically active in most marine environments and because of low N concentrations. Although it is thought that GDH functions primarily in the reverse direction based on kinetic arguments, activity measurements are sparse as are measurements of intracellular NH_4^+ concentrations. It has recently been argued that in higher plants, GDH may have a role in stress response (Dubois *et al.*, 2003), but this has not been examined in marine algae.

2.2.3.4. Information gained from assays and future potential   This enzyme is easily assayed *in vitro* but results from assays have rarely shown relationships with N assimilation, perhaps because this is not its major function. It might be time to revisit GDH assays and consider relationships with nonassimilatory pathways.

2.3. Organic nitrogen acquisition

Although inorganic N has traditionally been thought to be the primary N source for marine autotrophs, it is now apparent that this is not always true (see Chapter 7 by Mulholland and Lomas, this volume) and that organic N can be a major N source in many marine environments. With that in mind, enzymes involved in the hydrolysis or mobilization of organic N are examined.

2.3.1. Urease
2.3.1.1. Overview   Urease is found in diverse groups of marine bacteria, plants, and animals. In most organisms, urease serves to break down urea to mitigate its toxic effects in the cellular environment. However, urea is the most abundant identifiable form of dissolved organic nitrogen (DON) in most aquatic ecosystems and most organisms can use urea as an N source by taking it up into the cytoplasm where it can be hydrolyzed into two ammonia molecules which can then be assimilated. Intracellular hydrolysis of urea and its ultimate assimilation occurs through one of two enzymatic pathways: urease (urea amidohydrolase, EC 3.5.1.5) or ATP:urea

amidolyase (UALase). The latter has been demonstrated to exist exclusively in the chlorophyte algae (Leftley and Syrett, 1973). UALase complex catalyzes the production of two ammonia and two bicarbonate ions from urea and bicarbonate via a carboxylating reaction and then the produced allophanate, water, and hydroxyl group by hydrolysis (Bekheet and Syrett, 1977).

Urease is widespread in phytoplankton, including diatoms (Lomas, 2004; Milligan and Harrison, 2000; Oliveira and Antia, 1986; Peers et al., 2000), chrysophytes (Leftley and Syrett, 1973), dinoflagellates (Dyhrman and Anderson, 2003; Fan et al., 2003), a pelagophyte (Fan et al., 2003), and cyanobacteria (Herrero et al., 2001); and in bacteria, (Oliveira and Antia, 1986) and other organisms (see Antia et al., 1991; Leftley and Syrett, 1973). Urease activity involves the nickel–dependent hydrolysis of urea into two NH_4^+ molecules and CO_2. Urease is constitutive in many cases for algae but not for bacteria. Urease is generally cytoplasmic (Mobley and Hausinger, 1989).

Urease was the first enzyme whose functional structure was elucidated (see Zimmer, 2000). All together seven polypeptides are needed for functional urease. UreC is the major functional subunit of urease and is large (Collier et al., 1999) relative to the ureA and ureB subunits; all are highly conserved. In addition, four accessory genes, *ureD*, *ureE*, *ureF*, *ureG*, are needed for enzyme assembly.

2.3.1.2. Assay techniques

As for other N compounds, uptake is often estimated using isotopic tracers and urease activity is inferred from incorporation of labeled atoms into biomass. In addition to molecular methods of purifying and characterizing ureases in organisms, *in vitro* colorimetric methods for assaying urease activity in marine microbes have been developed (Peers et al., 2000). Hydrolysis of urea produces two NH_4^+ and a CO_2 molecule, both of which have been used as endpoints to estimate urease activity in marine organisms. $^{14}CO_2$ has been measured as an endpoint of urea hydrolysis using ^{14}C–labeled urea (Bekheet and Syrett, 1977; Ge et al., 1989; Leftley and Syrett, 1973). Assays have also measured NH_4^+ production from urease to estimate activity (Collier et al., 1999; Fan et al., 2003; Jahns et al., 1995; Oliveira and Antia, 1986; Peers et al., 2000). Unfortunately, easily measurable products of urease, NH_4^+ and CO_2, are subsequently released or consumed in both downstream and competing biochemical pathways.

2.3.1.3. Enzyme regulation and interpretation of activity assays

There appear to be species-specific differences in the degree of constitutive expression versus upregulation of urease activity depending upon nutrient prehistory. For example, urease activity has been shown to be upregulated in *T. pseudonana* grown on NO_3^- and urea (Peers et al., 2000), downregulated in *T. weissflogii* grown on NO_3^- (Lomas, 2004), and upregulated in *Synechococcus* WH7805 growing on NO_3^- (Collier et al., 1999). The pelagophyte, *Aureococcus anophagefferens*, and dinoflagellate, *Prorocentrum minimum*, exhibited high urease activities regardless of the N source (Fan et al., 2003a) while the dinoflagellate *Alexandrium fundyense* displayed inducible urease activity (Dyhrman and Anderson, 2003). Constitutive and ammonium–repressible ureases are present in cyanobacteria. However, expression of high affinity urea

uptake activity is subject to N control and has an ABC–type high–affinity transporter (Herrero *et al.*, 2001; Valladares *et al.*, 2002). As for nitrogenase and NR, urease expression in marine *Synechococcus* (WH7805, WH8102) is part of the *NtcA* operon (e.g., therefore, N regulated).

2.3.1.4. *Information gained from assays and future potential*   Urea uptake may be much more important than previously thought in the open ocean (see Chapter 7 by Mulholland and Lomas, this volume). Not only do autotrophs use urea, but bacteria also have ureases, suggesting that they can readily use urea, although the available data suggest that autotrophic phytoplankton have consistently lower K_m values for urea than do bacteria (Fan *et al.*, 2003; Jahns, 1992; Mobley and Hausinger, 1989). Another surprise arising from a genomic analysis of *T. pseudonana* is that this diatom has a fully-functional urea cycle. Such a cycle is typical of animals, where NH_4^+ generated during catabolism is converted into urea for excretion. It is unclear whether diatoms actually excrete "waste" urea since they also possess an apparently constitutively active urease that can hydrolyze urea to NH_4^+ and CO_2 and three urea transporters (Armbrust *et al.*, 2004). The function of the urea cycle in this diatom is still a mystery, but bacteria are known to produce urea and in general, we know little about the production or sources of urea in the marine environment, despite the observation that it can fuel much of the productivity at times (see Chapter 7 by Mulholland and Lomas, this volume). In toad fish, urea synthesis appears to act as part of a N salvage mechanism (Mommsen and Walsh, 1989), and in teleostean fish and elasmobranches, urea serves as an osmolyte. If in fact diatoms produce urea internally in order to turnover amino acids and recycle N, reports of constitutive urease activity indeed make sense.

2.3.2. Extracellular enzymes acting on organic nitrogen

2.3.2.1. *Overview*   In general, less is known about cell surface than intracellular enzymes, particularly for phytoplankton. One of the reasons is that although dissolved organic matter (DOM) is the largest pool of combined N in the ocean, its availability to organisms is unknown because DOM is a complex mixture of compounds, most of which are uncharacterized (see Hansell and Carlson, 2002). Because of this complexity, a variety of different substrate-specific extracellular enzymes are necessary to remineralize DOM in nature (Hoppe, 1991) so that it is available to microorganisms. Most of the DOM is ultimately derived from primary production and proteins typically represent at least 75% of phytoplankton cell N (Dortch *et al.*, 1984; Nguyen and Harvey, 1994) and 80% of bacterial cell N (Kirchman, 2000). Dissolved combined amino acids (DCAA) typically represent between 5 and 20% of the dissolved organic nitrogen (DON) pool (Bronk, 2002; Keil and Kirchman, 1991; Sharp, 1983), and 3–4% of the dissolved organic carbon (DOC) pool in seawater (Benner, 2002). The high molecular weight (HMW) DOM is thought to be the more bioreactive fraction of the bulk DOM pool and it is estimated that 75–85% of the nitrogen in HMW DOM is in amide structures (Benner, 2002). While much of this is resistant to chemical hydrolysis in the laboratory, organisms are clearly able to hydrolyze or use some of this N because the C:N ratio of particulate organic material (POM) and DOM decreases significantly as material is degraded.

Extracellular degradation of HMW DOM into usable components is necessary for microorganisms to take advantage of organically-bound N because most microbes and phytoplankton can take up only inorganic or small organic compounds (Antia *et al.*, 1991; Nikaido and Vaara, 1985) and most HMW DOM is just too big. Therefore, extracellular hydrolysis of proteins and peptides is required before this N can be used for growth. Particularly important are extracellular enzymes that degrade large polymeric biomolecules to small, labile compounds. In addition, some organisms may not be able to use organic compounds at all and require remineralization of DON prior to its uptake. Extracellular amino acid oxidases can facilitate production of dissolved inorganic nitrogen (DIN) from amino acids (Mulholland *et al.*, 1998; Palenik and Morel, 1990a,b; Palenik *et al.*, 1989) and there is close coupling between amino acid oxidation and uptake of NH_4^+ produced from these reactions (Mulholland *et al.*, 2003).

Extracellular enzymes include exoenzymes that occur free in the water or adsorbed to surfaces other than those of their producers whereas ectoenzymes are bound to the cell surface or are found in the periplasmic space (Chròst, 1991). Extracellular enzymes responsible for degrading proteins, peptides, and amino acids have been widely attributed to heterotrophic bacteria (Rosso and Azam, 1987; Sinsabaugh *et al.*, 1997; Hoppe, 1983, 1991; Hoppe *et al.*, 2002), although phytoplankton have been found to possess cell surface enzymes that can oxidize amino acids (Mulholland *et al.*, 1998; Palenik and Morel, 1990a,b; Palenik *et al.*, 1989; Pantoja and Lee, 1994) and hydrolyze peptides (Mulholland *et al.*, 2002, 2003; Stoecker and Gustafson, 2003). LAP activity has also been observed in cyanobacteria (Martinez and Azam, 1993; Stoecker *et al.*, 2005). Other types of plankton may also be responsible for dissolved protease activities. For example, heterotrophic flagellates are a source of protease activity (Karner *et al.*, 1994; Sala and Güde, 1999), and mesozooplankton grazers may also be important (Bochdansky *et al.*, 1995).

2.3.2.2. Assay techniques

Fluorogenic compounds and fluorescent derivatives have been commonly used to evaluate extracellular enzyme activity. Fluorogenic substrates are comprised of an artificial fluorescent molecule bound to a more natural molecule (e.g., amino acids) with a specific linkage (e.g., peptide binding). Fluorescence is observed after enzymatic cleavage of the bond. Assays employing fluorogenic compounds are very sensitive. Extrapolating enzyme activity from assays employing fluorogenic compounds can be complicated, however, by competing or inhibitory compounds naturally occurring in the environment. Two commonly used fluorogenic compounds are 4-methylumbelliferone (MUF) and 7-amino-4-methylcoumarin (AMC). Both L-leucyl-B-naphthylamide and L-leucine-4-methylcoumarinyl-7-amide (Leu–MCA) have been used to assay aminopeptidases in aquatic systems and MUF-*N*-acetyl-glucosaminide has been used to investigate chitinase activity (Berg *et al.*, 2002). These compounds are too large to cross cell membranes.

There are many types of proteases, but an important divison is endo- vs. exopeptidases. Endopeptidases (= proteinases) that cleave within polypeptide chains are likely important in the early stages of protein degradation, while exopeptidases that act on the termini of polypeptide chains (i.e., amino- or carboxypeptidases) are

probably more important during the intermediate and late stages of protein degradation (Barrett, 1986). A number of endo- and exopeptidases with different substrate specificities have been described, some of which are active at alkaline pH (Barrett, 1986). Only a few types have been reported in seawater, probably because of the limited number of artificial substrates available for use in investigating extracellular enzyme activity in aquatic ecosystems. Other extracellular enzymes have been examined in aquatic systems using fluorogenic substrates in natural assemblages or cultures (Berg et al., 2002; Hoppe, 1983; LeCleir and Hollibaugh, 2006; Martinez et al., 1996; Sherr and Sherr, 1999; Sinsabaugh et al., 1997).

There are fewer measurements of endopeptidase activity in aquatic samples (see below). In contrast, there have been numerous measurements of LAP, an exopeptidase, in freshwater and marine environments using artificial fluorogenic substrates, such as Leu-AMC (Martinez et al., 1996; Rosso and Azam, 1987; Sinsabaugh et al., 1997; Stoecker and Gustafson, 2003; Stoecker et al., 2005). LAP hydrolyzes a broad spectrum of substrates with a free amino group, but has a preference for N-terminal leucine and related amino acids (Mahler and Cordes, 1966). Measuring LAP may underestimate peptide utilization not only because dipeptides are directly incorporated (see below), but also because endopeptidases are not the only enzymes that hydrolyze protein-like material.

Alternative methods for measuring rates of amino acid oxidation and peptide hydrolysis in seawater samples are the application of fluorescently labeled amino acids and peptides, Lucifer Yellow Anydride-lysine (LYA-lysine) and Lucifer Yellow Anydride-tetraalanine (LYA-ala4), respectively (Mulholland et al., 1998, 2002, 2003; Pantoja and Lee, 1999; Pantoja et al., 1993, 1994, 1997 Fig. 32.2). These methods have the advantage of using real amino acids and peptides with the availability of several peptide bonds to cleave. Uptake of $^{15}NH_4^+$ from oxidation of ^{15}N-LYA-lysine has been demonstrated (Mulholland et al., 2003). In addition, the primary products of LYA-ala4 hydrolysis appear to be dipeptides (Mulholland et al., 2002, 2003, unpublished data) suggesting that it may measure endopeptidase activity and that endopeptidase activity exceeds exopeptidase activity in the environment. Direct uptake of dipeptides has also been observed suggesting that uptake competes with exopeptidase activity and that LAP assays may underestimate the hydrolysis and utilization of peptides by marine microbes (Mulholland and Lee, in revision).

Assays of extracellular enzyme activity must take care not to disrupt cells and thereby bias results by including intracellular enzyme activity in rate estimates. Berges and Falkowski (1996, 1998) found cell-associated LAP with peak activity between pH 7.5 and 8.5 (the pH range of seawater) in homogenates of marine phytoplankton, however, in this study no attempt was made to distinguish intracellular from ectocellular enzymes.

No molecular methods for cell surface enzymes are yet available, but one study by (Palenik and Koke 1995) found an N-regulated cell surface (membrane or wall) protein, nrp1, present in N-limited cells and during growth on urea. This method located enzyme on the cell surface using a biotinylation process. Derivatizing the cell-surface with a biotin-containing reagent causes the biotin to be transferred to cell-surface proteins which then allows the labeled proteins to be detected on
Figure 32.2 Cell surface peptide hydrolysis (A) and amino acid oxidation (B) using the fluorescent compound Lucifer Yellow Anhydride (LYA)–tetraalanine and lysine, respectively. Fluorescent products are measured along with the added tracer by high performance liquid chromatography (HPLC) and products can be further degraded or taken up by cells.

western blots because of the high affinity of the protein avidin to the biotin moiety (Palenik and Koke, 1995). While they were unable to identify the function of nrp1, they were able to rule out a cell surface amino oxidase, but it is possible that nrp1 is another type of degradative enzyme or transporter for organic N.

Other endpoints that have been used to estimate extracellular enzyme activity include monitoring the concentrations of substrates and products of oxidation or hydrolysis reactions (e.g., H_2O_2, α–keto acids, amino acids). These methods are limited however, because there are multiple sources and sinks of these compounds in the environment.

2.3.2.3. Enzyme regulation and interpretation of activity assays   Little to no information is available on the regulation of these enzymes although extracellular peptide hydrolysis and amino acid oxidation appear to be sensitive to the nutrient environment (Mulholland *et al.*, 2004a,b; Mulholland and Lee, in revision).

2.3.2.4. *Information gained from assays and future potential* The contribution of eukaryotic phytoplankton to protease activity in the water has only recently been reconsidered (Sala *et al.*, 2001). Most of the evidence for exo- or endopeptidase activity in phytoplankton is from research with cultures (Stoecker and Gustafson, 2003).

Langheinrich (1995) investigated plasma membrane-associated leucine and alanine aminopeptidase activities in *Chlamydomonas reinhardtii* as well as in several other freshwater microalgae. *C. reinhardtii*, can grow on histidine, thanks to presence of histidinase and urocanase (Hellio *et al.*, 2004). Berg *et al.* (2002) found that axenic cultures of the ''brown tide'' pelagophyte, *A. anophagefferens* had high rates of extracellular hydrolytic enzyme activity and could out-compete several groups of bacteria for organic compounds. Further, these cultures used the hydrolysis products to meet their N demands for growth. Mulholland *et al.* (2002) found high rates of peptide hydrolysis both in nature and in nonaxenic cultures of *A. anophagefferens* and measured rates of peptide hydrolysis varied depending on whether cultures were conditioned on NO_3^-, NH_4^+, or urea as an N source suggesting that enzyme activity is at least partially controlled by nutrients (Mulholland *et al.*, 2004a,b; Mulholland and Lee, in revision). Surveying cultures across a wide range of taxa suggests that the ability to hydrolyze peptides may be common (Fig. 3 from Mulholland and Lee, in revision). Other extracellular enzymes may also be common in the marine environment but far less is known about them.

2.3.3. Digestive proteases

2.3.3.1. *Overview* Heterotrophs represent a major sink for primary production, and thus a critical part of the marine N cycle. In the pelagic realm, there have been attempts to estimate zooplankton grazing (both micro- and macro-zooplankton) using two major enzymatic approaches: activities of digestive enzymes (especially proteases in the case of N) (e.g., Gonzalez *et al.*, 1993) and the activity of GDH, the
Figure 32.3 Turnover time for the fluorescent compound LYA-tetra-alanine by cultures of different phytoplankton species and taxa (data from Mulholland and Lee, in revision).

key step in the pathway of excretion of NH_4^+ following catabolism of protein (e.g., Bidigare *et al.*, 1982; Mayzaud, 1987; Park *et al.*, 1986). Attention has also been given to the digestive enzymes of benthic heterotrophs, though this has been related more to assessing digestive acclimation and food quality than to quantifying rates. Digestive enzymes have been examined in connection with food supply and feeding rates (e.g., Mayer *et al.*, 1997), and to help determine what materials might be degraded by different species in different environments (Roberts *et al.*, 2001).

2.3.3.2. Assay techniques

Traditional assays for digestive proteases were based on spectrophotometric measurements of substrate hydrolysis, but in some cases these substrates lacked the sensitivity necessary for field work and there may also be problems with specificity. In the past 10 years, due largely to the demands of the emerging proteomics field, a wide range of fluorometric substrates have become available, especially amino methyl-coumarin conjugates (AMC or MCA), which have been discussed above in the section on extracellular enzymes (see also Sarath *et al.*, 1989). A wide range of highly-specific substrates are available (e.g., Suc–Ala–Ala–Phe–AMC for chymotrypsin [http://www.bachem.com/]), as well as corresponding inhibitors).

2.3.3.3. Enzyme regulation and interpretation of activity assays

Because digestive enzymes are released into the guts of multicellular organisms, or contained within structures like food vacuoles of unicellular ones, they are not under the same degree of regulation as are many other enzymes that have been discussed. Control is exerted during synthesis by having inactive forms (proenzymes or zymogens), which are activated just prior to release. As a result, the major difficulty in interpreting digestive enzyme activities is that they may respond to feeding conditions with variable and unpredictable time lags (e.g., Hassett and Landry, 1990; Mayzaud *et al.*, 1992; Roche-Mayzaud *et al.*, 1991). There are also complications in comparing activities among species with differing gut morphology (see Han *et al.*, 2002). In terms of assays, generic substrates have often been used so that the precise identities of the proteases remain unknown; it is likely that intracellular and gut enzymes have often been measured together. For benthic macroorganisms, fitting digestive enzyme activities into N budgets has been challenging because the long recovery times and sharp changes in environment following capture of organisms are not ideal for preserving activities.

Despite the recognition that GDH may be more important in its catabolic role, GDH activities have been difficult to correlate with nitrogen excretion because of the complications of size-scaling; GDH activities scale differently with body size than do N-excretion rates (see Berges *et al.*, 1993). Assays are also potentially complicated by the presence of assimilatory GDH in other organisms in samples.

2.3.3.4. Information gained from assays and future potential

Digestive enzyme activities have proven most useful in indicating the potential for an organism to metabolize a given substrate, and also for inferring that an organism has had the substrate in its diet. In some cases, variation in enzyme activity has proven useful in establishing the presences of diel feeding rhythms (e.g., Head *et al.*, 1984).

Quantitative interpretations of digestive enzyme activities have proven challenging, but newer, more specific assays (involving highly fluorescent substrates) and improvements in image analyses may offer potential solutions, and these measurements are worth revisiting. Digestive enzyme assays have seldom been used for microzooplankton (but see Gonzalez *et al.*, 1993), but they may be more interpretable in these species because the enzyme are intracellular and thus may be under tighter control than those found in the guts of metazoans. Very few molecular characterizations of digestive enzymes have been conducted in any group of zooplankton.

2.4. Other enzymes connected with nitrogen cycling

There are a variety of other enzymes that cannot be excluded in our discussion of N assimilation.

2.4.1. Enzymes associated with Carbon metabolism: Carbon-fixation and respiratory pathways

2.4.1.1. Overview   While enzymes associated with C metabolism are not directly involved in marine N cycling, they are significant for two reasons. First, N is inextricably linked with C metabolism; without C skeletons, N cannot be assimilated by autotrophs (Huppe and Turpin, 1994; Young and Beardall, 2003), and virtually all N degradation also results in respiration of C (Collos *et al.*, 1992). Second, there is some evidence that algal species, like higher plants, may use the enzymes (especially Rubisco) as forms of N storage. This is clearest in the green algae where the pyrenoid of the chloroplast can contain the greater part of the Rubisco pool in crystalline form. Although it is not yet known how widespread such a strategy might be (see Ekman *et al.*, 1989 for an example in red macroalgae), starvation does result in degradation of Rubisco in several species (Falkowski *et al.*, 1989; Garcia–Ferris and Moreno, 1994). Carboxylase activities have been measured in marine systems for some time (e.g., Fontugne *et al.*, 1991; MacIntyre *et al.*, 1996) and more recently, species-specific measurements of gene expression of Rubisco in natural communities have become feasible (e.g., Pichard *et al.*, 1997; Wyman, 1999).

Because of the links between rates of N acquisition and C metabolism (e.g., Grobbelaar *et al.*, 1991), there have been attempts relate the two using the activities of respiratory enzymes and metabolic modeling (see Packard *et al.*, 2004). Metabolic rate has been estimated using specific enzymes (succinate dehydrogenase, isocitrate dehydrogenase, cytochrome *c* oxidase, citrate synthase), but also by using a multienzyme assay known as ETS activity (see Packard, 1985), or bulk reduction of tetrazolium substrates (Bamstedt, 2000).

2.4.1.2. Assay techniques   For Rubisco and other carboxylases, while some spectrophotometric methods exists (e.g., Gerard and Driscoll, 1996), the sensitivity necessary for measurements in the field makes radiochemical methods based on ^{14}C most useful (Ashton *et al.*, 1990; Keys and Parry, 1990). Most respiratory enzyme assays are spectrophotometric in nature, based on use of NADH or tetrazolium salts (e.g., Packard, 1985; Thuesen and Childress, 1993).

2.4.1.3. Enzyme regulation and interpretation of activity assays   Carboxylases and respiratory enzymes are heavily regulated *in vivo*, making interpretation of activity assays challenging. In the case of Rubisco, for example, there is a second enzyme system involved in posttranslational activation (Rubisco activase, Macintyre *et al.*, 1997; Pierce *et al.*, 1982). For respiratory enzymes, as well, control of fluxes through pathways may not rest with a single enzyme and may involve posttranslational regulation, so individual enzyme activities may be of limited use in predicting overall fluxes (Arnold and Kadenbach, 1997). As is the case for GDH (see above), there are issues involving metabolic size scaling of respiratory enzymes, as well (see Berges *et al.*, 1993). Moreover, enzymes involved in carbon metabolism are linked to those involved in nitrogen metabolism on a number of levels. The regulatory networks of well-studied microorganisms including bacteria and cyanobacteria include a transcriptional factor, the global nitrogen regulator, *NtcA*, and signal transduction proteins (e.g., P_{II}, glnK see above) which coordinate the metabolism of N and C in the cell (García-Fernández *et al.*, 2004; Herrero *et al.*, 2001; Tandeau de Marsac *et al.*, 2001).

2.4.1.4. Information gained from assays and future potential   Because of the high degree of regulation, C cycle enzyme activities may prove difficult to interpret by themselves. The potential for combining such measurements with activities of N cycle enzymes has been discussed (see Packard *et al.*, 2004) but not yet realized.

2.4.2. Esterases
2.4.2.1. Overview   The presence of esterase activity in seawater has been used as evidence for lysis of cells, which represents a potentially important pathway from PON to DON in marine environments (e.g., Brussaard *et al.*, 1995; van Boekel *et al.*, 1992). Esterases represent a large group of enzymes (EC 3.1.x.x) that catalyze the hydrolytic cleavage of an ester bond. These enzymes have very broad specificity, and a variety of other enzymes including proteinases have "esterolytic" action. Esterase methods are based on the assumptions that these enzymes are solely intracellular, and that they do not retain activity for very long outside the cell. Additional assumptions permit estimates of lysis rate to be calculated (e.g., Agusti *et al.*, 1998). Criticisms of the lysis rate methods have led to a number of modifications (see Agusti and Duarte, 2002; Riegman *et al.*, 2002), and the accuracy of the quantitative method is in some doubt, however, the basic measurements have been correlated with independent measurements of cell losses in at least some cases (e.g., Brussaard *et al.*, 1995). There is evidence to suggest that phytoplankton are the main source of dissolved esterase activity, and that grazing does not result in significant release of esterases.

2.4.2.2. Assay techniques   Esterases are measured using the substrate fluorescence diacetate (FDA). FDA cleavage leads to an increase in fluorescence, which can be measured with high sensitivity in a fluorometer. A number of controls for spontaneous degradation of substrate are necessary (Agusti and Duarte, 2002; Agusti *et al.*, 1998; Riegman *et al.*, 2002; van Boekel *et al.*, 1992).

2.4.2.3. Enzyme regulation and interpretation of activity assays   A major uncertainty in using esterases to estimate cell lysis is the very broad nature of the assay. It is quite clear that FDA can be hydrolyzed by a number of different enzymes, including some of the extracellular enzymes describe above (e.g., Schnurer and Rosswall, 1982); obviously this is not compatible with the assumption that they are solely intracellular. Within cells, esterases are typically regulated by compartmentalization rather than other mechanisms, and so regulatory features are not likely to complicate interpretations of activity assays.

2.4.2.4. Information gained from assays and future potential   The application of esterases assays have provided the first direct evidence that cell lysis (as distinguished from loss terms such as grazing and sedimentation) may be an important factor in marine systems (see Kirchman, 1999). While the meaning of cell lysis, its incidence and ecological importance remain unclear (see Franklin *et al.*, 2006), and there are concerns about the assay, we currently lack objective, independent methods with which to measure lysis (cf., Agusti and Duarte, 2002). In future, it may be possible to identify particular esterases that are truly found only within cells and choose substrates that are more specific for them.

2.4.3. Cell death-associated proteases
2.4.3.1. Overview   The esterase assays described above provide evidence for cell lysis, but they do not give information about the causes of cell lysis. One type of cell lysis that has received attention recently involves mortality driven by internal factors (e.g., nutrient or energy stress), often referred to as ''cell death.'' This process is poorly characterized, but it applies to both eukaryotic (Berges and Falkowski, 1998; Bidle and Bender, 2008; Segovia *et al.*, 2003; Vardi *et al.*, 1999, 2007) and prokaryotic cells (Berman-Frank *et al.*, 2004). There is considerable speculation about the origins and function of cell death pathways. Hypotheses about origins from transfer of genes following viral infections have been put forward, and suggestion of roles in preventing mass viral lysis, allowing survival of subpopulations of cells under stress, and facilitating formation of resting stages have been advanced (e.g., Bidle and Falkowski, 2004; Franklin *et al.*, 2006; Segovia *et al.*, 2003; Vardi *et al.*, 1999). Recently, activation of cell death–associated proteases have been associated with viral lysis in the coccolithophore, *Emiliania huxleyi* (Bidle *et al.*, 2007).

Cell mortality of this type appears to be related to the process of apoptosis described in multicellular systems. Apoptosis is mediated by a group of cysteine endopeptidases (EC 3.4.22.x), termed caspases, that cleave after aspartate residues. Thus, caspase activity (or what is better termed ''caspase-like activity,'' see Section 2.4.3.2) may prove to be a good marker of this form of cell mortality.

2.4.3.2. Assay techniques   Because cleavage after aspartate residues is uncommon among proteases, caspase substrates are highly specific. In animal systems, over a dozen caspases have been described, and specific substrates have been developed. Relatively little work has been done exploring caspase activities in other organisms, but gene sequence comparisons reveal that algae and bacteria appear to have variant forms of the animal caspases, termed ''metacaspases''; metacaspases are also the form found in higher plants (Aravind *et al.*, 2001; Bidle *et al.* 2007; Uren *et al.*, 2000). Although sequence

homologies between caspases and metacaspases are striking (especially in the active site regions), information about metacaspase proteins and the specificities of these enzymes are largely lacking. For this reason, the conservative term "caspase-like" has often been used to describe enzymes in algae and cyanobacteria that cleave caspase substrates (but note that use of "metacaspase" is becoming more common, e.g. Bidle and Bender, 2008).

As for the proteases described above, a number of spectrophotometric and fluorescent methods are available, but typically AMC conjugates are used (Stennicke and Salvesen, 2000). Aldehyde inhibitors can be used in order to verify specificity of the assays (Bedner et al., 2000), and labelled inhibitor can also be used for direct cell staining (Bidle and Bender, 2008).

2.4.3.3. Enzyme regulation and interpretation of activity assays Caspases are best characterized in animal species where a complex system of enzymes, proenzymes, and activation cascades exist (see Aravind et al., 2001). There is evidence suggesting that some components of these systems exist in algae (e.g., Segovia et al., 2003), but the nature of the regulation remains unknown. Some level of caspase activity is likely to be constitutive (Berman-Frank et al., 2004; Segovia et al., 2003), and it is also possible that algae and cyanobacteria contain non-caspase proteases that are able to cleave caspase substrates. Work in culture has correlated higher caspase-like activities with cell lysis events (e.g., Berman-Frank et al., 2004; Segovia et al., 2003), but relatively little can be deduced from activities measured using different substrates that are specific for mammalian caspases (see Segovia et al., 2003).

2.4.3.4. Information gained from assays and future potential So far, few field measurements have been made of caspase-like activities (Berman-Frank et al., 2004; Vardi et al., 1999), but the assay methods appear to be sensitive enough to allow use in natural communities. As work using cultures proceeds, and our understanding of cell death processes improves, assays of capase-like activity may offer an important means to distinguish different forms of cell mortality. Aside from bulk in vitro assays, the availability of cell-permeable substrates, coupled with flow cytometry will provide improved resolution and specificity (e.g. Bidle and Bender, 2008).

Interestingly, there is evidence that cell death processes in phytoplankton may be driven by allelopathy (e.g., Casotti et al., 2005), and that similar processes may also occur in zooplankton (e.g., Romano et al., 2003). So far, caspase activities have not been detected in these situations, but the potential usefulness of the assays should be assessed.

3. SUMMARY

For many enzymes, the period surrounding publication of the first edition of this volume was a peak in the application of activity assays to marine environments. Problems with interpretation of such measurements and inadequate characterization of the enzymes in marine organisms led to a period of decline in their use. In the years that have followed, we have made considerable progress in understanding

enzymes, the genes that encode them, and their regulatory pathways. Studies of gene expression in marine environments are now feasible and have provided new understanding. Now, as many areas of biological research move from genomics to proteomics and ''metabolomics,'' it seems timely to revisit enzyme activity measurements in marine systems using our new knowledge and technical advances in substrates and equipment. There are still very few integrated studies that examine relationships between *in situ* uptake rates, enzyme activities, and transcription and translation, yet such work is critical to understanding regulation of marine N cycling. It is also humbling that many of the problems identified in 1983 remain exactly the same as today. We are still not much closer to reconciling the species-specific measurements in cultures with the sort of bulk assays that can be made in the field. We now know that in many marine systems, bacteria compete for the same resources as phytoplankton (Chapter 7 by Mulholland and Lomas, this volume), but we still cannot effectively determine which organisms are responsible for enzyme activities in natural samples.

Ocean Nitrogen Cycle Modeling

Raleigh R. Hood *and* James R. Christian

Contents

1. Introduction

There has been a marked increase over the last decade in ocean biogeochemical modeling research, largely in response to the need for prognostic models to predict how ocean nutrient cycling and carbon export and sequestration will respond to global warming. Although much of this work is focused on the carbon cycle, it has stimulated research on nutrient cycling in general (Hood *et al.*, 2006; Le Quéré *et al.*, 2005) because carbon fixation and export are controlled by the availability of nutrients (N, P, Si, Fe), as well as by food web interactions, and physical and biological processes that control the sinking speed of particulate organic matter and remineralization rate. Understanding the N cycle and its connections to other elemental cycles is particularly important to understanding the current state of

the ocean and for predicting its future response to climate change because N is an essential and often a limiting element in organic matter production. Gaining such understanding will critically depend on further development and application of N cycle and multi–element models.

Historically, phosphorus has been the preferred currency of global box modelers who often address longer time scales over which the oceanic N inventory is variable, i.e., the full–ocean residence time of P is about 30,000 years—an order of magnitude longer than the residence time of N within the "fixed" N pool. This difference in residence time exists because the fixed nitrogen pool in the ocean does not derive primarily from terrestrial sources, but is instead regulated by N_2 fixation and denitrification. In contrast, phosphorus is mostly supplied from weathering. N is usually the preferred currency in studies with shorter time scales, such as simulations of the spring bloom (e.g., Steele and Frost, 1977) or episodic upwelling (e.g., Moloney and Field, 1991; Wroblewski, 1977), because it is the primary limiting nutrient for phytoplankton in these circumstances. When modelers began to simulate the full seasonal cycle of open-ocean ecosystems, N was used as the primary currency (e.g., Evans and Parslow, 1985; Fasham *et al.*, 1990) for the same reason. Nevertheless, the assumption of N limitation in open ocean environments is no longer considered robust. Over the last decade it has been shown that iron limits primary production in many ocean environments (e.g., Boyd *et al.*, 2000; Coale *et al.*, 1996; Martin *et al.*, 1991). More recent studies indicate the potential for significant phosphorus limitation or co-limitation in some regions (e.g., Ammerman *et al.*, 2003; Christian, 2005; Karl *et al.*, 2001; Wu *et al.*, 2000), and silica limitation is a very important factor that controls diatom growth (e.g., Dugdale and Wilkerson 1998; Whitney *et al.*, 2005) (see Hutchins and Fu, Chapter 38, this volume).

The importance (or not) of the distinction between N and P as a model currency is closely related to the concept of the Redfield ratio (Redfield *et al.* 1963). Because many models implicitly or explicitly enforce fixed elemental ratios, the distinction between N and P limitation is often of little importance in models. In most cases a fixed ratio (e.g., "Redfield") model will behave almost identically in terms of primary production, plankton abundance, and carbon fluxes, whether N or P is specified to be the primary limiting nutrient (the exception is when initial or boundary conditions are drawn from observations in which deviations from the Redfield N:P ratio are present).

Nonetheless, the N cycle is still the primary focus (and currency) in many oceanic modeling studies. The N cycle is intrinsically interesting because it is complex, with the oxidation state of N mediated by a wide range of biologically catalyzed reactions. Moreover, the oceanic N cycle is not fully understood. New reduction-oxidation reactions and the organisms that catalyze them are still being discovered (e.g., the "anammox" reaction (Codispoti *et al.*, 2001, see Devol, Chapter 6, this volume) and "microbial diazotrophs" (Montoya *et al.*, 2004; Zehr *et al.*, 2001; see Carpenter and Capone, Chapter 4, this volume). Furthermore, the global ocean nitrogen budget is still highly uncertain. Uncertainties in global estimates of nitrogen fixation and denitrification are so large that we don't know for sure whether or not the oceans are gaining or losing N (Codispoti *et al.*, 2001; Codispoti, 2007).

Models of the N cycle are still under active development with new pathways and processes being added all the time.

In the pages that follow we provide a broad overview of open-ocean N-cycle modeling. In this review we focus primarily on pelagic N-cycle research. Although we discuss a few studies from coastal waters and inland seas, we have made no attempt to systematically review nutrient cycle modeling work from these systems. Nor do we consider estuarine models, benthic environments, or paleo-oceanographic studies. This is not intended to be an exhaustive review. Rather, our goal here is to provide a general overview, citing some examples and seminal papers along the way (Table 33.1 provides a list of most of the N-cycle models that are discussed in this paper). Additional information on N-cycle modeling can be found in reviews by Ducklow (1994), Franks (2002), and Fennel and Neumann (2004).

2. Evolution of Nitrogen-cycle Modeling

The first mechanistic plankton and nutrient dynamics models were developed by Gordon Riley (Riley, 1946; Riley *et al.*, 1949) and shortly thereafter, John Steele (Steele, 1958). These models did not use nitrogen as a currency because, at that time, phosphorus measurements were more widely available. Two of the earliest N-cycle models were published by Walsh and Dugdale (1971) and Steele (1974). Steele's model, for example, included state variables for dissolved inorganic nitrogen (N), phytoplankton (P) and zooplankton (Z), where P and Z were represented in terms of carbon assuming a fixed C/N ratio. Nitrogen uptake by phytoplankton was formulated using a hyperbolic saturation (Monod) function and remineralization was by zooplankton excretion. This model was essentially similar to modern "NPZ" models (Franks, 2002). As with other NPZ-type formulations, it did not take into account different forms of inorganic nitrogen (i.e., NO_3 and NH_4) or the role of the "microbial loop" (small phytoplankton, bacteria, protozoa, and dissolved organic nitrogen) in the nitrogen cycle. (Throughout this chapter we will refer to nitrate and ammonium as NO_3 and NH_4, for simplicity ignoring the charges.) During this same period Caperon (1968) showed that the growth rate of an N (nitrate) limited continuous culture of *Isochrysis galbana* was not directly related to the ambient nitrate concentration but related to the calculated cell N quota. Droop (1968) independently arrived at essentially the same result using vitamin B_{12}-limited *Monochrysis* (now *Pavlova*) *lutheri*, and derived the model that is often called the "Droop cell-quota" model (see details below in section 3.1).

Early N-cycle models were incorporated into dynamic, spatially-explicit frameworks in the mid-1970s (e.g., Walsh, 1975; Wroblewski, 1977). For example, Wroblewski (1977) incorporated an N-cycle model into a two-dimensional upwelling model. This coupled system allowed simulation of primary production and ecosystem response in an idealized, wind-forced coastal upwelling circulation with NO_3 infusion from depth and offshore surface Ekman transport (Fig. 33.1).

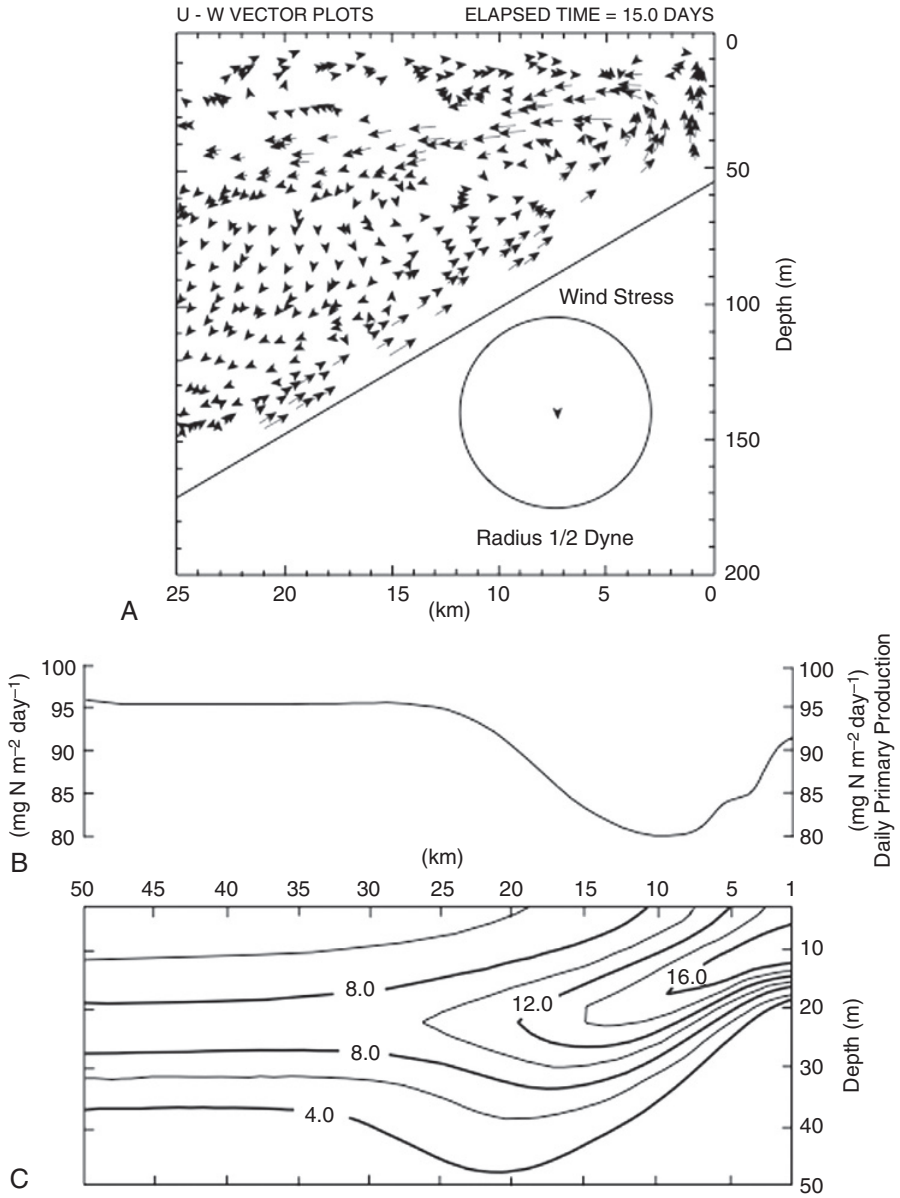
Biota defines the biomass pools included as state variables: P=phytoplankton, Z=zooplankton, B=bacterioplankton. H indicates nonspecific heterotroph population including both grazers and bacteria; nZ indicates multiple stages within a single zooplankton population. A indicates ammonium; N implies nitrate+nitrite if ammonium is included and total DIN otherwise. DON, PON, HBAC columns indicate which models have explicit pools of dissolved organic nitrogen, particulate organic nitrogen (detritus or fecal matter), and bacteria. A ★ under "DON" implies that the model has DOC but not DON. A ★ attached to Fe implies parameterized Fe limitation but no explicit Fe pools. A ★ under HBAC means that bacteria are subsumed within a generalized heterotroph group. In Dadou et al. (2001) bacterial biomass appears in the DON equations but is a specified model parameter.


Figure 33.1 Physical and biological upwelling response simulated by the Wroblewski (1977) 2-dimensional coastal upwelling model: (A) The circulation in the transverse plane normal to the coast, the bottom topography, and the wind stress. The maximum u and w velocities in the field are -2.9 cm s^{-1} and 1.4×10^{-2} cm s^{-1}, respectively. (B) The daily gross primary production of the water column. (C) The distribution of phytoplankton. Contour intervals are 1 µmol N l^{-1}. Redrawn with permission from Wroblewski (1977).

The N-cycle model included an explicit representation of detritus–N production, transport, sinking and remineralization. Moreover, this model carried both NH_4 and NO_3 with a representation of NH_4 inhibition of NO_3 uptake by phytoplankton. Although the inhibition approach is now generally considered to lack a convincing mechanistic basis (see Section 3.2), both the N-cycle model and the achievement of coupling it to a dynamic circulation model represent significant advances in ocean N-cycle modeling.

In the mid-1980s, simple NPZ-type N-cycle models were applied to address a variety of oceanographic and ecological questions using climatological or idealized forcing (e.g., Evans and Parslow, 1985; Frost, 1987). Although these models did not advance the state-of-the-art in N-cycle modeling per se, some of the earliest basin-wide N-cycle model applications were carried out using NPZ models (Wroblewski, 1989; Wroblewski *et al.*, 1988). Using climatological mixed layer depth, solar irradiance at the sea surface, and basin-scale distribution of nitrate, Wroblewski (1989) simulated phytoplankton bloom progression in both space and time from mid to high latitudes in the North Atlantic (Fig. 33.2). To our knowledge, this was the first time-dependent, basin-wide application of an N-cycle model.

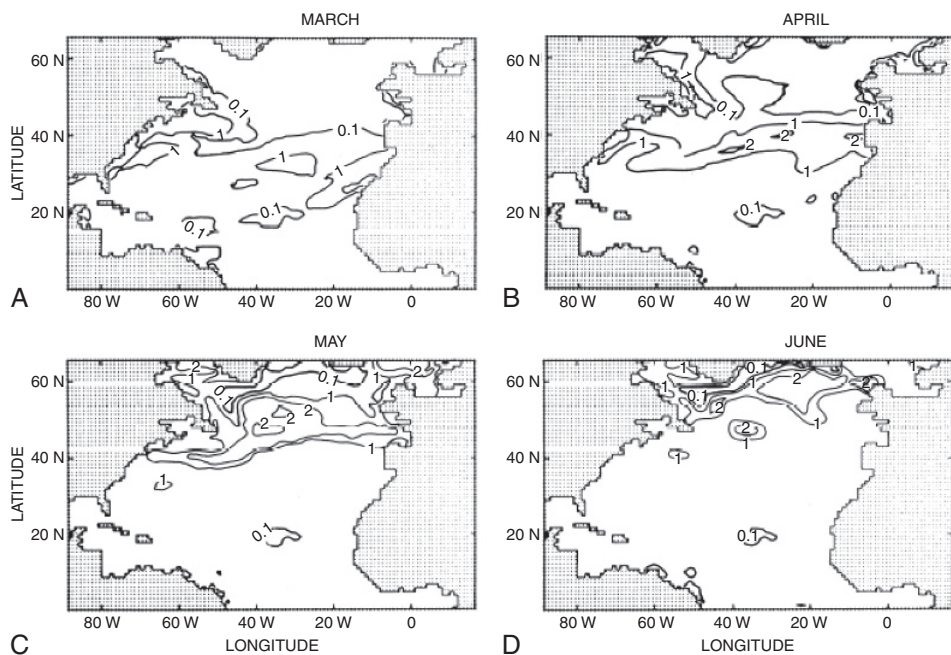
Another significant advance during this time period was the development of N-cycle models for simulating plankton dynamics that included more detail in both the P and Z compartments than previous N-cycle models (e.g., Hoffman, 1988;


Figure 33.2 Phytoplankton fields simulated by Wroblewski (1989) for the end of March (A), end of April (B), end of May (C), and mid-June (D). Concentrations >1 mmol m^{-3} were considered to be a phytoplankton bloom. Reproduced with permission from Wroblewski (1989).
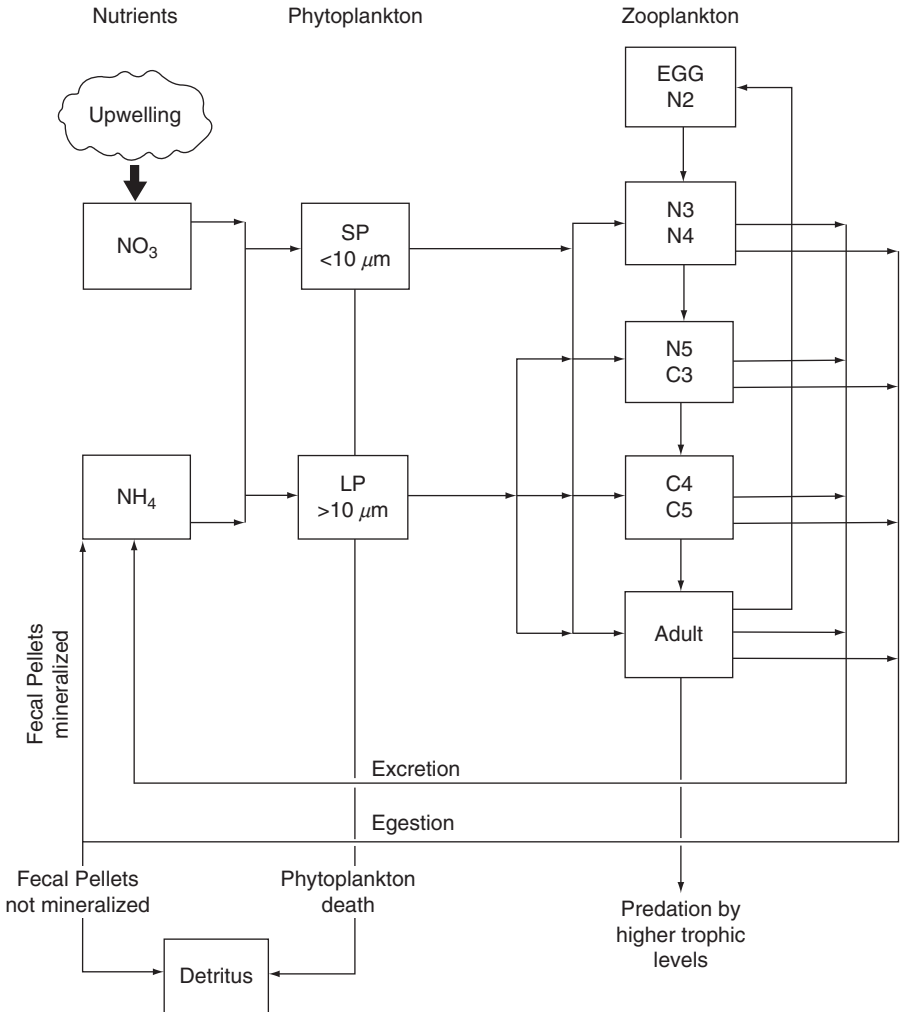

Figure 33.3 Schematic diagram of the components and biological interactions included in the Hofmann and Ambler (1988) time-dependent ecosystem model. Reproduced with permission from Hofman and Ambler (1988).

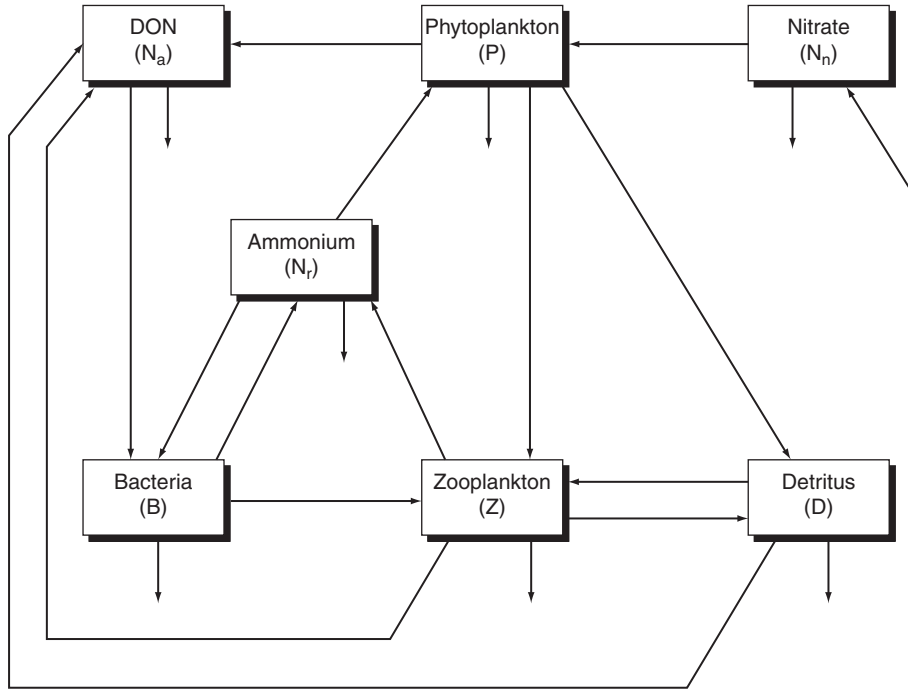
Hofmann and Ambler, 1988). The Hofmann and Ambler (1988) model had 10 compartments which included NO_3 and NH_4, large and small phytoplankton size classes and a copepod submodel (Fig. 33.3). The latter included parameterizations for N assimilation, excretion, egg production, molting and predation. Steele and Frost (1977) incorporated comparable levels of detail more than 10 years earlier. Although not, strictly speaking, an N-based model, it specified N as the limiting inorganic nutrient and assumed a fixed C/N ratio for biota defined in carbon units, so the distinction is to some degree semantic.


Figure 33.4 Schematic representation of the Fasham *et al.* (1990) model showing the compartments and the modeled nitrogen flows between compartments and to the deep ocean. Redrawn with permission from Fasham *et al.* (1990).

The Fasham *et al.* (1990) model was a major milestone in N-cycle model development and validation. This model had seven state variables: nitrate, ammonium, phytoplankton, zooplankton, detritus, bacteria and dissolved organic nitrogen (DON) (Fig. 33.4), and it included several important innovations. For example, in order to incorporate bacteria into the model the authors had to devise a means of determining how much nitrogen was taken up by the bacteria in the form of DON versus NH_4 (for details see section 3.3 below). The Fasham *et al.* (1990) model also introduced a formulation for specifying different zooplankton grazing rates on multiple food sources using preference terms, which has been widely adopted in subsequent models (e.g., Hood *et al.*, 2001). In addition, the model was applied and validated using an extensive biological data set that included, among other things, nitrate concentration, primary production and bacterial biomass measurements (Fig. 33.5).

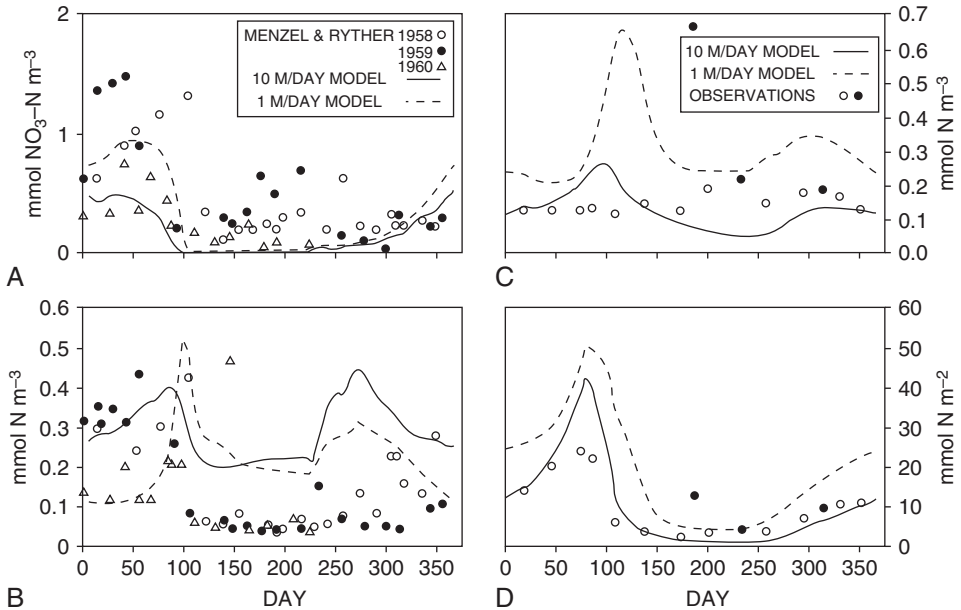
In retrospect the Fasham *et al.* (1990) model stands out for two primary reasons. Firstly, it was one of the first N-based marine ecosystem models that included explicit compartments for DON and bacteria. Secondly, and perhaps even more importantly, the model's source code was "open", i.e., the code was readily available to any one who wanted it. As a result of the latter, the Fasham *et al.* (1990) model was subsequently applied to a wide variety of modeling problems by numerous


Figure 33.5 Comparison of observed data near Bermuda with the Fasham *et al.* (1990) model output for (A) nitrate concentration, (B) phytoplankton N biomass, (C) bacterial N biomass, and (D) integrated bacterial N biomass. Reproduced with permission from Fasham *et al.* (1990).

investigators, and it became the starting point for the development of a new generation of marine N-cycle models that explicitly considered bacteria and DON (e.g., Anderson and Williams, 1998).

At about this same time, another new modeling approach was introduced by Moloney and Field (1991). They developed a model of both nitrogen (Fig. 33.6) and carbon cycling with three autotrophic size classes (pico-, nano- and net-phytoplankton) and four heterotrophic size classes (bacteria, heterotrophic micro-flagellates, and micro- and meso-zooplankton) where all model parameters were determined by body size, using empirically determined allometric relationships (Moloney and Field, 1989). In theory, because the model was based upon general ecological principles and not on a specific ecosystem or data set, it could be used to simulate N and C cycling within plankton communities of any ecosystem. In a companion publication, this model was applied to three contrasting southern Benguela food webs (Moloney *et al.*, 1991). It is interesting to note that in spite of the fact that this modeling approach included microbial cycling and was, in many respects, more novel and universally applicable than the Fasham *et al.* (1990) model, it was not as widely adopted and applied by the scientific community. This is, perhaps, attributable to the simple fact that the source code was not as easy to get.

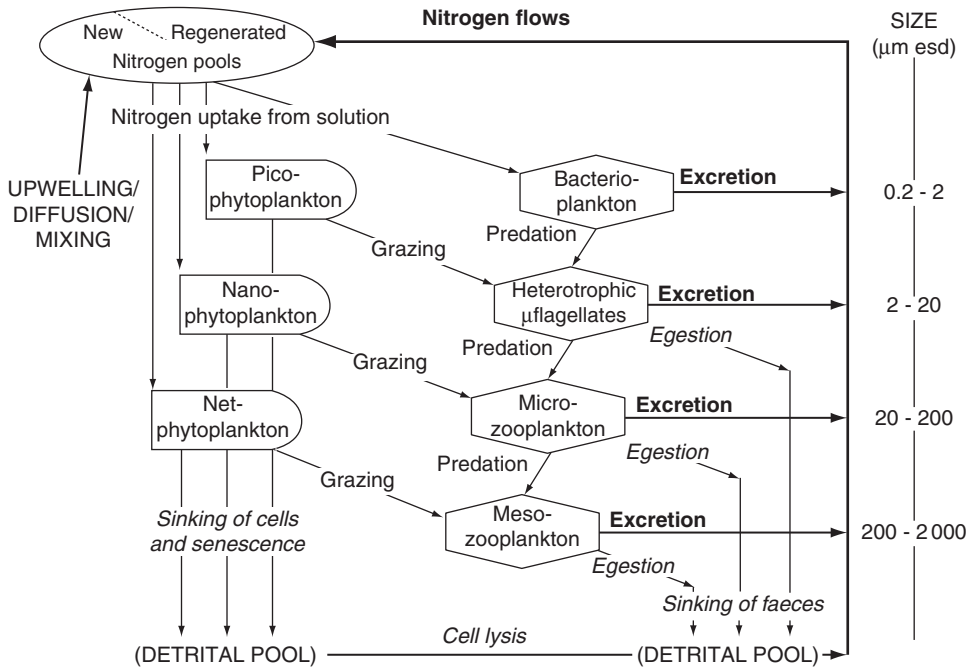
We conclude this section with a brief overview of some of the 3-dimensional, dynamic coupled physical-biological models that were developed in the 1990s. There is a historic split in the practice of ocean biogeochemical modeling, i.e., the field has been divided into large-scale global box and later circulation models with


Figure 33.6 Schematic representation of the N-cycle component of the Moloney and Field (1991) model. Bullets represent the size classes of autotrophs, and hexagons the size classes of heterotrophs. Reproduced with permission from Moloney and Field (1991).

highly parameterized biology (e.g., Maier–Reimer, 1993; Najjar *et al.*, 1992; Sarmiento and Toggweiler, 1984; Siegenthaler and Wenk, 1984) and "ecosystem" models with a simplified and often highly localized spatial frame of reference (e.g., Evans and Parslow, 1985; Fasham *et al.*, 1990; Wroblewski, 1977). These are often described as "geochemical" versus "ecological" modeling approaches, although these terms probably derive as much from the scientific backgrounds of their respective practitioners as from any real scientific meaning. It was only in the 1990's that the two approaches began to merge, with ecosystem models with fully explicit biology being embedded in general circulation models. As noted above, phosphorus has been the preferred currency of global box modelers. But as explicit ecosystem models have been increasingly implemented in three-dimensional frameworks, there has been a shift towards N as the primary model currency, although P-based models also exist (e.g., Six and Maier–Reimer, 1996).

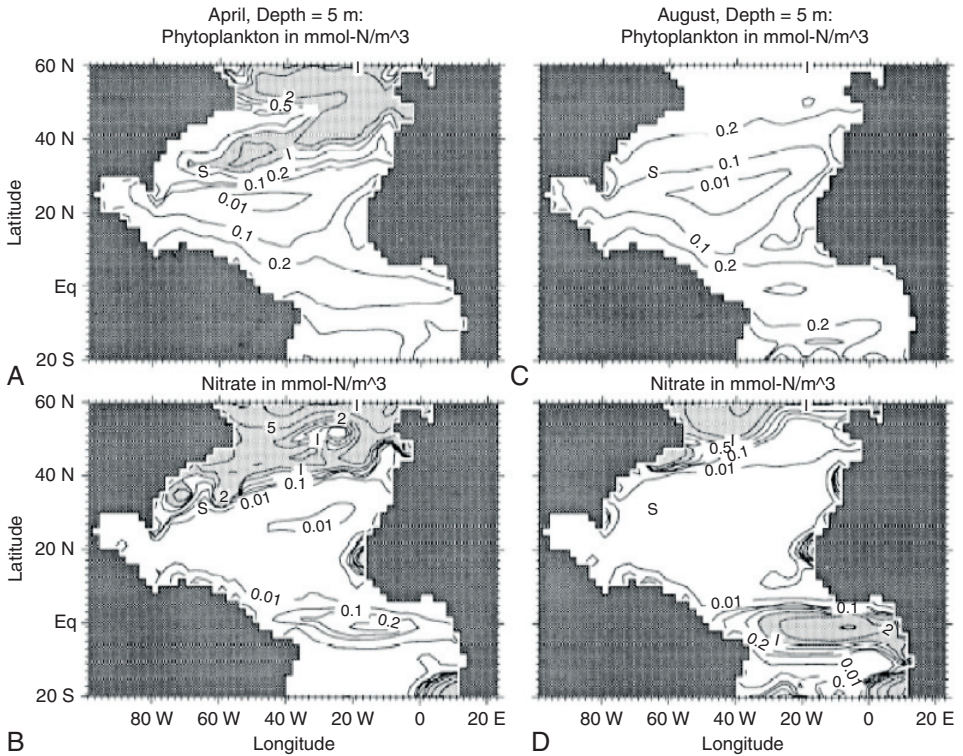
Fasham *et al.* (1993) and Sarmiento *et al.* (1993) describe one of the first efforts to couple a more complex N-cycle model to an ocean general circulation model. To represent the N cycle they used the 7 component Fasham *et al.* (1990) model (Fig. 33.4), which they coupled to a general circulation model running at 2° horizontal resolution in the North Atlantic with 25 vertical levels. Among other things, this model was used to estimate basin-wide phytoplankton biomass and nitrate concentrations (Fig. 33.7) and it suggested that, with the exception of some


Figure 33.7 Basin-wide contour plots of the Fasham *et al.* (1993) model solution of (A) modeled average phytoplankton concentration (mmol N m^{-3}) at 5 m during April, (B) modeled average nitrate concentration (mmol N m^{-3}) at 5 m during April, (C) and (D) as for Figures (a) and (b) but for August. Concentrations greater than 1 mmol N m^{-3} are shaded. The positions of Bermuda Station "S" and Ocean Weather Station "India" are indicated by the letters S and I, respectively. Reproduced with permission from Fasham *et al.*, 1993.

upwelling regions and high latitudes during winter, almost the entire Atlantic is NO$_3$ depleted (see section 4.1). Using a similar approach, Chai *et al.* (1996) coupled a 5 compartment N–cycle model to the modular ocean model (MOM), running at $1 \times 1/3°$ horizontal resolution to study the origin and maintenance of high nitrate conditions in the equatorial Pacific. McCreary *et al.* (1996) coupled an NPZD model to a reduced gravity circulation model, and used it to study the N cycle and bloom dynamics in the Arabian Sea. Reduced gravity models have the advantage of not having to include deep ocean layers in their calculations and so they can be run at somewhat higher resolution (the McCreary *et al.* (1996) model had only two active vertical layers and so could be run at 0.5° horizontal resolution over the entire Indian Ocean).

One of the more revolutionary aspects of these early coupled–modeling studies is that they could be used to determine the degree to which different physical processes were responsible for supplying new nitrogen to surface waters. For example, McCreary *et al.* (1996) showed that in their model, vertical mixing and entrainment

from the nitracline is the primary nutrient source for the offshore bloom in the central Arabian Sea during the Southwest Monsoon, but horizontal advection of nutrients from coastal upwelling areas also makes significant contributions to the nutrient flux. However, most of these early studies were subject to constraints imposed by computation speed, and so were forced to run at relatively low horizontal resolution (0.5°–2.0°). As a result, they could not fully resolve some important processes that control the supply of new nitrogen, e.g., coastal upwelling and filament formation (Hood *et al.*, 2003) and eddy pumping in the open ocean (McGillicuddy *et al.*, 1998). These issues are discussed in more detail in Section 4.

3. STATE OF THE ART AND EVOLUTION OF BIOLOGICAL PROCESS MODELS

3.1. Modeling phytoplankton growth and cell quota

Current phytoplankton growth models can be roughly divided into those that model intracellular N concentration (cell quota) and those that do not. When internal N is not modeled, growth rate is directly dependent on the ambient dissolved inorganic nitrogen (DIN) concentration. This has the advantage of minimizing the number of model pools that cannot be validated against observation, as intracellular concentration is rarely measured. Cell quota models, however, retain the observed (ambient) pool as well as the unmeasured (internal) pool, and model validation against other fields such as chlorophyll or total particulate N may be improved by incorporating a more mechanistic representation of processes relating these to DIN. At steady-state, the two models are more or less equivalent, as the N cell quota is constant.

The work of Droop (1968) has led to the use in many subsequent studies of the following equation to express the relationship between growth and cellular nutrient concentration:

$$\mu = \mu_{\max}\left(\frac{Q - k_{\mathrm{q}}}{Q}\right) \tag{33.1}$$

where μ is the realized specific growth rate, $\mu_{\max}$ is the maximum specific growth rate, Q is the cell quota and k_{q} is the minimum concentration of limiting nutrient per cell required for growth to occur. Although Droop's model was originally developed using vitamin B_{12} uptake measurements, it has since been shown to account for "luxury consumption" and variations in cell N:P ratio reported in the literature. However, the model fits some culture data poorly, especially under N-limitation, and it has been suggested that it works best for nutrients that constitute a small fraction of total biomass, e.g., P or vitamin B_{12} (Fogg and Thake, 1987).

More recently, models with varying cell N quotas have been developed by Geider *et al.* (1998) and Flynn (2001). Here we will discuss Geider's model in depth because it contains some important details specific to the ecophysiology of

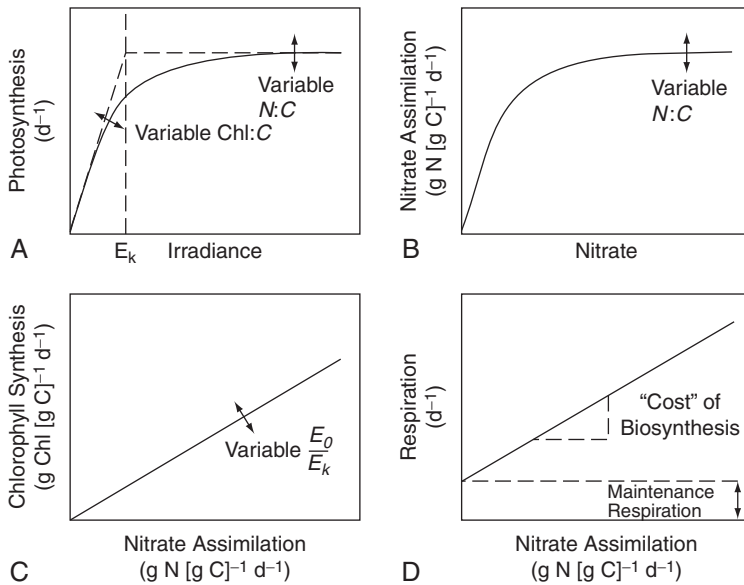
N and has also been incorporated into several other N-cycle models. The model of Geider *et al.* (1998, hereafter GMK98) contains separate state equations for phytoplankton C, N and chlorophyll. It has a variable N cell quota with specified maximum and minimum values (Q_{max}, Q_{min}). N uptake is weakly regulated by cell N status at N/C less than about 0.2 g/g but declines precipitously as the maximum N quota is approached. The light-saturated photosynthetic rate is proportional to $(Q - Q_{min})/(Q_{max} - Q_{min})$. Chlorophyll synthesis is regulated by N only indirectly, via the photosynthetic rate and the cell C/N; there is a maximal chlorophyll-to-nitrogen ratio but no specified limits on the chlorophyll-to-carbon ratio. The basic model functional relationships are illustrated in Fig. 33.8. This model was initially tested only against culture data, but variants have subsequently


Figure 33.8 Graphical summary of the Geider *et al.* (1998) model showing dependencies of Photosynthesis , nitrate assimilation, Chla synthesis, and respiration on environmental variables. (A) Photosynthesis is a saturating function of irradiance where the initial slope increases with increasing Chl:C and the light-saturated rate increases with increasing N:C. The light-saturation parameter (E_k) is given by the irradiance at which the initial slope intercepts the light-saturated rate. (B) The carbon-specific nitrate assimilation rate is a saturating function of nitrate concentration where the maximum uptake rate is downregulated at high values of N:C. (C) The rate of Chla synthesis is obligately coupled to protein synthesis and thus to nitrate assimilation. However, the magnitude of the coupling depends on the ratio of irradiance to the light-saturation parameter (E_o/E_k). At a given rate of nitrate assimilation the carbon-specific rate of Chla synthesis declines as E_o/E_k increases. (D) The carbon-specific respiration rate is a linear function of the rate of nitrate assimilation. It is assumed that there is no lag between nitrate assimilation and protein synthesis. Major respiratory costs are associated with reduction of nitrate to ammonium, incorporation of ammonium into amino acids, and polymerization of amino acids into proteins. Other respiratory costs are assumed to scale with the rate of protein synthesis. Figure and caption reproduced with permission from Geider *et al.* (1998).

been applied to field data by Moore *et al.* (2002a), Lefêvre *et al.* (2003), and Christian (2005). Models like GMK98 that decouple photosynthesis from cell production better reproduce carbon-based primary productivity measurements in nutrient-depleted low-latitude ocean areas where high rates of photosynthesis are observed in the absence of significant inorganic nutrients (Christian, 2005).

The GMK98 model has been questioned by Pahlow (2005) and Armstrong (2006) on the grounds that it fails to account for independent regulation of cellular C, N, and chlorophyll under both light- and N-limitation, and makes incorrect predictions about the maximum growth rate under low light. In GMK98 the growth rate is maximized when the cell N quota is at its maximum value (which is a specified model parameter), and the N-limited growth rate does not depend on the Chl/C ratio. However, because chlorophyll and its associated proteins contain N, the maximal cell N quota is itself light dependent, and the nitrogen-limited growth rate depends on the demand for N in chlorophyll synthesis. The models of Pahlow (2005) and Armstrong (2006) are based on optimal allocation of N to different cellular functions, and are better able to explain continuous culture data that suggest that the cell N quota is inversely related to growth rate under light limitation, which can not be easily reconciled with GMK98 or other earlier models.

3.2. Modeling new production, NO_3, and NH_4

The concept of ''new production'' (Dugdale and Goering, 1967; Eppley and Peterson, 1979) has received a great deal of attention in the last 2–3 decades, as a useful proxy for the fraction of primary production that is exported from the euphotic zone on seasonal to annual time scales. Knauer (1993) wrote that the equation of new production with carbon export had bestowed upon new production ''an almost mystical importance''. New production, defined in terms of measured rates of NO_3 and NH_4 uptake, can be a useful proxy for export production or net community production (NCP), which are difficult to measure directly. In models, however, NCP is known exactly. The question of whether the parameters for NO_3 and NH_4 actually differ sufficiently to justify separation is a complicated one. There are several possible rationales for separating NO_3 and NH_4 in ocean models: (1) NO_3 is measured much more frequently and therefore separation makes sense from a validation standpoint, (2) the model is to be validated against measured rates of NO_3 and NH_4 uptake, (3) the parameters of NO_3 and NH_4 uptake are sufficiently different that a single aggregated DIN variable cannot give an accurate growth rate, (4) the model contains distinct phytoplankton species that use only one or the other form of N, (5) the modeler wishes to account for the different metabolic costs of biosynthesis from NO_3 and NH_4, and (6) an explicit model of nitrification is required for some other purpose such as modeling production of N_2O or validation against measured nitrification rates. In the end, whether or not NO_3 and NH_4 are different enough relative to other model errors and uncertainties to justify introduction of additional state variables and parameters will depend on the model and the questions asked.

There is a relatively extensive literature on phytoplankton N uptake and particularly on the question of NH_4 inhibition of NO_3 uptake. In the early expression

introduced by Wroblewski (1977) the NH_4 inhibition is parameterized by multiplying the NO_3 uptake function by an exponential suppression term based on the NH_4 concentration:

$$V = V_m \left[\frac{NO_3}{K_{NO_3} + NO_3} e^{-\Psi NH_4} + \frac{NH_4}{K_{NH_4} + NH_4} \right] \qquad (33.2)$$

where V and V_m are the realized and maximum phytoplankton nitrogen uptake rate, respectively, the K_{NO_3} and K_{NH_4} values are half-saturation constants, and Ψ is an NH_4 inhibition intensity factor.

This function has been widely applied in ocean models (e.g., Chai et al., 1996; Fasham et al., 1990; Hofmann and Ambler, 1988; Leonard et al., 1999), but is generally considered to lack a convincing mechanistic basis, and has some unusual properties that the user should be aware of (Frost and Franzen, 1992; Yajnik and Sharada, 2003). In particular, the total N ($NO_3 + NH_4$) uptake rate or the N-limited growth rate under steady-state conditions, does not increase monotonically with [NH_4] for NO_3 concentrations greater than about 1 μM. It is also important to note that this expression can take on values greater than unity and therefore cannot be treated as a ''nondimensional'' nutrient-limitation term, which is multiplied by a light and/or temperature dependent growth rate.

Some formulations of jointly NO_3/NH_4 limited growth have not relied on inhibition. For example, Jamart et al. (1977) defined preference functions that divided the N ''sink'' between NH_4 and NO_3, while the two jointly regulate the phytoplankton growth rate by a single Monod function of their aggregate concentration. Similarly, Frost (1993) defined a Monod function for NH_4 uptake, but assumed that N is not limiting to phytoplankton growth, and that any additional N requirements would be met by NO_3.

Other inhibition models of NH_4 and NO_3 uptake have been based on enzyme kinetics (e.g., noncompetitive inhibition; Frost and Franzen (1992)). Whether or not the analogy is strictly applicable, this would appear to have a more sound biological basis than the Wroblewski (1977) exponential function. Yajnik and Sharada (2003) defined general equations for a two-nutrient interaction that can be reduced to hyperbolic inhibition such as that employed by Frost and Franzen (1992) and Parker (1993).

The generic uptake equations are:

$$\rho_1 = P V_1 \frac{N_1}{k_1 + N_1} \frac{1 + a_{12} N_2}{1 + b_{12} N_2} \qquad (33.3a)$$

$$\rho_2 = P V_2 \frac{1 + a_{21} N_2}{1 + b_{21} N_2} \frac{N_2}{k_2 + N_2} \qquad (33.3b)$$

where P is phytoplankton biomass, N_i is concentration of nutrient i, k_i the half-saturation coefficient for uptake of N_i, V is the asymptotic specific uptake rate of nutrient i as N_i approaches infinity in the absence of other nutrients, and a and b are

kinetic coefficients describing the nutrient interaction. These can be shown to reduce to the familiar coefficients of noncompetitive inhibition. For a, $b \geq 0$ there are four possible cases:

Case 1: $a_{12}/b_{12} = 0$. ρ_1 asymptotically approaches zero as N_2 approaches infinity.

Case 2: $0 < a_{12}/b_{12} < 1$. ρ_1 asymptotically approaches some positive "threshold" value.

Case 3: $a_{12}/b_{12} = 1$, in which case ρ_1 does not depend on N_2.

Case 4: $a_{12}/b_{12} > 1$, in which case ρ_1 increases with increasing N_2.

The literature on NO_3/NH_4 interactions generally assigns the effect of NO_3 on NH_4 to Case 3 (no effect) and the effect of NH_4 on NO_3 to Case 1. Yajnik and Sharada argue for Case 2, to which point we will return. Obviously, if $a = b$, Eq. (33.3) reduces to the familiar hyperbolic uptake without inhibition (Case 3). Case 1 is equivalent to the hyperbolic inhibition employed by Frost and Franzen (1992), Parker (1993), Loukos *et al.* (1997), and Christian *et al.* (2002a). Yajnik and Sharada (2003) further defined coefficients $k = 1/b$ and $c = 1-a/b$ such that Eq. (33. 3a) becomes

$$\rho_1 = PV_1 \frac{N_1}{k_1 + N_1} \left(1 - \frac{cN_2}{k + N_2} \right) \tag{33.4}$$

This is identical to the equation derived by Harrison *et al.* (1996) and to the models cited above, for the special case where $c = 1$ (which is Case 1, because if $c = 1$ a must be 0). Harrison *et al.* (1996) showed that NO_3 uptake converged towards a nonzero asymptotic value as NH_4 increased. However, this pattern is not universal (Armstrong, 1999).

A more detailed, mechanistic approach to NH_4 inhibition was taken by Flynn *et al.* (1997). In this model intracellular pools of NO_3 and NH_4 are explicitly simulated, as well as the concentration of glutamine, which is assumed to be the molecule responsible for feedback regulation of NO_3 transport and reduction (Fig. 33.9). In addition to these intracellular substrate pools, the model includes variable activities of the enzymes nitrate reductase (NR) and glutamine synthetase (GS) (for a description of the underlying biochemical pathways see Falkowski, 1983 and Mulholland and Lomas, Chapter 7, this volume). NR synthesis, as well as transport of both NO_3 and NH_4 into the cell, are repressed by high levels of glutamine, but there is no direct regulation of NO_3 reduction by glutamine or other forms of reduced N. An important consequence is that there is a "training period" for substrate switching, i.e., cells grown on NH_4 are not immediately able to take up NO_3 even when N-starved. No other model discussed here can simulate this effect, i.e., all of the others have instantaneous feedback. This model has also been condensed to simplified versions (Flynn and Fasham, 1997) and expanded to include interactions with other elements such as P, Fe, and Si (Flynn and Hipkin, 1999; Flynn, 2001).

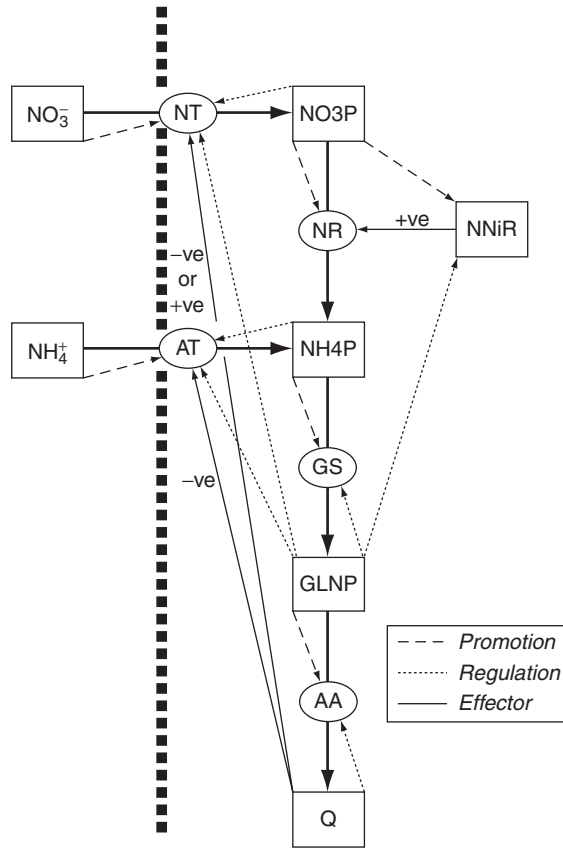
Armstrong (1999) approached NH_4 inhibition from the perspective of iron–light–nitrogen co-limitation. In this model, iron is allocated among different cell functions so as to maximize growth rate (Fig. 33.10). Iron is allocated to nitrate reduction only if this will maximize growth given the availability of light and NH_4.


Figure 33.9 Schematic diagram of the Flynn *et al.* (1997) model. NO3P, NH4P, GLNP and Q are internal pools of nitrate, ammonium, glutamine and other organic cellular N, respectively. NNiR is nitrate–nitrite reductase, and GS glutamine synthetase activities. NT and AT are nitrate and ammonium transporters, respectively, NR describes the process of nitrate reduction through to ammonium, and AA the synthesis of amino acids and all other nitrogenous compounds from GLN. "Promotion," "regulation" and "effector" are used in general terms, with no specific biochemical meaning, indicating positive, negative or complex feedbacks, respectively. Figure and caption reproduced from Flynn *et al.* (1997) with permission.

Armstrong (1999) used this model to explain differences among various NH_4-inhibition experiments that showed distinct patterns of repression of NO_3 uptake (Fig. 33.11). When iron is not limiting, NO_3 uptake declines asymptotically with increasing NH_4, whereas under Fe limitation nitrate uptake declines approximately linearly to a value near 0, sometimes at quite low concentrations of NH_4. The model permits five possible limitations: light-limitation, nitrogen-limitation, iron–light co-limitation, nitrogen–light co-limitation, and nitrogen–iron–light co-limitation. As NH_4 concentration increases, iron is reallocated to functions other than nitrate reduction, but the replacement is not one-for-one. The relative reduction in NO_3 uptake depends on light because NO_3 reduction requires energy as well as iron.
Figure 33.10 A schematic flow diagram of the Armstrong (1999) model. In this model it is assumed that a fraction η of iron uptake is allocated to reducing nitrate and that a fraction determines the maximum flux of reduced nitrate, $\rho_{NO_3,red}$, that is available for growth. When added to the ammonium uptake rate, ρ_{NH_4}, which itself influences the optimal value of η, the flux of reduced nitrate, $\rho_{NO_3,red}$, determines the potential nitrogen uptake rate, $\rho_{N,pot}$, and hence the potential nitrogen limited growth rate, $\mu_{N,pot}$. It is also assumed that a fraction $1 - \eta$ of iron is reserved for energy (carbon)–related transport, and that this fraction determines a potential carbon-limited growth rate, $\mu_{C,pot}$. Finally, the model assumes that η is dynamically altered to make the best use of limited iron by maximizing overall growth rate, $\mu = \min\{\mu_{C,pot}, \mu_{N,pot}\}$. Schematic and figure caption reproduced from Armstrong (1999) with permission.

Although there are now several different formulations to choose from for representing NO_3/NH_4 interactions, we are not aware that these differences in the treatment of NH_4 inhibition etc. has had much impact on the overall behavior of N–cycle models. In contrast, as we discuss in the next section, it is clear that other aspects of these model formulations, such as the form of the grazing functions, can have a profound impact on model behavior.

3.3. Loss terms, remineralization and the microbial loop

The loss terms in N–cycle models that transform particulate and dissolved organic nitrogen into other forms can include a variety of processes (e.g., phytoplankton exudation, zooplankton grazing, sloppy feeding, phytoplankton and zooplankton mortality, bacterial remineralization, etc.). Different models may differ substantially in terms of which of these are included and their formulation (Christian and Anderson, 2002). Many N–cycle models now include significant "phytoplankton exudation" loss terms. This is often parameterized by simply specifying that some fixed fraction of the DIN uptake by phytoplankton is shunted directly to the DON pool (e.g., Anderson and Williams, 1998). "Sloppy feeding" by zooplankton can be similarly accounted for. Many models also include linear loss terms in the phytoplankton equation that represent either "natural mortality" or phytoplankton respiration (e.g., Hood *et al.*, 2001).

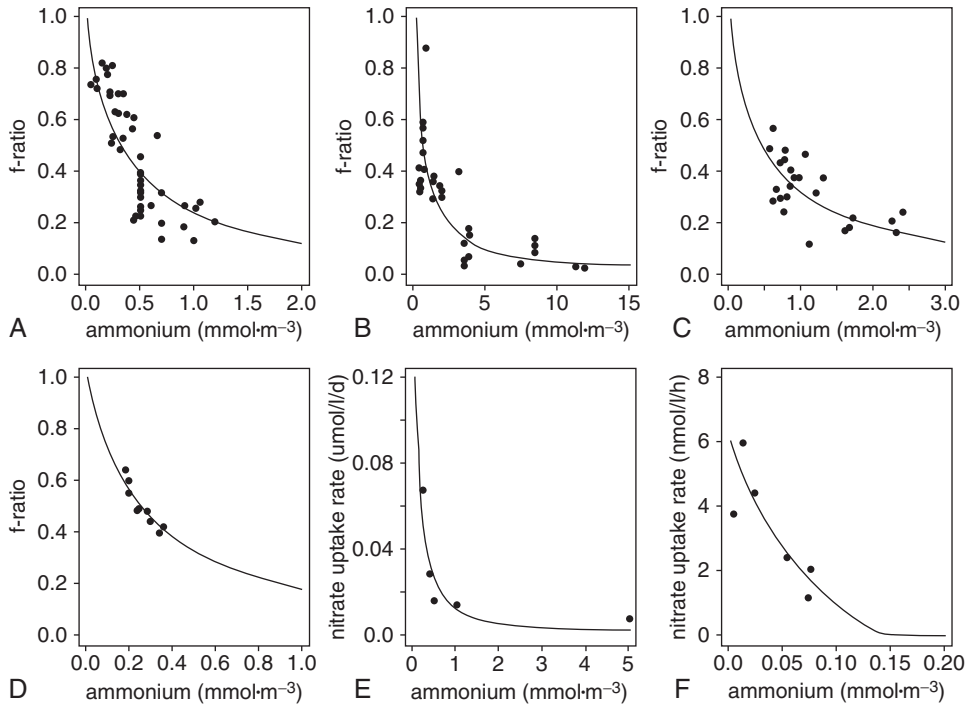
However, in most N–cycle models the primary balance between autotrophic formation of PON and the recycling of that PON back to the DON and DIN pools


Figure 33.11 Fits of the Armstrong (1999) model to six data sets: (A) Cochlan (1986), (B) Garside (1981), (C) Glibert *et al.* (1982), (D) Olson (1980), (E) Price *et al.* (1994), (F) Wheeler and Kokkinakis (1990). Figure reproduced with permission from Armstrong (1999).

is maintained by zooplankton grazing. In simple NPZ and NPZD models, all of the grazing is represented by a single Z compartment, whereas in more complex models this grazing may be represented by multiple zooplankton size classes. This grazing is typically specified using classical functional forms, e.g., Holling's type I, II, III functional responses. One (or some combination) of these functions is also usually used to specify the zooplankton mortality, or ''closure'' in the model. It is well known that these different grazing formulations have a profound impact on N-recycling rates and also model stability (Gentleman *et al.*, 2003; Kemp *et al.*, 2001; Steele and Henderson, 1992). Yet, remarkably little attention has been focused on the grazing formulations in N-cycle models (Gentleman *et al.*, 2003). Suffice it to say that the representation of grazing losses in all N-cycle models is extremely crude compared to reality.

Remineralization of PON and DON to DIN is clearly a key process in models, and also provides some useful illustrations of the classification and evolution of models. The earliest NPZ models represented loss terms from phytoplankton and zooplankton as fluxes directly to the DIN pool. An NPZD model differs from an NPZ model in having an explicit compartment for ''detritus,'' or nonliving organic matter (Edwards, 2001; Franks, 2002). Remineralization from this pool is most simply expressed as

$$\frac{\partial N}{\partial t} = -\frac{\partial D}{\partial t} = eD \tag{33.5}$$

where e can be constant, or an exponential or Arrhenius function of temperature. This basic expression is commonly used, but models differ widely in the exact representation of remineralization. Some models have explicit compartments for bacteria and/or DON, some partition DIN into different species (e.g., NO_3 and NH_4 as discussed in the previous section), and some have fluxes to DIN directly from phytoplankton and zooplankton as well as from detritus.

In the absence of an explicit detrital compartment, the vertical flux needs to be parameterized, i.e., the fraction of production or losses that is exported to greater depths must be defined in some fashion (see section 3.5 below). Steele (1998) devised a scheme for parameterizing microbial recycling based on a priori knowledge of how the partitioning of production between recycling and export varies with nutrient influx. This simple NPZ model does not include detritus, which its author believed is "very poorly defined ecologically, and normally has no basis in data." The basic hypothesis is that because large inputs of inorganic nutrients favor large phytoplankton, metazoan grazers, and export, the exported fraction (f- or e-ratio) can be described as a hyperbolic function of nutrient concentration

$$G(N) = G(NO_3) = \frac{NO_3}{K_N + NO_3} \tag{33.6}$$

where K_N is the equivalent of a half-saturation constant. The relative rates of uptake of NO_3 and NH_4, and partitioning of grazing losses between recycling and export, are described by hyperbolic functions

$$N_{\text{tot}} = \frac{e^{-\phi NH_4} NO_3 + ANH_4}{K_N + NO_3 + ANH_4} \tag{33.7}$$

$$f = \frac{NO_3}{NO_3 + e^{-\phi NH_4} NO_3 ANH_4} \tag{33.8}$$

where N_{tot} is the total N uptake by phytoplankton and A, ϕ, and K_N are constants. So this model makes export directly dependent on the relative availability of NO_3 and NH_4. The overall objective here is to parameterize nutrient recycling by the microbial community so that the Z in the NPZ model is unambiguously associated with macro- rather than microzooplankton, and to represent the effects of community structure on the export ratio in a simple and computationally efficient model. The simulations with this model conducted by Steele (1998) were for a single layer, so the vertical redistribution of nutrients would need to be formulated before it could be used in a full ocean model. Nonetheless, it offers some promise for representing within an NPZ model processes for which single-species models are generally considered unsuitable (Armstrong, 1994).

Other models have represented the "microbial loop" explicitly to varying degrees, incorporating bacteria, micrograzers, and DON, and considering the remineralization pathways in different ways. As discussed above, the Fasham *et al.* (1990) model (Fig. 33.4) included bacteria, DON, NO_3, and NH_4. These authors assumed that under balanced growth, the ratio of bacterial NH_4 uptake to DON uptake should be constant in order to ensure that bacterial biomass of the required C:N ratio (R_b) is produced from DON with a given C:N ratio (R_d). The rates of DON (U_1) and NH_4 (U_2) uptake are

$$U_1 = \frac{V_b B [\text{DON}]}{K_4 + S + [\text{DON}]} \tag{33.9}$$

$$U_2 = \frac{V_b B S}{K_4 + S + [\text{DON}]} \tag{33.10}$$

where B is bacterial biomass, V_b is the maximum bacterial uptake rate, K_4 is the half-saturation coefficient for uptake, and $S = \min(NH_4, \eta \text{DON})$. η defines the ratio of bacterial uptake of NH_4 and DON based on R_b and R_d and the bacterial growth efficiencies for carbon (g_c) and nitrogen (g_n):

$$\eta = \frac{g_c R_d}{g_n R_b} \tag{33.11}$$

This formulation ensures that the uptake of NH_4 will be η times the DON uptake, as required by balanced growth, as long as there is sufficient NH_4 present to meet this demand. If there is insufficient NH_4, then the uptake rate of both DON and NH_4 are reduced accordingly. So the model permits both N and energy limitation of bacteria, or co-limitation, without having an explicit DOC pool. However, by treating DON as a proxy for DOC it implicitly treats the C/N ratio as fixed.

Anderson and Williams (1998, hereafter AW98) modified this model to include both DON and DOC (including "fast" and "slow" pools of each), for a more explicitly stoichiometric treatment of bacterial metabolism. In AW98 the C/N of dissolved organic matter (DOM) is variable, and the controlling parameters are the C/N ratio of bacteria (5.5 mol/mol) and the (carbon) growth efficiency. By specifying these two quantities as constant, bacteria can utilize DIN or remineralize DON, depending on the substrates available. In FDM90, remineralization of DON can occur, but the specific rate of respiration is fixed, i.e., respiration is subsumed within a constant biomass-specific rate of "excretion" of NH_4. Respiration is, strictly speaking, the process of deriving energy from C compounds, although it is clearly related to catabolism of protein or RNA that can generate inorganic N as a byproduct. Ideally, respiration should be represented as a process fed by the supply of C, and so that heterotroph biomass is not lost to the DIN pool if the supply of C is adequate. This approach was employed for microzooplankton grazers by Christian (2005), who employed a fixed C/N for grazers but a variable ratio for their phytoplankton prey.

The stoichiometry of remineralization by grazers as a function of prey C/N was derived in detail by Anderson (1992) and Landry (1993). The latter argues that microzooplankton, not bacteria, are primarily responsible for remineralization of organic N to NH_4 in the ocean, as bacteria need substrates that are more N-rich than are generally found in the ocean DON pool to be net remineralizers. Anderson and Pondaven (2003) allowed grazers to graze on phytoplankton (C/N = 7.5), bacteria (C/N = 5.1), and detritus (variable C/N), so that grazers will be N-limited if the C/N of the total prey ingested exceeds the threshold value

$$\theta_f^* = \frac{\beta_N \theta_Z}{\beta_C k_c} \qquad (33.12)$$

where β_X is the assimilation efficiency for element X, θ_Z is the grazer C/N ratio and k_C is the C net growth efficiency.

Bacteria also provide a potential pathway for transferring DON and detritus N to higher trophic levels, i.e., bacteria constitute a potential ''link'' for trophic transfer up the food web as well as a ''sink'' in terms of remineralization (Sherr et al., 1987). This link is represented in all N-cycle models that include explicit representations of bacteria that consume DON and/or detritus N, and are in turn grazed by zooplankton. The Fasham et al. (1990) model, for example, includes this link by including bacteria that consume DON, which provide an additional food source to a generic zooplankton compartment (Fig. 33.4). According to the model, this link constitutes a small fraction of the total annual zooplankton food supply at the Bermuda Atlantic Time-series (BATS) station, i.e., an N flux of 0.021 mol m^{-2} year^{-1} from bacteria to zooplankton compared to 0.126 mol m^{-2} year^{-1} from phytoplankton in the 10 m day^{-1} sinking rate case. In contrast, the AW98 model, which is based on the Fasham et al. (1990) model, indicates that the food supply from DOM via bacteria can provide up to 50% of the needs of the zooplankton during winter in the English Channel (Anderson and Williams, 1998).

3.4. Modeling nitrification

Most models that include both NH_4 and NO_3 consider nitrification. In general, nitrification has been treated as a relatively simple process that converts NH_4 to NO_3 with a fixed rate or a first-order dependence on [NH_4], and a time scale of days to weeks. Nitrification is inhibited by light (see Ward, Chapter 5, this volume), so generally it is only applied below the euphotic zone. For example, Christian et al. (2002a) set a cutoff of 120 m (Table 33.2), which has since been modified to a light level (daily mean) of 5 µmol m^{-2} s^{-1} (Wang et al., 2005). The daily mean is used so that nitrification does not occur in the surface layer during the day. Some authors do not specify a nitrification function because the term is considered small compared to fluxes of nitrate and detritus across the open lower boundary. For example, in Fasham et al. (1990) the ocean below the mixed layer consists of a single infinitely deep layer where [NO_3] is fixed and [NH_4] is zero, so any PON that sinks into this layer is implicitly remineralized to NO_3. When this ecosystem model was

embedded in a 3D GCM, nitrification was included as a first-order process at depths greater than 123 m (Sarmiento *et al.*, 1993, see Table 33.2).

Wroblewski (1977) modeled nitrification as a first-order process, but did not include light or depth-dependence because it was not demonstrated until the early 1980s that light was the controlling factor (see Ward, Chapter 5, this volume and Mills (1989) for an extensive discussion of early hypotheses and investigations). Even some relatively recent models have permitted nitrification throughout the euphotic zone (e.g., Jiang *et al.*, 2003; Kawamiya *et al.*, 1995; Levy *et al.*, 1998). A few models have taken more explicit approaches to the light-dependence of nitrification. McClain *et al.* (1999) included a spectral irradiance model from 280–700 nm, with nitrification dependent on the integrated irradiance from 300–470 nm. Denman (2003) defined a nitrification profile using the function $z^n / (z_{ox}^n + z^n)$ where $z_{ox} = 60$ m and $n = 10$. This function specifies nitrification increasing at depth with higher values of the exponent n giving a sharper cutoff around z_{ox}^n rather than a gradual decline. Tian *et al.* (2000) created a very similar profile using a hyperbolic term $(E^\star - E)/E^\star$, where E is irradiance and $E^\star$ is 10% of the maximum daily value at the sea surface (there is no nitrification when $E > E^\star$). Bissett *et al.* (1999) included a hyperbolic dependence on NH_4 concentration with a half-saturation of 0.1 µM, for total irradiance <1 µmol m^{-2} s^{-1}. The Bissett *et al.* (1999) and McClain *et al.* (1999) models also specified a maximum rate of nitrification rather than a rate constant. Their values differ substantially: 2 vs 40 nmol L^{-1} day^{-1} for McClain *et al.* and Bissett *et al.*, respectively. Perhaps uniquely, Oguz *et al.* (2000) made the rate of nitrification a function of oxygen concentration (see Section 3.6.2). Oxygen is obviously a necessary substrate, but most open-ocean nitrification occurs in the upper thermocline where oxygen is often near saturation, so its role in regulating nitrification rates is ignored. In the Black Sea, however, the oxic-anoxic interface occurs immediately below the euphotic zone.

3.5. Modeling export

Export in N–cycle models is typically handled in one of two ways, i.e., it is either parameterized using a "Martin curve" type of approach which distributes the N flux according to an empirically defined profile (Martin et al., 1987) or it is modeled explicitly through the generation of detritus N particles that sink and remineralize. The advantage of the former is simplicity: with a Martin curve, export and remineralization at depth can be modeled by simply specifying the particulate N export flux from the euphotic zone (F_0) and then redistributing that flux over depth $F(z)$ instantaneously using an empirical function of the form:

$$F(z) = F_0(z/z_0)^{-b} \qquad (33.13)$$

where z represents depth in meters and b is a dimensionless parameter. The obvious disadvantage of using this approach in a dynamic 3D model is that it cannot account for changes in the remineralization profile that may occur due to physical controls (e.g., changes in temperature) or changes in the quality of organic N that is formed and exported, unless these are specified by changing the exponent b as a function of space and/or time. Nor does this parameterization account for the time it takes for particles to sink and thus the potential impact of horizontal advection on particle export and deposition (Siegel and Deuser, 1997).

Other N–cycle models simulate detritus N formation, sinking and remineralization explicitly (e.g., Hood et al., 2001; McCreary et al., 1996; Sarmiento et al., 1993). In its simplest form this involves specification of a detritus (D) pool that sinks with a constant sinking rate w_s and remineralization rate e. If detritus is not produced or consumed by any other processes, then the detritus equation has the form

$$\frac{\mathrm{d}D}{\mathrm{d}t} = w_s D - eD \qquad (33.14)$$

At steady state this equation simplifies to $D_z = (e/w)D$, which has the solution

$$D(z) = D_0 e^{z(e/w_s)} \qquad (33.15)$$

where D_0 is the detritus concentration at some initial depth. Thus, this simple explicit formulation generates an exponential remineralization/detritus flux profile with a decay length scale e/w_s. Elaborations on this approach may include addition of temperature controlled remineralization rate, multiple size classes that sink at different rates and/or additional biological terms (e.g., consumption by bacteria or zooplankton).

Most modern N–cycle models simulate N export using one or the other of these approaches, but details vary and some models combine aspects of explicit sinking and remineralization with Martin curve parameterizations. For example, Chai et al. (1996) modeled a 5-component N-based ecosystem including a detrital N compartment with explicit sinking, but did not permit detrital remineralization within the euphotic zone. In contrast, Christian et al (2002a) used a Martin curve to redistribute detrital N vertically, but rather than remineralizing at the specified depth, it is returned to the

detrital pool where it is subject to all of the processes in the detritus state equation including advection, mixing, and further sinking. Christian (2005) employed parameterized sedimentation, with instantaneous downward transport and solubilization to DON, but no direct remineralization from the "sinking" flux.

Particle aggregation effects can also be parameterized in explicit formulations by making the sinking rate of the detritus a function of detritus concentration. For example, Hood *et al.* (2003) applied this kind of simple parameterization in an NPZD model to account for aggregation that can occur in diatom blooms. In their model phytoplankton sink at the rate

$$
w_p = \begin{cases} w_a, & P \le P_a \\ \dfrac{w_a + (P - P_a)(w_b - w_a)}{P_b - P_a}, & P_a < P < P_b \\ w_b, & P \ge P_b \end{cases} \tag{33.16}
$$

where P_a and P_b are threshold phytoplankton (P) concentrations. When $P \le P_a$ the phytoplankton sink at the rate w_a, i.e., very slowly or not at all, whereas when $P \ge P_b$ the phytoplankton sink very rapidly at the rate w_b. In the concentration range $P_a < P < P_b$, the sinking rate is linearly ramped up from w_a to w_b. This simple formulation crudely reproduces the observed phenomenon of diatom aggregation/flocculation that can occur under bloom conditions and lead to rapid sinking and export (Alldredge and Gotschalk, 1989). It significantly improved the NPZD model's simulation of chlorophyll concentrations in coastal upwelling regions in the Arabian Sea. Much more sophisticated approaches for modeling the effects of aggregation have also been formulated. For example, Jackson (2001) incorporated a mechanistic coagulation dynamics model into the Fasham *et al.* (1990) food web model and showed that coagulation can have an important effect on particle flux even in low particle concentration oligotrophic environments because it increases average particle settling speed (for a review of coagulation theory and models of oceanic plankton aggregation see Jackson (2005)). Thus, a wide range of formulations are available for accounting for particle aggregation effects in N cycle models. In addition, studies have shown that the presence of mineral ballast (i.e., calcite or silica) can have a very significant impact on the remineralization profiles and deep fluxes of particulate organic carbon (e.g., Armstrong *et al.*, 2002), and presumably nitrogen.

3.6. Modeling reduction-oxidation reactions that impact total fixed nitrogen in the oceans

3.6.1. N$_2$-fixation

Another area where there has been significant progress in recent years has been the development of models that account for oxidation-reduction reactions that impact the nitrogen inventory of the oceans, i.e., N$_2$-fixation and denitrification. N$_2$-fixation has been considered in several open-ocean modeling studies. Tyrrell (1999) developed a simple two-box global model with an explicit representation of diazotrophs with both nitrogen and phosphorus cycling. In this model the

N$_2$-fixation rate is a function of the supply ratio of inorganic nitrogen and phosphorus. The underlying assumption is that N$_2$-fixation increases when reactive nitrogen concentrations become low relative to Redfield N:P. Neumann (2000) included N$_2$-fixation in a mechanistic 3-dimensional N-cycle model of the Baltic Sea that includes cycling of both nitrogen and phosphorus, but without an explicit representation of diazotrophs. The N$_2$-fixation rate in this model depends on phosphorus supply, temperature and irradiance. Bissett *et al.* (1999) similarly included N$_2$-fixation implicitly, i.e., as an N flux to the dissolved organic matter pool using a simple parameterization that assumes a nitrogen source that is proportional to temperature and irradiance. Christian (2005) took a similar approach but without temperature-dependence and divided new N equally between DIN and DON.

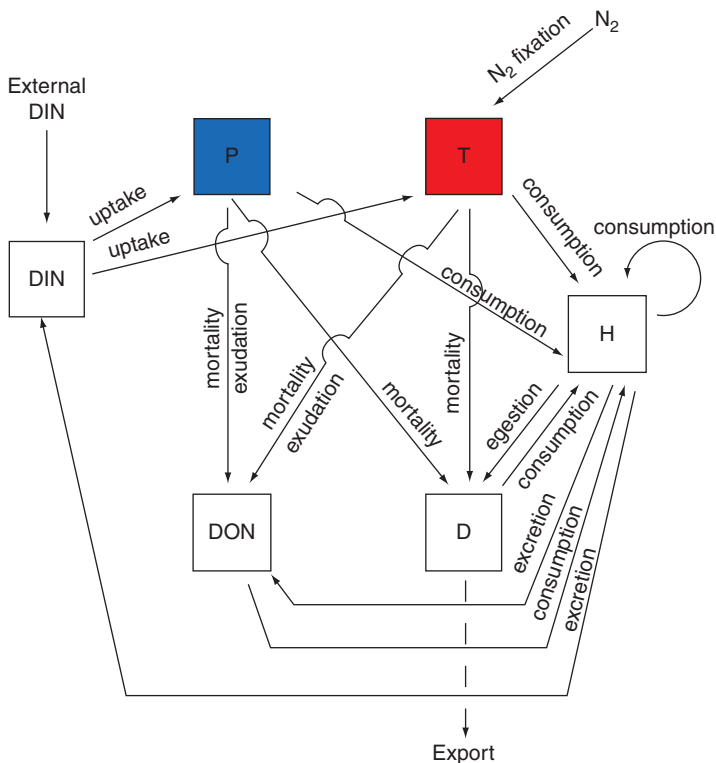
Several more recent efforts have provided models that can be used to incorporate dynamic representations of diazotrophs and N$_2$-fixation in N-cycle models, although all of these models have deficiencies that potential users should be aware of. Hood *et al.* (2001) explicitly included a state variable for *Trichodesmium* in a 6 compartment N-cycle model (Fig. 33.12). In this model, growth of phytoplankton (G_P) and *Trichodesmium* (G_T) are specified by the following equations:


Figure 33.12 A schematic box diagram of the Hood *et al.* (2001, 2004) ecosystem model. The state variables are dissolved inorganic nitrogen (DIN), dissolved organic nitrogen (DON), phytoplankton (P), *Trichodesmium* (T), heterotrophs (H), and detritus (D). Redrawn and modified with permission from Hood *et al.* (2004).

$$G_P = \mu_p \left(1 - e^{-I/I_p}\right) e^{-I/I_{\beta P}} \, DIN/(DIN + PKS) \qquad (33.17)$$

$$G_T = \mu_T \left(1 - e^{-I/I_T}\right) \qquad (33.18)$$

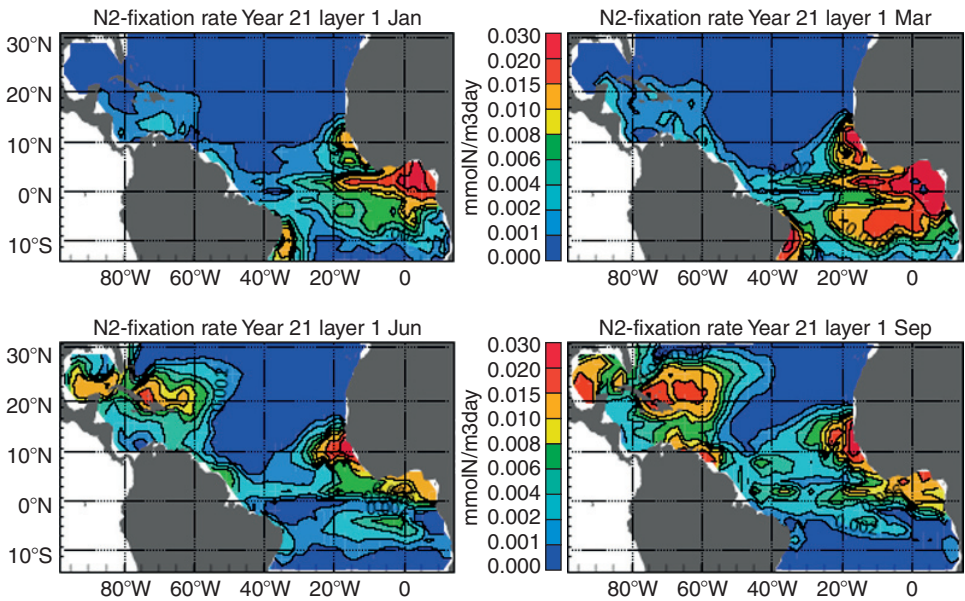
where μ_P and μ_T are the maximum growth rates for phytoplankton (P) and *Trichodesmium* (T) and I is irradiance. The terms I_P and I_T are the light saturation parameters for P and T, $I_{\beta P}$ is the photoinhibition parameter for phytoplankton (Platt *et al.*, 1980), and PKS is the half-saturation coefficient for N limitation of phytoplankton. Thus, in the Hood *et al.* (2001) model P and T growth differ in that P is subject to photoinhibition and nitrogen limitation whereas T is not. In addition, μ_T is substantially lower than μ_P. Nitrogen fixation is implicit, i.e., when *Trichodesmium* grows in the absence of DIN uptake it introduces N into the system. The N$_2$-fixation rate in this model is assumed to depend entirely upon light, which is primarily regulated by mixed-layer depth/stratification. In subsequent studies, Hood *et al.* (2004) and Coles *et al.* (2004) coupled this model to a 3-dimensional circulation model of the tropical and subtropical Atlantic and, among other things, attempted to simulate basin-wide temporal and spatial variability in *Trichodesmium* biomass and N$_2$-fixation rate (Fig. 33.13). The obvious deficiency in this model is that it does not account for the effects of either P or Fe limitations.


Figure 33.13 Hood *et al.* (2004) model–estimated nitrogen fixation rate in the mixed layer as a function of season. The fields are synoptic, from the middle of the specified month. The rates are expressed in mmol N m^{-3} day^{-1}. Reproduced with permission from Hood *et al.* (2004).
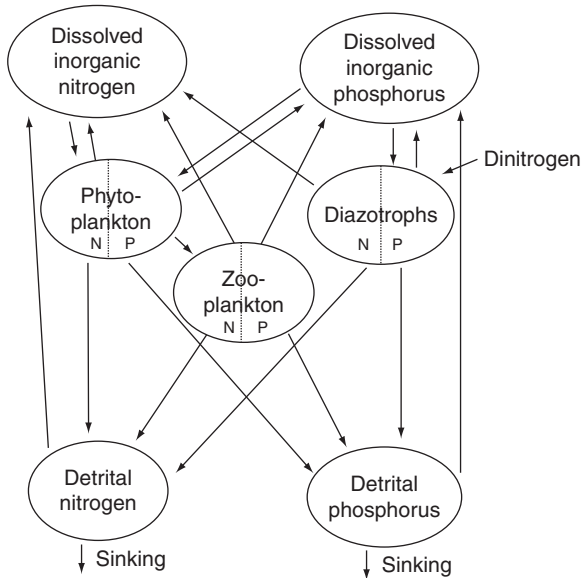

Figure 33.14 Schematic diagram of the Fennel *et al.* (2002) ecosystem model. Reproduced from Fennel *et al.*, 2002 with permission.

Fennel *et al.* (2002) developed a seven compartment model (Fig. 33.14) with temperature-controlled N_2-fixation and P limitation (Fig. 33.15). This model specifies different stoichiometry for different taxa (high N:P ratio in diazotrophs) and permits differential export of nitrogen and phosphorus from the upper ocean. This model also includes a term that applies direct wind speed modulation of diazotroph growth rate, i.e., the observed association of N_2-fixation with calm conditions is directly incorporated into the model in a non-mechanistic fashion. An obvious deficiency in this model is that it does not include a mechanism for supplying additional phosphorus to the surface waters where diazotroph populations and nitrogen fixation rates are typically highest (Capone *et al.*, 1997). As a result the model generates subsurface diazotroph/N_2-fixation maxima that, at least for *Trichodesmium*, are probably unrealistic. One potential mechanism for supplying additional phosphorus to the surface is ''phosphorus mining,'' i.e., the idea that large diazotrophs like *Trichodesmium* can migrate down to the phosphocline periodically to satisfy their phosphorus requirement (Karl *et al.*, 1992). Another, perhaps more likely, mechanism is that phosphorus availability can be maintained at the surface to support diazotrophic growth by simply recycling it faster than nitrogen (Coles and Hood, 2007; Hood *et al.*, 2006; Wu *et al.*, 2000).

Finally Moore *et al.* (2002a; 2002b; 2004) included explicit representations of diazotrophs and N_2-fixation in their multi-species, multi-element biogeochemical model. In this model the growth rate of diazotrophs is subject to light, nitrogen, phosphorus, iron and temperature control. These global simulations generate spatial patterns in N_2-fixation in the Atlantic that are similar to those reported in Hood *et al.* (2004) suggesting that diazotrophic growth and N_2-fixation is, to a large extent,
Figure 33.15 The growth rate of diazotrophs as a function of temperature and dissolved inorganic phosphorus concentration in the Fennel *et al.* (2002) model. Reproduced from Fennel *et al.* (2002) with permission.

controlled by mixed layer depth and light. However, Moore *et al.* (2002b) and Moore *et al.* (2004) also report widespread phosphorus limitation of diazotrophs in the Atlantic, particularly in Moore *et al.* (2004), where the N/P ratio is fixed. Both Fennel *et al.* (2002) and Moore *et al.* (2004) include a P requirement for diazotrophy but do not include the (admittedly speculative) mechanisms, such as P mining or enhanced P recycling, that permit diazotrophs to grow in P-depleted subtropical surface waters. Until such mechanisms are better understood, model-derived inferences of P-limitation must be considered tentative.

3.6.2. Denitrification

In contrast to N_2-fixation and nitrification, examples of open ocean N-cycle models that include dynamic models of denitrification are much more limited. This is not due to an absence of a chemical, mathematical or numerical foundation for modeling denitrification (Fennel and Neumann, 2004). Numerous models that include denitrification have been developed and applied in coastal/benthic systems (e.g., Fennel *et al.*, 2006). Denitrification has not been included in many open ocean N-cycle models because in many regions, and over shorter time scales, its impact on the N inventory can be assumed to be negligible. But another likely factor is the difficulty inherent in simulating organic matter loading and oxygen concentrations in hypoxic/anoxic mesopelagic regions (i.e., oxygen minimum zones or OMZs), which are pre-requisites for making a truly prognostic denitrification rate calculation. And there is also the practical constraint that any attempt to model all of the

denitrification in a particular basin must also account for it in shelf/slope waters and sediments. Most GCMs applied at these scales do not resolve the continental shelves.

Anderson *et al.* (1982) published an early modeling study investigating nitrate deficits and the secondary nitrite maxima that result from denitrification regions within OMZs in the Arabian Sea, the eastern tropical North Pacific, and coastal waters off Peru. They integrated the 1-D form of an advective-diffusion-reaction equation set that tracked nitrate and nitrite. Rates were specified for nitrification and the consumption of nitrate and nitrite by denitrification, with nitrite being reduced directly to N_2. An additional simplification consisted of characterizing the OMZ as a two-layer system with separate nitrifying and denitrifying layers.

In addition, several important modeling efforts have been focused on the Black Sea low oxygen environment that include denitrification. For example, Yakushev and Neretin (1997) developed a 1-D advection-diffusion-reaction model to study chemical transformations in the low oxygen mid-water regions of the Arabian Sea and the Black Sea. Oxygen-dependent cycling of nitrogen in the marine environment was included in their model, along with denitrification. In this model the transition from denitrification to nitrification between the anoxic core and the surrounding oxic waters is determined by linear relations that modify the rate of each process, with O_2 thresholds taken from the available literature.

A subsequent effort in the Black Sea consisted of coupling models of biological production and export, nitrogen cycling and redox cycling to a turbulence closure mixed layer model (Oguz *et al.*, 2000). This study represents a significant advance in simulating the linkage between nitrifying and denitrifying regimes because both mixing and export production from the overlying euphotic zone were dynamic components of the modeling scheme. Nitrification and denitrification were explicitly included in this model with nitrite as an intermediate byproduct. Changes in NO_2 and NO_3 concentrations were specified as follows:

$$\frac{dNO_2}{dt} = k_1 f_n(O_2)NH_4 - k_2 f_n(O_2)NO_2 \\ + k_3 f_d(O_2)NO_3 - k_4 f_d(O_2)NO_2 \tag{33.19}$$

and

$$\frac{dNO_3}{dt} = k_2 f_n(O_2)NO_2 - k_3 f_d(O_2)NO_3 \tag{33.20}$$

where the k_x values are reaction rate constants. In (33.19) the first two terms represent the ammonium to nitrite and nitrite to nitrate oxidation reactions in oxygenated waters, and the third and fourth terms represent denitrification under oxygen deficient conditions, i.e., the third term models nitrate to nitrite reduction, and the fourth term represents the nitrite reduction to N_2 (the second stage of denitrification). Changes in nitrate in (33.20) involve increases from the second stage of nitrification (the first term) and decreases from the first stage of denitrification (the second term).

In these equations oxidation reaction rates are determined using a hyperbolic saturation function:

$$f_n(O_2) = \left[\frac{O_2}{O_2 + R_O}\right] \quad \text{for } O_2 \geq 3\mu M \qquad (33.21)$$

where R_O = 10 μM. This equation specifies rates that decrease with decreasing oxygen concentrations and vanish when $[O_2] < 3$ μM in the water column. In contrast, reduction reaction rates are determined using a complementary function of oxygen:

$$f_d(O_2) = \left[\frac{K_O}{K_O + O_2}\right] \quad \text{for } O_2 < 3\mu M \qquad (33.22)$$

where K_O = 2.5 μM. This function specifies that the maximum rate occurs at zero oxygen concentration and decreases gradually as the oxygen concentration increases. When $O_2 \geq 3$ μM, the rate is set to zero.

More recently, Konovalov et al. (1999) and Murray et al. (2005) built upon these previous achievements in modeling biogeochemical cycles in the Black Sea by incorporating a more realistic model of physical exchange (Ivanov and Samodurov, 2001) and including additional biogeochemical constituents. Specifically, transformations of O_2, PON, DON, NO_3, NO_2, N_2, NH_4, H_2S, S°, and dissolved and particulate Mn(II) and Mn(IV) and Fe(II) and Fe(III) were included in their model. Equations that parameterize biogeochemical transformations were written to follow either chemical or biological uptake (e.g., Michaelis-Menten) kinetics; biogeochemical processes are stoichiometrically coupled; and all of the biogeochemical components are conserved. This model generates remarkably detailed and realistic vertical profiles of all of the above constituents (Fig. 33.16).

We are not aware of any basin or global scale coupled N-cycle models that have attempted to include a dynamic, prognostic model of denitrification that is anywhere near the level of sophistication and complexity of the Oguz et al. (2000) or the Konovalov et al. (1999)/Murray et al. (2005) models. Moore and Doney (2007) recently incorporated a prognostic denitrification module into the Moore et al. (2004) global biogeochemical model. In this formulation oxygen is dynamically determined and NO_3 is used in place of O_2 in decomposition of organic carbon when $[O_2] < 4$ μM. For the ocean N inventory to remain in a quasi–steady-state there must be stabilizing feedbacks between denitrification and N_2 fixation. In the model N_2 fixation is stimulated when water that is depleted in N (relative to P) by denitrification is upwelled to the surface.

The authors found strong stabilizing feedbacks in the northern Indian Ocean and in the North Atlantic that act to minimize changes in the marine N inventory over relatively short timescales (~30–200 years) and concluded that rates of N_2 fixation are tightly linked to N:P ratios in surface waters and thus denitrification, locally for the Indian Ocean and more remotely for the Atlantic Ocean. However, the strength of these stabilizing feedbacks was weaker in other regions mainly due to Fe
Figure 33.16 Model simulations of biogeochemical constituents in the Black Sea generated by the Konovalov *et al.* (1999)/Murray *et al.* (2005) model. Figure reproduced with permission from Murray *et al.* (2005).

limitation of diazotrophs and also due to spatial separation between areas of N_2 fixation and denitrification, i.e., the feedbacks occur regionally, but globally they aren't strong enough to balance the N budget over the time scales examined. In their base model run the global N inventory goes down by 7% over 200 years. In addition, the authors found that maintenance of the OMZs is dependent, in part, on N_2 fixation driven export production and they concluded that Fe limitation of diazotrophs significantly hampers the ability of N_2 fixation to compensate for N losses due to denitrification in the current climate, leading the oceans to lose fixed nitrogen.

Perhaps the most significant caveat in the Moore and Doney (2007) study is that their model does not include shelf denitrification, which would suggest that they are missing more than half of the global marine denitrification signal and its associated N sink (Codispoti *et al.*, 2001), or they are producing this sink in the wrong place, i.e., in the open ocean rather than on the shelves. If the former is true, then the imbalance (loss) of N from the oceans in their model is even greater. Regardless, the Moore and Doney (2007) study represents an important step forward in large-scale N cycle modeling. It is one of the first to incorporate dynamic representations of both denitrification and N_2 fixation and feedbacks between them. The study also provides

important insights into the potential linkages between Fe supply, N_2 fixation, denitrification and the maintenance of open ocean OMZ regions.

Nitrous oxide (N_2O) is both an important greenhouse gas and a byproduct of both nitrification (see Bange, Chapter 2, this volume and Ward, Chapter 5, this volume) and denitrification (see Devol, Chapter 6, this volume), and has been the subject of several modeling studies. Suntharalingam and Sarmiento (2000) and Suntharalingam et al. (2000) coupled a simple N_2O production model to a coarse resolution ocean general circulation model, with N_2O production given as a function of oxygen consumption, i.e., it was assumed to be proportional to remineralization of organic matter, and therefore to nitrification. In the latter paper, a dependence of N_2O yield on O_2 concentration was introduced, based on studies of ammonia-oxidizing bacteria in culture. These data suggest that yields are extremely high at the O_2 concentrations at which denitrification occurs. So by replacing oxygen consumption with a C- or N-based estimate of remineralization, this model could be extended to include a parameterization of N_2O production from denitrification as well as nitrification. In a follow on study, Jin and Gruber (2003) further elaborated the Suntharalingam et al. (2000) model and used it to assess the potential impacts of iron fertilization on ocean N_2O emissions. They found that increased N_2O production could significantly offset the radiative benefit from fertilization-induced atmospheric CO_2 reduction.

At present, the relative importance of nitrification and denitrification as sources of N_2O remains unknown, and models linking all of these processes to environmental conditions remain tentative. As noted above, the efforts of Yakushev and Neretin (1997) and Oguz et al. (2000), respectively, employ linear and hyperbolic forms of O_2-dependent relations to capture the transition between the two processes, and while the former effort provides for an overlap regime, the latter does not. It should also be noted that, although Redfield's stoichiometry for denitrification (e.g., Richards, 1965) has been assumed to be applicable for all the denitrification modeling efforts discussed above, there is growing evidence that this is not the case (Codispoti et al., 2001; Van Mooy et al., 2002). Codispoti et al. (2001) point out that there are a number of factors that can alter the apparent stoichiometry of denitrification. These include variations in the C:N composition of the organic matter substrate (Van Mooy et al., 2002) as well as the influence of more exotic processes that produce dinitrogen gas, such as the ''anammox'' reaction and transformations involving Mn as a ''pseudo-catalyst'' (Luther et al., 1997). None of these reactions have been considered in N-cycle modeling studies. These and many other challenges remain.

4. Nitrogen in the Ocean (Modern Coupled Models)

4.1. Nitrogen fluxes and ocean circulation

The supply of new nitrogen (mostly NO_3) to the euphotic zone has been a primary focus for oceanographers for the past two decades. As noted above, models can provide estimates of quantities that are not directly observable, such as fluxes of nutrients by different physical processes. For example, Sarmiento et al. (1993) used a

basin-scale model of the North Atlantic (20°S-60°N) to estimate fluxes of nitrate by different physical processes and examine controls on surface nitrate concentrations. For the full model domain, they found that flux of nitrate to the euphotic zone was 64% from upwelling, 29% from convective overturning, and 7% from mixing. The largest N flux was from upwelling in the subpolar gyre and the equatorial zone associated with large scale Ekman transport. Horizontal advection as a local source of N was a "mirror image" of vertical transport, i.e., highest in regions of down-welling. The degree to which N can be advected from upwelling to downwelling regions depends strongly on the rate of export and therefore on the ecosystem model used. In Sarmiento *et al.* (1993) downward transport was predominantly by sedimentation, but downward advection and mixing of particulate and dissolved N (NH_4, DON) accounted for 15%. The basin-averaged *f*-ratio was 0.43.

The companion paper by Fasham *et al.* (1993) focused on two specific sites: Ocean Weather Station India (OWSI) in the subarctic and BATS in the subtropics. At BATS, vertical nitrate supply to the euphotic zone was overwhelmingly from winter convection (more than 25 times larger than vertical mixing). More than half of this was removed by vertical advection (Ekman pumping). They also found that a significant fraction of the nitrate at this location was supplied by lateral advection. Subsequent studies with eddy-resolving models suggest that some of these results are artifacts of the coarse-resolution ($2 \times 2°$) model used (McGillicuddy *et al.*, 2003; Oschlies, 2002).

In this model, nitrate concentration remained above 1 μM in summer over large areas of the subpolar gyre. Sarmiento *et al.* (1993) discuss the difference between transport-dominated and uptake-dominated regimes. In a transport-dominated regime, uptake does not keep up with the physical supply of nitrate and concentrations rise above the biologically-regulated concentration, which is the half-saturation point for phytoplankton uptake (in this case 0.5 μM). This occurs in the equatorial Atlantic in boreal summer when the strongest upwelling-favorable winds are present (see also Frost and Franzen, 1992), and in the subpolar gyre in winter when phytoplankton are light-limited. Over most of the model domain, the fraction of surface NO_3 removed by the biota (relative to accumulation in an abiotic run) exceeds 90%. However, there is a region of the subpolar North Atlantic where nitrate concentration remains high even in summer, which is attributed primarily to grazing control of phytoplankton (see also Armstrong, 1994). As discussed above, physical transport of nutrients depends in part on the ecosystem model structure.

A subsequent study using the same ecosystem model was carried out in the equatorial Pacific by Toggweiler and Carson (1995). They calculated N fluxes in the equatorial *x-z* plane (integrated to ±5° latitude), showing that the primary source of N to the surface waters of the equatorial upwelling is upwelling from depths >100 m, the approximate depth of the equatorial undercurrent (EUC). In the 90–144 m depth stratum there is an eastward advective flux of 6.9 Tmol N year^{-1} at 135°W, of which about 15% is advected east of 90°W, 10% advected poleward of 5°, and the remainder upwelled to the surface layers. In the surface layer (0–40 m) the upwelling flux between 90–135°W is 10.2 Tmol year^{-1}. About half of this N is exported as particulates, and the remainder divided equally between zonal and meridional advection. A subsequent study using a different ecosystem/circulation

model (Jiang et $al.$, 2003) used the same geographic boundaries, although their vertical levels differ. Jiang et $al.$ found that upwelling across 112 m transported 5.6 Tmol N year^{-1} between 90–135°W, in between Toggweiler and Carson's values for 90 and 144 m, but nearer to the low end (based on linear interpolation of the depth levels). Losses were divided between particulate export ($\sim$2/3) and meridional advection ($\sim$1/3), with a negligible contribution from zonal advection when integrated from 0–112 m.

An important conclusion of the Toggweiler and Carson (1995) study is that the EUC is the most important source of N to the equatorial zone; paradoxically, NO_3 concentration in the EUC is lower than in the surrounding waters. The resolution of this apparent paradox lies in the nonconservative nature of bioactive elements such as N. The primary mass balance for N is between zonal advection by the EUC and sedimentation of particulate N, while the mass balance for water is between zonal advection and poleward advection of surface waters that have been depleted of N by the biota. This is not intended to minimize the importance of vertical advection, which is of course very important for equatorial ecosystems, but to understand sources to the region as a whole, by calculating fluxes in and out of a "box" encompassing the upper equatorial ocean down to the base of the thermocline.

A similar analysis of the equatorial Atlantic, using a model with 16 vertical layers and a simple N-based biogeochemical model was conducted for the years 1983 and 1984 by Loukos and Memery (1999). In their model, vertical advection along the equator shows a distinct maximum that follows the slope of the thermocline, with maximal values at 40–80 m depending on longitude, while the vertical mixing flux is maximal in the surface layer in the central basin, coincident with the maximal biological uptake. Loukos and Memery emphasize the importance of mixing for vertical N fluxes: upwelling accounts for most of the flux to the euphotic zone, but mixing brings it to the surface layer, where most of the biological uptake occurs. This may differ between the Atlantic and the Pacific because in the Pacific vertical gradients of N concentration are less steep due to iron and/or silicate limitation. Although the discussion here has focused primarily on DIN fluxes and specifically NO_3, it should also be noted that upwelling can transport significant amounts of NH_4 and organic N from the aphotic zone to the euphotic zone in the coastal zone (Gruber et $al.$, 2006), and probably also in intense open ocean upwelling regions (e.g., Christian et $al.$, 2002b).

As we have variously discussed in previous sections, there are several other sources that contribute to the new nitrogen supply to the euphotic zone in the open ocean, i.e., in addition to the supply of new nitrogen (mostly NO_3) due to physical processes. Atmospheric inputs include NO_x and NH_3 deposition derived from anthropogenic (e.g., fossil fuel combustion and domestic animal waste) and natural (e.g., lightning) sources. Although rates of N_2-fixation in open ocean waters are still not well constrained, it is generally thought that this process provides the most significant atmospheric source of new nitrogen (Galloway et $al.$, 2004; Michaels et $al.$, 1996), about 120 Tg N year^{-1} globally, as compared to $\sim$25 Tg N year^{-1} from the other atmospheric sources. It is believed that this influx of N from N_2-fixation is restricted primarily to tropical and subtropical waters where it can be comparable to the supply of new NO_3 from depth (Capone et $al.$, 1997; 2005; Karl

et al., 1997). Yet most open ocean N–cycle models do not account for any of these atmospheric N sources, although some now include N_2-fixation as discussed above. The model results of Hood *et al.*, (2004) and Moore *et al.*, (2002a; 2002b) suggest that new nitrogen inputs from N_2-fixation significantly alter phytoplankton production patterns in tropical and subtropical waters.

4.2. Mesoscale processes

The pioneering studies of Sarmiento *et al.* (1993) and Fasham et al (1993) illustrate both the strengths and weaknesses of basin-scale coarse-resolution models. Despite some unrealistic aspects of the modeled circulation, these allowed oceanographers to examine the time-dependent dynamics of basin-scale processes. The weakness is that low model resolution can result in important processes being entirely overlooked. For example, Fasham *et al.* (1993) found that vertical advection (Ekman pumping) is a sink for NO_3 at BATS and horizontal advection a significant source. Eddy-resolving models, by contrast, suggest that both of these results are artifacts of low resolution (McGillicuddy *et al.*, 2003).

There is a long-standing controversy over levels of new production in the Sargasso Sea. Estimates from integrative geochemical tracer methods cannot be sustained by the traditionally accepted mechanisms of vertical nutrient supply (Jenkins and Goldman, 1985; Shulenberger and Reid, 1981). McGillicuddy and Robinson (1997) used a high-resolution coupled physical-biological model to show that mesoscale upwelling could supply the required amount of NO_3. In a later study, McGillicuddy *et al.* (2003) simulated the entire North Atlantic at eddy-resolving resolution ($0.1° \times 0.1°\cos\phi$, ϕ = latitude). They compared N fluxes with both the coarse resolution model of Fasham *et al.* (1993) and an eddy-permitting, but not eddy-resolving, model by Oschlies *et al.* (2000). The eddy-permitting model had a much lower input of NO_3 from horizontal advection at BATS than the 2° model, but had a similar loss to vertical advection (0.13 mol m^{-2} year^{-1}) and relied on winter convection as the dominant source. Convection is an important source in McGillicuddy *et al.* (2003) as well, but the 0.13 mol m^{-2} year^{-1} N sink from vertical advection becomes a 0.12 mol m^{-2} year^{-1} source. However, another eddy-resolving simulation by Oschlies (2002) found a relatively modest eddy-induced N flux of 0.05 mol m^{-2} year^{-1} and concluded that mesoscale upwelling does not by itself provide a solution to the conundrum.

An important difference between these two models is that Oschlies (2002) incorporated an NPZD ecosystem model, whereas McGillicuddy *et al.* (2003) parameterized biological uptake, and continually relaxed NO_3 concentrations back to a climatological nitrate-density regression immediately below the euphotic zone. McGillicuddy *et al.* (2003) argue that the model of Oschlies (2002) underestimates NO_3 concentrations in precisely the depth/density range where it has a large effect on fluxes to the euphotic zone. Whatever the reasons for the discrepancies between these two models, this example provides a useful illustration of the importance of the choice of the biological model even for estimates of N fluxes determined primarily by physical processes. Furthermore, it indicates that sedimentation and remineralization are very important aspects of the model that remain poorly understood (see Sections 3.3 and 3.5).

4.3. Modern nitrogen-cycle model structures

As we discussed at the end of section 2, the modern era of basin–scale N–cycle modeling began with the seminal work of Fasham *et al.* (1993) and Sarmiento *et al.* (1993). Current models encompass a wide range of biological complexity and spatial resolution. Although simple N–cycle models (e.g., NPZD) are still being used to address a variety of important questions (e.g., Hood *et al.*, 2003; Kawamiya and Oschlies, 2003; Oschlies, 2002), there has been a general movement toward the application of N–cycle models that include more detail in the food web (e.g., Christian *et al.*, 2002a), that incorporate important reduction-oxidation reactions such as N_2–fixation (e.g., Fennel *et al.*, 2002; Hood *et al.*, 2001; 2004), and that consider limiting nutrients other than nitrogen (e.g., Aumont *et al.*, 2003; Christian *et al.*, 2002a,b; Gregg *et al.*, 2003; Moore *et al.*, 2002a,b, 2004).

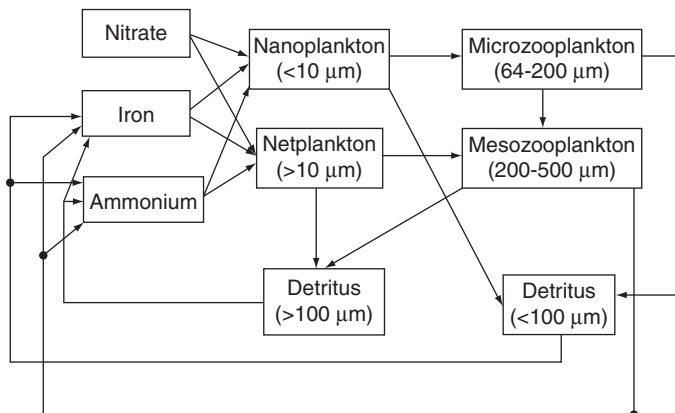
Several N–cycle models have been developed in recent years that have explicit representations of both the small (slow sinking) and large (fast sinking) components of the planktonic food web. For example, Fig. 33.17 shows a schematic diagram of a 9-component N–cycle model that was originally developed by Leonard *et al.* (1999) and subsequently applied in three-dimensional studies in the tropical Pacific, Atlantic and Indian Oceans (Christian *et al.*, 2002a; Christian and Murtugudde, 2003; Wang *et al.*, 2005; Wiggert *et al.*, 2006). This model includes state variables for large and small autotrophs (i.e., net–phytoplankton and pico–phytoplankton) along with large and small grazers (i.e., macrozooplankton and microzooplankton), which then produce fast and slow sinking detrital components (large and small detritus). NO_3 and NH_4 are included along with Fe, and photoacclimation of the carbon-to-chlorophyll ratio. This model was intended to include aspects of the N–cycle that are essential for partitioning between export and recycling, but does not include explicit compartments for bacteria or DON. The implication of the latter is that bacteria and DON are *not* essential for representing export and recycling in N–cycle models; this is discussed further below.


Figure 33.17 Schematic box diagram of the Leonard *et al.* (1999) model.
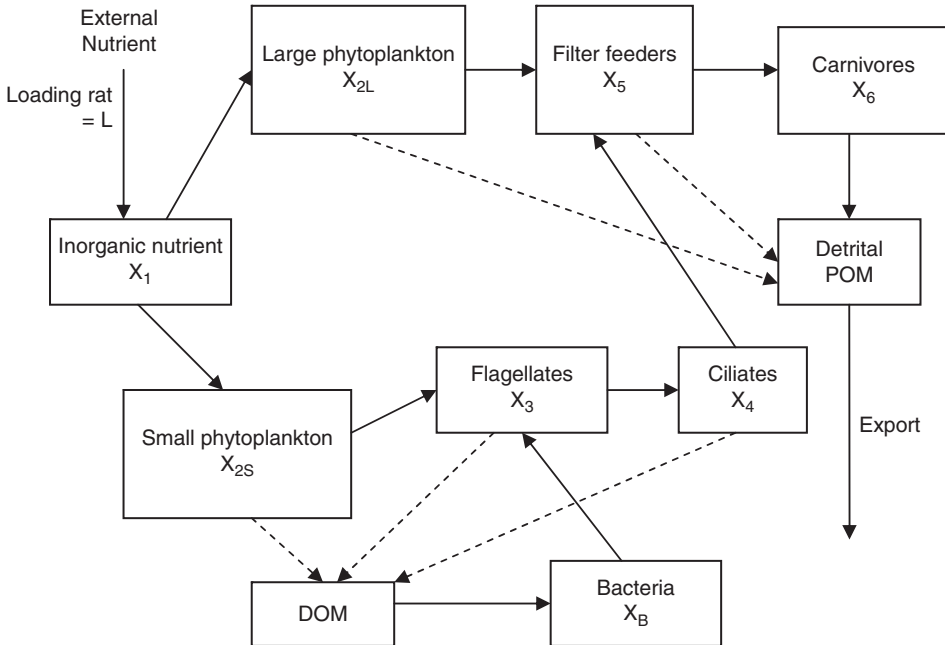

Figure 33.18 Schematic box diagram of the Laws *et al.* (2000) model. Redrawn with permission from Laws *et al.* (2000).

Additional variations on this basic model form are the Laws *et al.* (2000) and the Fennel *et al.* (2006) models. The Laws *et al.* (2000) model (Fig. 33.18) has 10 state variables and includes bacteria and DOM plus additional higher trophic level grazers, but only one fast-sinking detritus compartment and one inorganic nitrogen compartment. This model is structured so that consumers of large phytoplankton produce detritus that sinks, whereas consumers of small phytoplankton produce DOM that does not sink, thereby partitioning production into export and recycling. In contrast, the Fennel *et al.* (2006) model (Fig. 33.19), which has only 6 state variables, accomplishes this partitioning by explicitly including fast (large) and slow (small) sinking detritus compartments. However, rather than generating different size classes of detritus via different size classes of phytoplankton and zooplankton, instead this model produces large detritus through aggregation of small detritus and phytoplankton. The Fennel *et al.* (2006) model also includes nitrification and an explicit representation of shelf/sediment biogeochemical processes, i.e., a simple parameterization of nitrogen losses associated with sediment denitrification following Seitzinger and Giblin (1996).

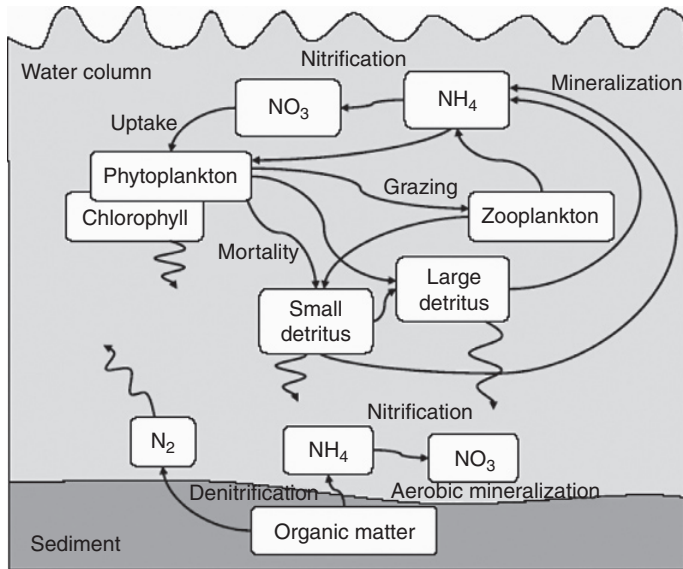
As discussed in the previous section, an alternative approach that has been advocated by Steele (1998) and more recently by Denman and Pena (2002) and Denman (2003), is to stick with simple NPZ and NPZD formulations and, instead, try to "parameterize" additional food web complexity (see also Pahlow and Vezina, 2003). In his review of these various simplifying approaches, Denman (2003)


Figure 33.19 A schematic diagram of the Fennel *et al.* (2006) N-cycle model. In addition to the pelagic components, this model also includes benthic N-cycle processes, i.e., sediment denitrification. Reproduced from Fennel *et al.* (2006) with permission.

concluded that there are compelling reasons to consider adopting relatively simple N-cycle model formulations that represent increasing complexity in compact forms. Among other things, he points out that more complex model formations tend to exhibit more unstable behavior, and adding compartments usually leads to a non-linear increase in the number of parameters in the model that often cannot be adequately constrained. However, recent model intercomparison studies suggest that some of the more complex N-cycle models can provide better predictive skill and can be more readily ported, without reparameterization, from one ocean basin to another (Friedrichs *et al.*, 2007). It appears that the latter is a consequence of increased flexibility in more complicated model structures which allows them to "adapt" to different forcing conditions, for example, by automatically altering the balance between N recycling and N export. However, these improvements in skill and portability appear to be highly model specific, i.e., some complex model formulations perform better than simple ones while others do not. The reasons for these differences in model performance are not yet fully understood.

5. Future Challenges and Conclusions

In this paper we have provided a brief overview of the history and state-of-the-art of marine N-cycle modeling. Our emphasis has been on prognostic open-ocean models and coupled physical–biological model systems. There has been significant

progress in the development of these models over the past 30 years, i.e., we have progressively and substantially improved the degree to which they represent the relevant biological and chemical constituents and processes that are important for N cycling in marine systems. There have also been significant advances in the correctness and completeness of the functions and formulations that are used in these models.

However, most of the N–cycle models employed today are fundamentally similar to the ones that were developed in the early 1970s, i.e., relatively simple models composed of a fixed number of state variables representing a relatively small fraction of the dissolved and particulate constituents in the marine N cycle compared to those that are present in nature. Simple NPZD models are still widely employed in large scale modeling studies in spite of the fact that these models do not explicitly represent some of the most important agents that drive N-cycling in marine systems such as bacteria, protozoa and the microbial loop, and they aggregate all autotrophs and all grazers into single ''P'' and ''Z'' boxes. The use of these models has persisted because they are simple and computationally efficient, and because they appear to reproduce to first order the variability of the modeled N pools. These models can also be made to represent different aspects of the marine ecosystem by changing the parameters to represent, for example, diatoms in one context and *Prochlorococcus* in another. Although a wide variety of new models and modeling approaches have been developed over the last three decades, there is still no consensus in the ocean modeling community as to which are best, and what model compartments are crucial or not (but see also Friedrichs *et al.*, 2006; 2007, as examples of recent efforts to quantitatively assess the performance of different N–cycle model formulations).

A prime example of this lack of consensus is the question of whether or not it is necessary to include explicit representation of bacteria in N cycle models. The short answer is obviously no, because there are numerous modern N–cycle model formulations that seem to work quite well without them (e.g., Christian *et al.*, 2002a; Gregg *et al.*, 2003; Hood *et al.*, 2003; Moore *et al.*, 2002a; see Table 33.1). Rather, these models have simple parameterizations of the net effects of bacteria on the N cycle, where dissolved and particulate organic matter are remineralized directly to inorganic nutrient pools. The omission of bacteria is often justified on the grounds that bacteria are ubiquitous, and their biomass and activity tends to co–vary with primary production and organic matter concentrations. Hence they can be parameterized as a component of the detritus and/or DON pool. But these assumptions are gross oversimplifications. While bacterial biomass and production are positively correlated at large scales to phytoplankton biomass and production, respectively, there is significant variability in the ratios of these parameters among various ocean systems (Cole *et al.*, 1988; Ducklow, 1999). Thus, assuming a constant relationship between bacterioplankton and phytoplankton and detritus properties in models is not appropriate for all oceanic regimes and may be a poor assumption for global applications. However, we are not aware of any quantitative studies of model performance that definitively show that including explicit bacteria substantially improves representation of the marine N cycle (for additional discussion on this topic see Hood *et al.*, 2006).

Numerous marine N–cycle models have been constructed that include representations of DON production and cycling (e.g., Anderson and Williams, 1998;

Fasham *et al.*, 1990; Kawamiya *et al.*, 1995; Levy *et al.*, 1998). These models include, at most, two state variables representing rapidly cycling DON constituents (i.e., "labile" DON with turnover rates on the order of hours to days), and slower cycling DON constituents (i.e., "semi–labile" DON with turnover rates on the order of weeks to months). The typical sources of DON in these models include direct DON production from phytoplankton exudation and/or lysis, excretion and sloppy feeding from zooplankton, and DON production associated with bacterial degradation of organic detritus. Typical sinks for DON include uptake by phytoplankton and bacteria. Photochemical degradation of DON is also potentially important but has received little consideration from modelers to date. To our knowledge few, if any, models have been constructed that represent DON production, composition and cycling at a significantly higher level of detail.

It is important to note that DON may provide an important vector for transport of organic N in the ocean. It has been hypothesized that some of the more refractory constituents of the DOM pool may get transported over long distances horizontally and/or vertically before they are remineralized, providing the potential for linkages between fixation of inorganic nutrients into organic matter at one place, and release of this nutrient at some other place in the ocean (e.g., Roussenov *et al.*, 2006). Obviously, models that represent the DON pool with only one labile component cannot account for this transport vector. If it is ultimately determined that long-distance transport of DON is a quantitatively important component of the N cycle in the ocean, then N-cycle models will need to include *at least* two state variables representing both rapid and slower cycling DON constituents.

Perhaps the greatest challenge we face in terms of modeling DON is presented by the uncertainty in its composition, i.e., the majority of the compounds that comprise DON are still not characterized (Bronk, 2002). As a result, we are constrained to model bulk properties, i.e., binning a very complex mixture of compounds into a small number of boxes. Another significant challenge in DON modeling is presented by the uncertainty in the relative importance of different DON sources and the relative proportions of labile and refractory compounds produced by these different sources. Finally, the processes by which labile forms of DON are transformed into more refractory constituents, i.e., via microbial consumption and recycling and photodegradation, are also not well understood and so are difficult to incorporate into models in a meaningful way. The reader is referred to Christian and Anderson (2002) for additional details on how DOM cycling is represented in models. Suffice it to say here, that the current state-of-the-art in DON modeling reflects, to a large extent, the current state of our knowledge of DON composition and cycling, which is still rudimentary.

The relatively recent discovery of large numbers of viruses (Bergh *et al.*, 1989), especially bacteriophages, in all marine waters has opened up an entirely new area of modeling exploration in recent years. Maintenance of these high viral abundances may involve high incidences of host (bacteria) mortality, which could have a profound effect on the microbial loop (Section 3.2) and the nitrogen cycle (Proctor *et al.*, 1988; Suttle, 1994).

One of the first models that included an explicit representation of viruses in order to explore their role in nutrient cycling was a steady-state food web model by

Murray and Eldridge (1994), which was designed to show how a range of virus-induced bacterial mortalities affects the amount of production that reaches meso-zooplankton. Thingstad (2000) created a model, based on earlier work by Thingstad and Lignell (1997), that included multiple strains of bacteria with a common predator and host-specific viruses. To date, most prognostic "biogeochemical" models that have accounted for the influences of viruses on nutrient cycling have done so via a generic mortality term to account for loss processes including viral lysis (Christian and Anderson, 2002).

Despite these early developments, models with explicit representations of viruses have not yet been widely applied or tested in natural marine systems. The major question that needs to be addressed is, do we need to account for the impact of viruses in pelagic N–cycle models and if so, at what level of realism? Do viruses need to be explicitly modeled or can their effects be parameterized as a component of the generic death terms that we already have in our models?

As we pointed out at the beginning of this section and elsewhere in the paper, very simple N–cycle models are still being employed in large scale, coupled physical–biological modeling studies (e.g., Hood *et al.*, 2003; McGillicuddy *et al.*, 2003; Oschlies, 2002). However, there has been a general trend towards increasing model complexity. This trend has been motivated by our ever-increasing appreciation of the details and complexity of microbial foodwebs, and it has been permitted by the ever increasing power of computers. This raises an important question: Is our ability to simulate and predict N–cycle variability in marine systems increasing in proportion to the complexity of our models? Models become more flexible as you increase the number of degrees of freedom. So we can expect that this trend will result in models that are able to fit available data sets progressively better. But better fits may not reflect increased predictive skill or even increased levels of understanding. As the order of a polynomial regression model increases, the fit to data improves, but this in no way reflects an increase in understanding. Moreover, if this increase in degrees of freedom allows the model to fit noise in the data, then it will also give rise to a model with lower predictive skill. The same principles apply to mechanistic N–cycle models, i.e., the degree to which a model can fit a particular data set says little about how well the model can predict observations that were not used to constrain it, and complex model formulations do not necessarily give rise to improved understanding because they are more difficult to diagnose. Clearly, our ability to judge the efficacy of the current trend toward increasingly complex models is going to be dictated by the availability of the data to constrain and judge their skill, and the ability of modelers to devise effective means to determine why more complex models behave the way they do.

The focus of this review has been on the history and state-of-the-art of N–cycle models. One can legitimately ask how relevant these models are given recent advances in our understanding of the factors that control primary production and particulate matter export in the ocean. Fifteen to twenty years ago, when the Fasham *et al.* (1990) model was still under development, the potential importance of iron limitation was only beginning to be appreciated. The emphasis at that time was on N limitation, the intricacies of the food web and the potential importance of bacteria and the microbial loop. We now know that iron limits phytoplankton growth over

vast areas. We also know that the availability of other nutrients, like silica and phosphorus, has a strong influence on the export of both nitrogen and carbon. Moreover, there is reason to believe that on longer time scales phosphorus ultimately controls primary production and export in the ocean, with nitrogen availability alternating from limitation to excess in response to shorter time-scale changes in the nitrogen inventory, i.e., the balance of nitrogen fixation and denitrification (Gruber, 2004; Moore and Doney, 2007; Tyrrell, 1999).

Nonetheless, N-cycle models are still relevant and useful tools for several important reasons. Although phosphorus may be an appropriate model currency for longer time-scale studies, in our contemporary oceans, N *is* one of the primary limiting nutrients and so is a natural choice as a currency for a variety of applications. Fe is also a primary limiting nutrient in the ocean, but our current understanding of Fe chemistry and cycling, and regulation of biological Fe requirements, is still too rudimentary to use it as a model currency. Moreover, we don't have nearly enough *in situ* measurements of the different phases and forms of Fe to constrain Fe-based biogeochemical models. One of the major challenges we face is dealing with co-limitation and switching between N and Fe limitations, and also accounting for the effects of low P and Si concentrations when they arise. N-based models provide a logical foundation for carrying out studies along these lines and for developing the multi-element models of the future. As these multi-element models become more complete the distinction of an element as the primary currency will become progressively more obsolete, i.e., when the models get to the point where all of the elements are represented as separate state variables in all of the model compartments, then each element can be regarded as a model currency as much as any other.

Finally, the N cycle is important because understanding it is essential to understanding the C-cycle in the ocean. The N cycle is also of great interest in its own right for both modeling and observational studies because there are still many aspects of it that are not fully understood or adequately captured in models. Given recent advances in molecular/genetic methods that can be used to identify and quantify new genes, enzymes and their biogeochemical expression, we can expect to learn many new things about the marine N cycle in the near future. The challenge for N-cycle modelers will be to figure out how to incorporate these into our models, and use these models to help understand their significance.

NITROGEN IN PAST MARINE ENVIRONMENTS

Eric D. Galbraith, Daniel M. Sigman, Rebecca S. Robinson,
and Thomas. F. Pedersen

Contents

1. INTRODUCTION

Many reservoirs of biologically important elements turn over so rapidly at the Earth surface that modest differences between input and output could either remove them completely or double their concentrations in the geologically short span of thousands to millions of years. Despite this precarious situation, evidence indicates that the Earth has been remarkably stable in its habitability, allowing the chain of multicellular life to persist for more than a half billion years. Such continuity requires a conspiracy of feedbacks within the Earth system that stabilizes the availability of life's key ingredients. Yet we know little about these feedbacks, how they develop, or the constraints that they impose on the environment and life. Beyond these

fundamental scientific questions, an understanding of the regulatory mechanisms is the key to predicting how the system will respond to anthropogenic climate change.

The marine nitrogen budget provides an important test case in the broader effort to understand the stabilizing environmental feedbacks on the Earth surface. Because both the principal source (N_2 fixation) and sink (denitrification) of fixed nitrogen in the oceans are mediated entirely by marine organisms, the marine nitrogen (N) cycle is particularly well-suited to the development of biological homeostasis, providing an important contrast in this regard to nutrients such as phosphorus, silicon, and iron. However, it is difficult to quantify, on the basis of temporally and spatially limited modern observations, the sensitivities of the N budget to environmental parameters. Fortunately, geological and glaciological archives have recorded past events that approximate large-scale experiments in which the oceanic N budget responds to naturally imposed forcings.

Although some studies have explored the nitrogen cycle of the distant past (e.g., Fennel *et al.*, 2005; Jenkyns *et al.*, 2001; Kuypers *et al.*, 2004; Rau *et al.*, 1987; Saltzman, 2005), we focus on the cycles of ice ages and interglacial periods that have dominated the last 2 million years of Earth history. Several aspects of these cycles make them well suited to this application. First, they are relatively well recorded in sediment and ice core records. Second, the glacial and interglacial periods are each at least three times longer than the residence time of oceanic fixed N (≤ 3 kyr, (Codispoti *et al.*, 2001)). Thus, a given glacial/interglacial transition (such as the last deglaciation) approximates a discrete natural experiment, with the ocean N budget beginning near steady state, responding to the climate-driven forcing and then potentially reaching a new steady state condition. It has been suggested that the marine N budget during the last glacial maximum was markedly different from today (Altabet *et al.*, 1995; Falkowski, 1997; Ganeshram *et al.*, 1995), which may have impacted atmospheric concentrations of the greenhouse gases CO_2 (Broecker, 1982; McElroy, 1983) and N_2O (Gruber, 2004; Suthhof *et al.*, 2001). By comparing the modern nitrogen budget to this alternate state from the recent geological past, we gain insight into the potential for future change.

While the budget of fixed N is unique among the nutrients, the internal cycling of nitrogen and phosphorus appear to be tightly coupled through the stoichiometry of algal uptake and subsequent remineralization in the modern ocean (Redfield, 1934). Thus, if we can understand the controls on the oceanic distribution of nitrate, we would gain similar insight into the phosphate distribution. It has been posited that coupled changes in polar ocean overturning and algal nutrient consumption drive the observed variation in atmospheric CO_2 over glacial/interglacial cycles (see Sigman and Boyle (2000) for a review). If the relationship of high latitude nitrogen cycling with climate over past glacial/interglacial cycles can be determined, it would also shed light on the oceanic control of $p\text{CO}_2$.

In this chapter, we review the ongoing efforts to use sediment and ice core records to understand the dynamics of oceanic fixed N, focusing on recent glacial–interglacial cycles. Research has, up to this point, followed the reductionist approach of trying to reconstruct either changes in the ocean N budget (largely through low latitude records) or changes in the internal cycling and distribution of N (largely through high latitude records). However, evidence is building for a coupling of high

and low latitude changes, connecting the processes that control the distribution of N in the ocean with those that control the size of the whole ocean N inventory. We begin by considering how the nitrogen cycle of times past may have differed from that of today, followed by an overview of how nitrogen cycle features are recorded in marine sediments and, finally, summarize the observations and interpretations made from available records.

2. POTENTIAL CHANGES IN THE MARINE NITROGEN CYCLE DURING THE PAST 2 MILLION YEARS

We divide the potential changes frequently considered by paleoceanographers into two broad categories: those that most directly involve changes in the ocean nitrogen inventory, that is, the total mass of fixed (non-gaseous) nitrogen in the oceans, and those that most directly involve changes in the distribution and cycling of fixed nitrogen within the ocean.

2.1. Inventory changes

Fixed nitrogen is continuously added to the ocean surface and removed from its interior by the processes depicted schematically in Fig. 34.1. As discussed elsewhere in this volume, the emerging view of the Holocene marine nitrogen budget is largely independent of terrestrial nitrogen inputs and is dominated by the single
Figure 34.1 Schematic view of the major sources (green arrows) and sinks (white arrows) of fixed N in the marine environment. Important factors for controlling the variation of each source or sink term over time are given in italics, with (+) and (−) indicating direct and indirect proportionality, respectively.

input term of marine N_2 fixation and by the output terms of sedimentary and water column denitrification (where ''denitrification'' refers to the total conversion of fixed N to gaseous products by any pathway, including anammox). Given their dominance with respect to mass flux, the potential for inventory changes is determined by the temporal variability of these three terms. As described below, it has been suggested that the N inventory was larger during the last glacial maximum (LGM), which would have allowed for greater biological sequestration of CO_2 in the deep sea, helping to explain the glacial pCO_2 decrease.

2.1.1. Marine nitrogen fixation

Fixed nitrogen is supplied to the global ocean by specialized microbes, termed diazotrophs, near the ocean surface (see Chapter 4, Carpenter and Capone this volume). It has been proposed that the low supply rate of iron to the present-day ocean hampers the growth rates of diazotrophs, exacerbating nitrogen limitation among marine ecosystems (Falkowski, 1997). If the degree of global Fe-limitation varies over geological time, then the rate of N_2 fixation might be expected to follow. It is believed that greater dust fluxes during glacial times (Petit *et al.*, 1999; Winckler *et al.*, 2008) probably would have led to higher trace metal concentrations in the oceans, though it is not clear by what degree (Parekh *et al.*, 2004). If true, this could have allowed diazotrophs to fix N at greater rates during ice ages, and the resulting increase in N_2 fixation rates could have increased the whole ocean N inventory (Falkowski, 1997). Comparison of ice core records of atmospheric pCO_2 and dust led Broecker and Henderson (1998) to promote this idea.

2.1.2. Sedimentary denitrification

Organic matter is rapidly delivered to continental shelves of the modern ocean, producing sediments that are generally anoxic very close to the sediment-water interface. The physical proximity of oxygen-bearing bottom waters to anoxic sediments with high concentrations of labile organic matter allows diffusion and bioturbation to effectively supply oxygen to nitrifying organisms and nitrate to nitrate-reducing organisms in the sediment, leading to high rates of denitrification in shelf sediments (see Chapter 6, Devol, this volume). During ice ages, sea level dropped by up to 120 m, exposing ~75% of global shelf area (Hay and Southam, 1977). As a result, organic matter from highly productive coastal ecosystems would have been shunted to the deep sea. Because this organic matter must settle through a greater height of water column, more organic matter oxidation would have been accomplished there instead of in sediments. One would expect, therefore, that the lowering of sea level would have significantly reduced the global rate of sedimentary denitrification, as proposed by Christensen *et al.* (1987). To obtain a rough maximal estimate of this effect, we can assume that the area-normalized rates of sedimentary denitrification on slopes and in the deep sea remained constant during glacial maxima, despite the fact that they would be the primary depositional sites for coastally produced sinking organic matter during low sea level. In this extreme case, a reduction in global shelf area to 25% of the modern area would have produced a decrease in sedimentary denitrification of 75 Tg N/year (Middelburg *et al.*, 1996), representing a ~30% decrease in the global rate.

Hypsometry is not the only parameter affecting global sedimentary denitrification rates. A higher flux of organic matter to the sediment strongly increases sedimentary denitrification (see Section 2.2.2). The oxygen content of bottom waters has a secondary and less certain effect. In some cases, higher denitrification rates would be expected under more oxygen-poor conditions (Middelburg *et al.*, 1996), though this may be reversed if nitrification becomes limited by oxygen (Devol and Christensen, 1993).

2.1.3. Water column denitrification

The other large sink of marine nitrogen is by denitrification in suboxic regions of the water column. This process only occurs in the most poorly ventilated regions of the modern ocean, where dissolved oxygen has been depleted through aerobic respiration, to below 2–5 μM O_2 ((Codispoti *et al.*, 2005) see Chapter 6, Devol, this volume). In the modern ocean, this is limited to less than 0.2% of the ocean volume, almost entirely within the upper 1000 m of the Eastern Tropical Pacific and the Arabian Sea. These subsurface regions are driven to suboxia by the coincidence of rapid organic matter delivery with a slow re-supply of dissolved oxygen (Olson *et al.*, 1993; Sarma, 2002; Wyrtki, 1962). In theory, the extent of water column denitrification could be significantly altered by changing the export rate of organic matter to the subsurface (Altabet *et al.*,1995; Ganeshram *et al.*, 2000), and/or by changing the oxygen supply through a physical mechanism (Broecker and Peng, 1982; Galbraith *et al.*, 2004; Meissner *et al.*, 2005). The relative balance between surface ocean fertility and the oxidizing capacity of the subsurface can be approximated by the ratio of nutrient to oxygen concentrations of global thermocline waters; all else being equal, when this is high, denitrification is abundant. Because the concentrations of nutrients and oxygen in the thermocline are both strongly influenced by those at high latitude outcrop regions (Galbraith *et al.*, 2004; Meissner *et al.*, 2005; Sarmiento *et al.*, 2004), water column denitrification has an acute sensitivity to the surface conditions at high latitudes (see Section 4.3).

Since nearly all subsurface respiration on the global scale is supported by oxygen, there is no clear *a priori* reason that water column denitrification should have been similarly important at all times in the past; increases in the rate of oxygen supply relative to consumption could have nearly eliminated it. However, the strong sensitivities of water column denitrification, while rendering this process susceptible to climate-driven variability, probably also make it more responsive to stabilizing negative feedbacks (see Section 2.2.3).

2.2. Internal stabilizing feedbacks on the marine nitrogen inventory

The conceivable potential for nitrogen source and sink fluxes to vary independently of each other would appear to characterize the marine nitrogen cycle as highly unstable. However, modern process studies have illuminated stabilizing (negative) feedback mechanisms that would tend to limit excursions in the N cycle (see Fig. 34.2). The strengths of these feedbacks on centennial to millennial timescales should determine the responsiveness of the marine N cycle to climate change, but they remain largely unquantified.
Figure 34.2 Hypothesized feedbacks within the marine N cycle on centennial-millennial time-scales. A direct proportionality, i.e., producing a change of equal sign to that of the forcing, is shown as a black arrow, while an indirect proportionality is shown as a grey arrow. Note that each complete loop contains exactly one indirect proportionality, therefore each represents a negative (stabilizing) feedback on the fixed N inventory. Modified after Deutsch *et al.* (2004).

2.2.1. N$_2$ fixation self-limiting feedback

It is widely held that N$_2$ fixers tend to be at a competitive disadvantage to non-diazotrophs under nitrate-replete conditions: only where nitrate is nearly exhausted but phosphorus remains available are N$_2$ fixers expected to provide substantial new nitrogen. If so, N$_2$ fixation would tend to be self-limiting: greater rates increase new N input to an ecosystem, reducing the degree of N limitation of non-diazotrophic competitors and, hence, the net availability of phosphate to diazotrophs (Broecker, 1982; Redfield *et al.*, 1963; Tyrrell, 1999; Deutsch *et al.*, 2007). This self-limiting feedback, illustrated on the left side of Fig. 34.2, intimately ties N$_2$ fixers to the global aggregate rate of denitrification, which sets the global deficiency of N relative to P and, consequently, the availability of nitrate-limited environments exploitable by N$_2$ fixers. The sensitivity of this feedback depends largely on the degree of disadvantage that diazotrophs suffer in the presence of nitrate, which is poorly quantified.

The residence time of marine P is 3–15 times longer than that of fixed N (Delaney, 1998; Ruttenberg, 2003) and it has been argued that its source and sink fluxes are less sensitive to glacial-interglacial climate change than those of fixed N (Ganeshram *et al.*, 2002). Given this apparent stability of the P inventory, the relatively robust relationship between N and P concentrations in bulk algal stoichiometry (Redfield *et al.*, 1963) is critical when considering potential changes in the global N$_2$ fixation rate. This ratio reflects the nutritional requirements of the surface ocean algal community, thereby determining its ability to utilize a given phosphate supply with available nitrate, and hence, the potential for excess phosphate to be available to N$_2$ fixers. Although there is some degree of localized discrepancy from the canonical "Redfield" N:P value of 16:1, including among individual species and in local environments, the ratio holds remark-ably well throughout the modern ocean (see Gruber (2004) for a review and Chapter 1, Gruber, this volume). Broecker and Henderson (1998) (Section 2.1.1) invoked a global biomass N:P of ∼24:1 during glacial periods to explain lower atmospheric pCO$_2$. This degree of flexibility is not immediately suggested by the low variability of remineralized N:P in the modern ocean, particularly with near-Redfield N:P in the modern Fe-replete subtropical North Atlantic (Hansell *et al.*, 2004). Nonetheless, nitrate to phosphate ratios in the deep Mediterranean Sea can be as high as 25:1 (Krom *et al.*, 2005), indicating that substantial divergences above Redfield N:P are

possible under some conditions. Without a better appreciation of the mechanisms underlying this master variable, the possibility of significant changes in the N:P of past oceans cannot be dismissed, and the strength of the N_2 fixation self-limiting feedback remains in question.

2.2.2. Nitrogen-limitation feedback on denitrification

Denitrification in the ocean interior only occurs under extremely low oxygen concentrations. Oxygen is depleted by the respiration of reduced carbon compounds, most of which are derived from the ecosystems above. If the ability of those ecosystems to export fixed carbon is impaired due to nitrogen limitation of export production, the resulting alleviation of the subsurface oxygen deficiency will cause a reduction in denitrification. This constitutes a general stabilizing feedback on both types of denitrification, illustrated on the right side of Fig. 34.2.

The extent of water column suboxia is sensitive to organic matter flux from the surface, and would quickly respond to changes in export production. This sensitivity is evident in the delicate balance between oxygen supply and oxidant demand in the global subsurface: the respiration history of suboxic waters (oxygen utilization plus denitrification) is almost entirely supported by oxygen, typically having consumed $\sim$250 μM O_2 versus 15 μM NO_3^- (Codispoti *et al.*, 2001). Denitrification in suboxic waters is, therefore, a relatively small residual term in the difference between total respiration and oxygen supply. As a result, small changes in the total respiration, driven by export production, could have large effects on denitrification. Because waters from denitrification zones supply the local upwellings that are, in turn, largely responsible for maintaining the suboxia below, this is a geographically tight coupling and would be expected to provide a strong feedback. The sensitivity of this feedback depends on the degree to which diazotrophs near the upwelling zone are capable of eliminating any N-limitation caused by a nitrate deficit in upwelled waters, thereby mitigating changes in export production. In this regard, a stronger expression of the N_2 fixation self-limiting feedback posed above would weaken the denitrification-driven feedback described here, and vice versa.

Sedimentary denitrification would respond similarly to a productivity change caused by nitrate limitation, as it is largely determined by the organic carbon flux to the seafloor (Middelburg *et al.*, 1996). Hence, if a decrease in denitrification rates promotes higher export production via a relaxation of nitrate limitation, the enhanced organic carbon flux to the seafloor would reinvigorate sedimentary denitrification. Conversely, an increase in denitrification encourages nitrogen limitation and limits large increases in export production. This reflexive feedback would tend to dampen any massive swings in the N inventory.

2.3. Nitrate distribution and the nutrient-rich surface regions

The macronutrient-rich surface waters of the equatorial upwellings and polar oceans are a particularly dynamic component of the global carbon cycle. In the Southern Ocean, for example, the nutrient-rich and CO_2-charged waters of the deep sea are exposed to the atmosphere and returned to the subsurface before the available nutrients are fully utilized by phytoplankton for carbon fixation. This incomplete utilization of upwelled nutrients allows for the leakage of biologically sequestered

CO_2 back into the atmosphere, raising atmospheric pCO_2 (Knox and McElroy, 1984; Sarmiento and Toggweiler, 1984; Siegenthaler and Wenk, 1984). On this basis, increased nutrient utilization in the Southern Ocean has been invoked as the cause of the lower pCO_2 concentrations of glacial times, through a reduced leakage of carbon into the atmosphere (Francois *et al.*, 1997; Martin and Fitzwater, 1988).

The potential changes in the polar ocean over glacial/interglacial cycles are too diverse to be usefully covered in this review (Sigman and Boyle, 2000; Sigman and Haug, 2003). Nevertheless, it is illustrative to consider how the nutrient status of the polar ocean would respond to a given change in ocean circulation, depending on the parameters that most strongly control algal growth in these regions (a topic of ongoing research in the modern ocean).

We consider the hypothesis that the polar oceans were more vertically stable during the last ice age than they are today (Francois *et al.*, 1997; Jaccard *et al.*, 2005; Robinson *et al.*, 2004; Sigman *et al.*, 2004; Toggweiler, 1999), focusing on the Antarctic region. According to this hypothesis, increased density stratification of the upper Antarctic water column would have reduced the rate of exchange between nutrient-rich deep water and the euphotic zone. If algae growing in the Antarctic are most critically light limited, their growth rates would be expected to have remained similar regardless of climate state, so that decreased access to the deep nutrient pool would have led to greater relative nutrient utilization (i.e. a greater ratio of nutrient assimilation to gross nutrient supply).

On the other hand, if suggestions that Fe availability provides the overriding control on algal production in the Antarctic are correct (Martin *et al.*, 1991), the predominant route of Fe supply to the surface would become a critical parameter. If the Fe supply has always been dominated by dissolved Fe upwelled from below, its supply would have decreased in step with the glacial decrease in the gross supply of the macronutrients nitrate and phosphate (assuming a constant Fe: macronutrient ratio in Antarctic subsurface water). In this case, the degree of relative nitrate utilization in the glacial surface would have been more similar to that of today. By contrast, if direct atmospheric Fe supply is important (either during the last ice age or both during the last ice age and today), the relative utilization of nitrate and phosphate in the glacial Antarctic surface would have increased with increasing stratification, as in the case of light-limitation. Sedimentary records of export production, which should be proportional to the net flux of macronutrients to the euphotic zone at steady state, can be used to help untangle competing scenarios such as these. Clearly, reconstructing the nutrient status of the polar oceans in the past and developing an understanding of the controls on algal growth in these regions go hand in hand.

3. Recorders of the Past Nitrogen Cycle

Unfortunately, there are no existing direct records of past nitrate concentration; one must rely instead on proxy evidence. We focus here on the most specific and frequently used proxy for studying the history of the ocean N cycle, the nitrogen isotopic ratio of organic matter preserved in marine sediments.

3.1. Nitrogen isotope systematics

There are two stable isotopes of N, ^{14}N (which constitutes 99.63% of the N in the environment) and the rare isotope ^{15}N (see Sigman and Casciotti (2001) for a review and Chapter 29, Montoya, this volume). Measurements of the $\delta^{15}N$ of nitrate ($\delta^{15}N_{nitrate}$) in the deep sea (below 1000 m) have shown it to be fairly homogeneous, at about 5‰ relative to atmospheric N_2 (Sigman *et al.*, 2000) ($\delta^{15}N = (^{15}N/^{14}N_{sample}/^{15}N/^{14}N_{air} - 1) \star 1000$‰). In certain regions and depth intervals of the ocean, the $\delta^{15}N_{nitrate}$ diverges significantly from the mean deep $\delta^{15}N_{nitrate}$ because of regionally specific processes, as described below. To understand the signals that might be retrieved from sedimentary N isotopes, we first look individually at each of the key fractionating processes (Fig. 34.3).

3.1.1. Inputs

Inputs of nitrogen to the marine environment appear to be isotopically similar to atmospheric N_2. N_2 fixation occurs with little effective isotope discrimination, so that marine N_2 fixers produce reduced nitrogen with a $\delta^{15}N$ only slightly lower than that
Figure 34.3 Nitrogen isotopic fractionation processes. The vectors approximate the isotopic changes associated with the indicated addition or removal of nitrogen from an initial nitrate pool with a $\delta^{15}N$ of 5‰ (black filled circle). Note that the fractionating processes (water column denitrification and nitrate uptake) are actually nonlinear, due to the progressive enrichment of $\delta^{15}N$ in the residual pool, a feature not evident in this discrete view. The return of organic N to the nitrate pool by remineralization is not shown despite a large isotope effect associated with nitrification (Casciotti *et al.*, 2003), since ammonium in typical open-ocean subsurface water is completely oxidized to nitrate. As a result, the nitrate produced should be similar to the organic matter being remineralized. However, remineralization can lead to significant ^{15}N enrichment in the small fraction of organic matter that survives extensive degradation, as in the case of deep sea sediments (see Section 3.3.1). After Sigman and Casciotti (2001).

of air (0 to $-2‰$, e.g., (Carpenter *et al.*, 1997)). In regions of the subtropical ocean, thermocline $\delta^{15}N_{nitrate}$ can be as low as 2‰, $\sim$3‰ lower than the mean deep ocean $\delta^{15}N$. This observation is most readily explained by N_2 fixation in the overlying surface waters and the subsequent remineralization of this low-$\delta^{15}N$ organic material in the waters below (Karl *et al.*, 2002; Knapp *et al.*, 2005; Liu *et al.*, 1996; Pantoja *et al.*, 2002) (Fig. 34.4, North Atlantic).

Fixed N is also transferred from terrestrial to marine ecosystems by riverine and atmospheric vectors, in roughly equal parts (Galloway *et al.*, 2004). This probably contributed no more than one quarter, and perhaps less than one eighth, of the input flux of fixed N to the pre-industrial ocean (Galloway *et al.*, 2004). Although it has been suggested that the $\delta^{15}N$ of terrestrial inputs sums to near 0‰ (Brandes and Devol, 2002), their isotopic compositions are very poorly constrained and may in fact be distinct from the N introduced by oceanic N_2 fixation. There is currently a need for a systematic study of the isotopic composition of N inputs to the ocean from rivers and groundwater that takes into account the multiple chemical forms of N involved as well as the reactions that occur as rivers deposit N into the coastal ocean. Terrestrial
Figure 34.4 Water column profiles of nitrate concentration (open symbols) and $\delta^{15}N_{nitrate}$ (filled symbols) in the Eastern Tropical North Pacific (ETNP, coastal Baja California), Southern Ocean and North Atlantic (Sargasso Sea). The ETNP shows a large increase in $\delta^{15}N_{nitrate}$ in the thermocline owing to local water column denitrification. The Southern Ocean shows little deviation from the global deep mean $\delta^{15}N_{nitrate}$ except at the surface, where partial NO_3^- assimilation leaves residual nitrate enriched in ^{15}N. The North Atlantic profile shows low $\delta^{15}N_{nitrate}$ in the thermocline owing to the nitrification of locally fixed N. Note that the ETNP profile also includes deep measurements from near Hawaii (diamonds); the smooth transition between samples at distant locations emphasizes the homogeneity of the deep Pacific.

inputs of fixed N are also a concern in paleoceanographic work given their potential to be delivered directly to ocean margin sediments, thereby contaminating the paleoceanographic signal in sediment records (see Section 3.3.2).

3.1.2. Outputs

Unlike N_2 fixation, nitrate reduction has a strong isotopic bias, favoring the light N isotope and leaving behind a residual nitrate pool that is progressively enriched in ^{15}N with increasing degree of nitrate consumption. Culture studies collectively yield a relatively broad range in the isotope effect, ϵ (i.e. $(^{14}k/^{15}k - 1)^{\star}1000$‰, where ^{14}k and ^{15}k are the rate coefficients of the reactions for the ^{14}N- and ^{15}N-bearing forms of NO_3^-, respectively) for nitrate consumption by denitrifying bacteria, from roughly 15‰ to 30‰ (Barford et al., 1999; Mariotti et al., 1981; Granger et al., in press). By analogy with work on nitrate assimilation (Granger et al., 2004; Needoba et al., 2004), it would appear that isotopic discrimination primarily takes place upon reduction of nitrate to nitrite by the intracellular enzyme nitrate reductase which, in its assimilatory form, has an intrinsic isotope effect of 15–30‰ (Ledgard et al., 1985; Schmidt and Medina, 1991). The expression of this fractionation is registered by the $\delta^{15}N$ of unconsumed nitrate that diffuses from the cells back into the ambient waters (Granger et al., in press).

Water column studies, in which denitrification rates are calculated from nitrate deficits relative to phosphate, have led to estimates of 22–30‰ for the isotope effect of denitrification (Altabet et al., 1999b; Brandes et al., 1998; Cline and Kaplan, 1975; Liu and Kaplan, 1989; Sigman et al., 2003; Voss et al., 2001). Regardless of the exact value of the expressed isotope effect, water column denitrification clearly results in very high $\delta^{15}N_{nitrate}$ in the thermocline within, and adjacent to, actively denitrifying regions of the water column (see Eastern Tropical North Pacific (ETNP) profile, Fig. 34.4). We note that although there are no existing measurements to explicitly resolve the isotopic impact of anammox, it is implicitly included in all existing water–column (and sedimentary) denitrification studies as part of the overall fixed N loss.

Sedimentary denitrification, in contrast, shows very little expression of the enzymatic isotope effect. Benthic flux experiments have shown that, even with high rates of sedimentary denitrification, minimal increase of $\delta^{15}N_{nitrate}$ is observed (Brandes and Devol, 1997, 2002; Lehmann et al., 2004). The common explanation is that nitrate is nearly completely consumed at the locus of sedimentary denitrification. Because no nitrate escapes the denitrification zones, there is no expression of the isotope effect. This view is supported by the observation of extreme ^{15}N enrichment of nitrate in sediment porewaters (Sigman et al., 2001; Lehmann et al., 2007), which indicates that the lack of isotopic expression of denitrification in sediment cannot be explained by a lack of isotopic fractionation at the scale of the organism. In any case, in the context of budgetary calculations, sedimentary denitrification is typically assumed to have a negligible isotopic effect (Brandes and Devol, 2002; Deutsch et al., 2004; Sigman et al., 2003).

These two extremes of expression of the organism-level isotope effect of denitrification—complete expression in the water column and no expression in sediments—are unlikely to apply perfectly in the ocean. Instead, we might expect

some degree of under-expression of the isotope effect in the water column under some conditions (Deutsch *et al.*, 2004; Sigman *et al.*, 2003), particularly if alternate dissimilatory pathways, such as anammox, fractionate differently and are of variable importance depending on environmental conditions. An extreme case of this is provided by the Cariaco Basin, where water column denitrification appears to consume nitrate completely very near the oxic/anoxic interface, leading to minimal expression of the isotope effect of denitrification (Thunell *et al.*, 2004). In addition, measurements of N_2/Ar in the Arabian Sea (Devol *et al.*, 2006) imply that the loss of nitrogen through denitrification there is greater than previously thought, which would suggest that the isotope effect of water column denitrification has been significantly overestimated. Reciprocally, isotopic discrimination by denitrification is partially expressed in some sediments, albeit to a small degree relative to water column denitrification (Brandes and Devol, 2002; Lehmann *et al.*, 2004, 2007). Nevertheless, the end-member view presented above provides a useful conceptual starting point.

3.1.3. Internal cycling

Fixed nitrogen occurs in many forms in the marine environment, and most transformations among nitrogen pools involve some degree of isotopic fractionation. The most important fractionation for understanding changes in nitrate distribution (as opposed to changes in the input/output budget) occurs during nitrate assimilation, when discrimination by the enzyme nitrate reductase causes the $\delta^{15}N$ of the first organic matter produced from a given pool of supplied nitrate to be lower than $\delta^{15}N_{nitrate}$. The $\delta^{15}N$ of both the residual nitrate and the subsequently produced organic N increases as nitrate consumption progresses. Measurements of $\delta^{15}N_{nitrate}$ in the upper ocean suggest an isotope effect of 4–10‰ for nitrate assimilation, with most estimates closer to 5–8‰ (Altabet, 1988; Altabet and Francois, 2001; Altabet *et al.*, 1999b; DiFiore *et al.*, 2006; Sigman *et al.*, 1999b; Wu *et al.*, 1999). Fractionation in cultures appears to be more variable, with isotope effects as high as 20‰, although many cultures yield effects of ≤ 6‰ (Needoba *et al.*, 2003).

Developing a predictive understanding of the isotope effect of nitrate assimilation has been a goal of marine N isotope studies. The isotope effect varies among species grown under similar growth conditions (Needoba *et al.*, 2003; Wada and Hattori, 1978; Waser *et al.*, 1998) and, for at least some species, as a function of growth conditions (Granger *et al.*, 2004; Needoba and Harrison, 2004). For example, the cultured diatom *Thalassiosira weissflogii* displays a greater organism-level isotope effect under light-limitation than under iron-limitation or maximal growth rate (Needoba and Harrison, 2004; Needoba *et al.*, 2004). The potential variability of the isotope effect represents a critical uncertainty in paleoceanographic application of nitrogen isotopes to changes in nutrient utilization in the nitrate-replete regions of the surface ocean.

When nitrate is completely utilized, the accumulated organic matter has the same $\delta^{15}N$ as the original nitrate source. Hence, in regions where the consumption of nitrate is complete over the course of the year, isotope fractionation during nitrate assimilation has only a transitory (i.e. seasonal) effect that disappears when integrated over the seasons of growth. From the perspective of paleoceanography, the $\delta^{15}N$ of

organic N exported from such an environment must be identical to that of the N supply; if subsurface nitrate is the dominant supply term, then the export should have the same δ^{15}N as the sub-euphotic zone nitrate transferred to the sunlit surface ocean. In contrast, within nutrient-rich regions of the surface ocean, where nitrate consumption is persistently incomplete, the δ^{15}N of sinking N is lower than sub-euphotic δ^{15}N$_{nitrate}$, and the δ^{15}N of the residual surface nitrate is higher than both the sub-euphotic zone nitrate and the sinking N (Fig. 34.4, Southern Ocean) (DiFiore *et al.*, 2006; Lourey *et al.*, 2003; Sigman *et al.*, 1999b).

3.1.4. Deep nitrate

Despite dramatic variations of δ^{15}N$_{nitrate}$ within the nutrient-bearing surface ocean, nitrate assimilation has little effect on the global distribution of N isotopes. Complete nitrate utilization in most of the surface ocean and virtually complete remineralization in the subsurface prevents the accumulation of isotopically distinct non-nitrate pools. Dissolved organic nitrogen, the only other pool of appreciable size, has a very similar isotopic composition to that of nitrate where it has been measured (Knapp *et al.*, 2005) and therefore can have little impact on the global distribution of ^{15}N. Nitrate concentrations in the deep sea are so high that the small amount of low-δ^{15}N organic matter supplied from the nutrient-rich surface has only a minimal effect on the δ^{15}N of deep ocean nitrate (Sigman *et al.*, 2000) (compare Southern Ocean deep water *vs.* Sargasso Sea, Fig. 34.4).

Instead, the modern deep sea is remarkably homogeneous with nitrate δ^{15}N of $5 +/- 0.5‰$, so that it should represent a well-integrated measure of global input and output rates, rather than internal cycling. Mean deep ocean δ^{15}N$_{nitrate}$ therefore has the potential to provide a monitor of whole-ocean inventory change.

3.2. Ocean δ^{15}N$_{nitrate}$ through time

It seems safe to assume that N$_2$ fixation, water column denitrification and sedimentary denitrification have been the dominant input/output terms of the marine N budget throughout, at least, the past 2 Myr. With this assumption in place, one can begin to consider how potential changes would have altered the δ^{15}N of marine nitrate, both within a given region and at the scale of the whole ocean.

3.2.1. Local variations

Because the isotope fractionating processes are not evenly distributed throughout the ocean, temporal variations at fixed points will produce predictable changes in the δ^{15}N of local nitrate pools. As examples: (1) an increase in denitrification rates within the water column on the Oman margin would increase the δ^{15}N$_{nitrate}$ of the Arabian Sea thermocline (Altabet *et al.*, 1995; Schafer and Ittekkot, 1993), (2) an increase in N$_2$-fixation in surface waters of the eastern Mediterranean would cause a decrease in δ^{15}N$_{nitrate}$ in the eastern Mediterranean thermocline (Struck *et al.*, 2001), and (3) an increase in relative nitrate consumption in Antarctic surface waters would cause an increase in local near-surface δ^{15}N$_{nitrate}$ (Francois *et al.*, 1997). However, it must be kept in mind that these local signals are imprinted upon any variation in the δ^{15}N baseline of mean ocean nitrate. A similar principle operates at finer scales, with

changes in a N-cycle process in one region contaminating adjacent regions to various degrees (e.g., Kienast *et al.*, 2002; Martinez *et al.*, 2006; Galbraith *et al.*, 2008).

3.2.2. Steady state mean

At steady state, the flux-weighted mean $\delta^{15}N$ of fixed N outputs (dominated by water column and sedimentary denitrification) must equal that of the inputs (dominated by marine N_2 fixation). The $\delta^{15}N$ of nitrogen supplied by N_2 fixation is tied to the $\delta^{15}N$ of the atmosphere, which does not vary on a million year time scale. The $\delta^{15}N$ of nitrogen removed by water column and sedimentary denitrification, on the other hand, is tied to the mean $\delta^{15}N$ of oceanic nitrate, subject to the effective isotope discriminations. That the mean ocean $\delta^{15}N_{nitrate}$ is higher than the $\delta^{15}N$ of atmospheric N_2 is fundamentally due to isotope discrimination during denitrification.

At steady state, the mean ocean $\delta^{15}N_{nitrate}$ approaches the value at which total denitrification (occurring in both the water column and sediment) removes nitrate with the same $\delta^{15}N$ as N added to the ocean by N_2 fixation, i.e. ~ -1‰. Given this condition, the ratio of rates of sedimentary versus water column denitrification provides the overarching control on the mean $\delta^{15}N$ of nitrate (Brandes and Devol, 2002). Roughly speaking, since water column denitrification discriminates against ^{15}N-nitrate while sedimentary denitrification does not, a higher ratio of water column to sedimentary denitrification will tend to yield a higher mean nitrate $\delta^{15}N$ (Fig. 34.5). For example, if water column denitrification were homogeneously distributed throughout the oceans, an expressed isotope effect of 25‰ for water column denitrification would require that sedimentary denitrification be responsible for roughly 80% of the modern loss of fixed nitrogen from the ocean in order to maintain a mean ocean nitrate $\delta^{15}N$ of 5‰ (Brandes and Devol, 2002). The fact that water column denitrification takes place in <0.2% of the ocean's volume, with relatively high degrees of nitrate loss (typically exceeding 40%), means that water column denitrification causes less ^{15}N enrichment than would arise if water column denitrification were homogeneously distributed. The first effort to account for this "dilution effect" (Deutsch *et al.*, 2004) indicates that the preindustrial balance would require $\sim 30\%$ of denitrification to take place in the water column (i.e., 50% more than if the ocean were approximated as homogeneous). But such quantitative estimates remain preliminary; there is more to be learned about the net isotopic effect of both water column and sedimentary denitrification and their potential to vary over time.

3.2.3. Application to the past

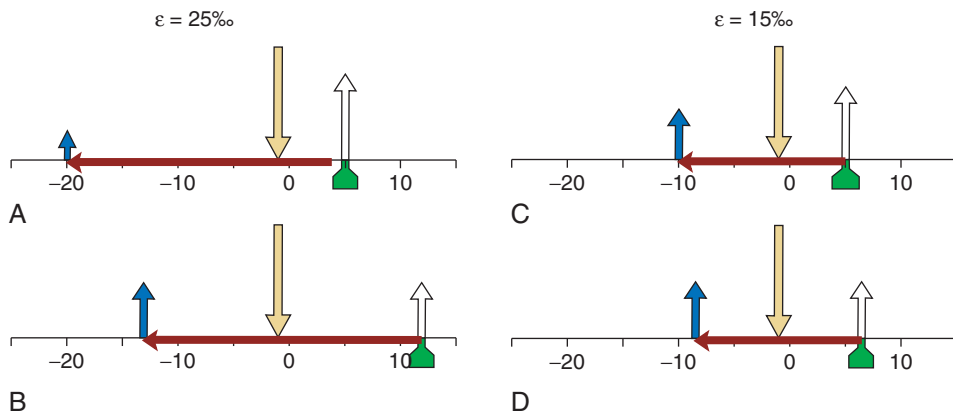
As mentioned above, a given sediment core will simultaneously provide information on at least three separate quantities: changes in mean ocean nitrate $\delta^{15}N$, changes in regional ^{15}N depletion or enrichment relative to the whole ocean, and changes in the completeness of nitrate consumption in the local surface layer. Obviously, the existence of a record of past variations in the mean ocean $\delta^{15}N_{nitrate}$ would allow quantitative assessment of local and regional phenomena in other records; however, the global background signal has yet to be explicitly resolved from among the array of local changes. Sediment cores from the low and mid-latitudes contain the remains of plankton grown on N supplied from the thermocline and not directly from the


Figure 34.5 Mean ocean steady-state N isotope balance. Vertical arrows represent global input and output fluxes, in which the flux is proportional to the length of the arrow and the isotopic composition is shown by the position on the horizontal axis (showing δ^{15}N in ‰). The yellow downward-pointing arrow represents the N_2 fixation flux, the white arrow represents the sedimentary denitrification flux, and the blue arrow represents the water column denitrification flux. Sedimentary denitrification removes N of δ^{15}N close to that of mean ocean nitrate. Water column denitrification removes nitrogen depleted in ^{15}N by the expressed isotope effect, ϵ (red arrow). The green reservoir below the axis represents the δ^{15}N of mean ocean nitrate, which is determined by the ratio of sedimentary to water column denitrification. At steady state, mass and isotopic balance requires that the sum of the denitrification fluxes equal the N_2 fixation flux and that the denitrification fluxes be balanced about the N_2 fixation "fulcrum." Hence, a balanced isotope budget with an expressed isotope effect of 25‰ for water column denitrification requires a much larger flux of sedimentary denitrification in order to maintain a mean ocean δ^{15}N of 5‰, close to the fulcrum (the δ^{15}N of N_2 fixation, -1‰), as shown by (A). Keeping the total N_2 fixation flux equal and increasing the relative proportion of water column denitrification to equal that of sedimentary denitrification pushes the mean ocean reservoir to a higher value (B). If the expressed isotope effect of water column denitrification is less than 25‰, the mean ocean nitrate would be less sensitive to changes in the relative proportion of water column denitrification, but deviations from 5‰ would still be possible (C, D).

deep sea; given the regional heterogeneity of thermocline δ^{15}N$_{nitrate}$ (which exhibits a ≥ 15‰ range in the modern ocean), it is difficult to extract the global mean background variability from a foreground of changes in surface and thermocline nitrate δ^{15}N. Although polar ocean regions sample deep nitrate more directly, the possibility that the degree of nitrate consumption has varied means that records from these regions cannot be interpreted solely in terms of the deep nitrate supply. Before exploring this further, however, we must discuss the development of sedimentary records of the N isotopes.

3.3. Sedimentary nitrogen isotope records

The most common paleoceanographic proxy used to reconstruct past changes in the oceanic N cycle is the δ^{15}N of total combustible, or "bulk," sedimentary nitrogen (hereafter δ^{15}N$_{bulk}$). Such measurements provide a record, with a variable degree of accuracy, of the N sinking out of the surface ocean at times past (Altabet and Francois,

1994). Below, we review the robustness of the connection between the organic N sinking out of the surface ocean and that preserved in paleoceanographic records as bulk sedimentary N. We also briefly discuss the ongoing development of alternatives to the bulk measurement.

3.3.1. The δ^{15}N of sinking nitrogen relative to local nitrate

In low latitude regions where nitrate is nearly completely consumed, sedimentary δ^{15}N records are typically thought to reconstruct the δ^{15}N of the sub-euphotic zone nitrate that is supplied to the euphotic zone by upwelling and/or mixing. But, in some cases, the δ^{15}N of the sinking flux may not match the δ^{15}N of the nitrate supplied to the euphotic zone. For instance, in some regions, diazotrophic biomass may account for a significant fraction of the sinking N, such that the δ^{15}N of N sinking out of the surface ocean may be significantly lower than the subsurface δ^{15}N$_{nitrate}$ (Brandes *et al.*, 1998; Horikawa *et al.*, 2006; Karl *et al.*, 1997; Pantoja *et al.*, 2002). As discussed in Section 3.1.3, in nutrient-rich regions such as the Antarctic and Subarctic Pacific, the gross nitrate supply to the surface is only partially consumed before being mixed or subducted back into the ocean interior or transported laterally out of the system. In this case, the δ^{15}N of sinking organic matter will be lower than the δ^{15}N of the nitrate initially supplied to that region of the surface ocean (Altabet and Francois, 1994, 2001; Sigman *et al.*, 1999b; Wu *et al.*, 1999). It has been suggested that the progressive consumption of nitrate can also be gleaned from sedimentary transects underlying coastal upwelling cells (Holmes *et al.*, 1996), though delicate gradients such as these would be prone to obliteration by lateral sediment transport on the slope (Mollenhauer *et al.*, 2003) and should be interpreted with caution.

Beyond these upper ocean processes, poorly understood phenomena alter the δ^{15}N of sinking nitrogen during transit through the water column and burial. In a variety of oceanographic settings, sinking particulate δ^{15}N has been observed to decrease with depth in the water column (by up to 2‰ over several kilometers of depth) (Altabet and Francois, 1994; Lourey *et al.*, 2003; Nakanishi and Minagawa, 2003). Explanations for this range from the addition of low-δ^{15}N bacterial biomass, to the contamination of shallower traps by zooplankton ''swimmers''. More recently, other deviations from expectations have been observed. The sinking nitrogen δ^{15}N in the Southern Ocean is highest during the wintertime low flux period and then decreases into the higher flux, spring bloom period as [NO$_3^-$] declines (Altabet and Francois, 2001; Lourey *et al.*, 2003). This sense of change is the opposite of what is expected from simple isotopic fractionation during algal assimilation of surface nitrate. It may reflect domination of the wintertime sinking flux by very slowly sinking material that has been enriched in ^{15}N by progressive degradation, analogous to observations of high δ^{15}N in deep suspended particles (Saino and Hattori, 1987).

3.3.2. The δ^{15}N of sedimentary nitrogen

Despite these observations, excellent correlation is found between the δ^{15}N of bulk surface sedimentary N and that of the local sub-euphotic zone nitrate at sites where export production is high and/or organic matter preservation is good (many of which are from continental margins, Fig. 34.6) (Thunell *et al.*, 2004). In these
Figure 34.6 Fidelity of sedimentary $\delta^{15}N$ as a recorder of $\delta^{15}N_{nitrate}$ at coastal margins. This plot shows the $\delta^{15}N_{nitrate}$ of water at the base of the euphotic zone versus the $\delta^{15}N$ of surface sediment at or near the same locations. Despite the complexity of nitrogen cycling within the water column, the sediment records the $\delta^{15}N$ of thermocline nitrate with a high degree of accuracy at all of these diverse locations. Data from (Altabet *et al.*, 1999b; Emmer and Thunell, 2000; Kienast *et al.*, 2002; Liu, 1979; Pride *et al.*, 1999; Thunell *et al.*, 2004), figure modified after Thunell *et al.*, (2004).

settings, alteration during sinking and incorporation in the sediments does not appear to confound bulk sedimentary N as a recorder of the $\delta^{15}N$ of the N sinking out of the surface ocean. It also attests to the generally tight connection between the $\delta^{15}N$ of the nitrate supply to the surface and that of the annually integrated sinking flux under conditions of essentially complete nitrate consumption in surface waters (Altabet *et al.*, 1999b).

Measurements of $\delta^{15}N_{bulk}$ from slowly accumulating sediments at the deep sea floor have uncovered spatial patterns that qualitatively mirror expectations for the spatial variation in the $\delta^{15}N$ of sinking N (Altabet and Francois, 1994; Farrell *et al.*, 1995; Holmes *et al.*, 1996). However, in contrast to the ocean margin settings, a significant ^{15}N enrichment (on the order of 1–5‰) is observed in bulk sedimentary N at core tops relative to sinking particles (Altabet and Francois, 1994; Gaye-Haake *et al.*, 2005). This $\delta^{15}N$ increase is apparently due to preferential remineralization of ^{14}N during the oxidation of organic matter in sediments, and the isotopic effect of this process appears to be greatest in organic-poor deep-sea sediment, where accumulation rates are low (Prokopenko *et al.*, 2006). As one might expect, there is some evidence for a continuous range in the $\delta^{15}N$ difference between sinking and sedimentary N, from no difference in the high-preservation margin environments described above to ~5‰ in the most organic-poor, slowly accumulating sediments of the open ocean (Nakanishi and Minagawa, 2003; Pichevin *et al.*, 2007). As a result,

there is concern that pronounced changes over time in sedimentation rate, or in the conditions at the sediment-water interface, could produce a time-varying degree of diagenetic enrichment of sediment δ^{15}N (Sachs and Repeta, 1999).

Sedimentological processes introduce additional uncertainties that deserve mention. Two sedimentary δ^{15}N records from adjacent sites on the northern margin of the South China Sea show quite different features over the past 40 kyr despite being separated by less than 15 km (Higginson *et al.*, 2003; Kienast, 2005). This is apparently due to sediment transport that redistributes the fine fraction of sediment, including the organic matter in which the N resides, over large distances (Freudenthal *et al.*, 2001; Kienast, 2005). Other complicating factors can include the presence of terrestrial organic matter, which may have a distinct N isotopic composition (McKay *et al.*, 2004; Peters *et al.*, 1978), and inorganic N, which can be a significant component in the lattices of some clays, particularly illite (Schubert and Calvert, 2001).

Because of concerns about seafloor processes affecting the δ^{15}N of bulk sedimentary N, the isotopic composition of targeted sedimentary N fractions is being pursued. Most work of this type has focused on the N bound within the silica frustules of diatoms, which should record past surface ocean processes while being protected from the isotopic effects of bacterial degradation during sinking and incorporation in the sedimentary record (Crosta and Shemesh, 2002; Robinson *et al.*, 2004; Shemesh *et al.*, 1993; Sigman *et al.*, 1999a). The δ^{15}N of organic matter in foraminiferal tests has been explored following the same rationale (Altabet and Curry, 1989). Chlorophyll degradation products have also been isolated from sediments for N isotopic analysis (Ohkouchi *et al.*, 2006; Sachs and Repeta, 1999).

The ongoing research into such specific N fractions is critical to address the fundamental issue of isotopic alteration of exported organic N in the water column and sediments. This work also raises a host of new questions. Consider the case of diatom frustule-bound N (Fig. 34.7). The organic N of diatoms exported from the surface layer could differ from the integrated sinking N, for instance, if the isotope effect of nitrate assimilation by diatoms differs from that of the entire phytoplankton population. Moreover, the δ^{15}N of N trapped and preserved within the diatom frustule (here δ^{15}N$_{\text{frustule}}$) appears to be quite different from the bulk biomass of the diatom that produced it. Thus, δ^{15}N$_{\text{frustule}}$ need not be a direct reflection of integrated sinking flux δ^{15}N, and the relationship between the two could change over time (Galbraith, 2006). Nevertheless, the concerns regarding the interpretation of bulk δ^{15}N demand that approaches be developed for the analysis of specific N fractions, at least for open ocean records. The combination of bulk δ^{15}N with specific N fractions from the same sediment samples may yield important complements in the effort to reconstruct changes in the N cycle.

4. Observations and Interpretations

Although questions remain regarding the fidelity of sedimentary N isotopes as recorders of oceanic N dynamics, significant progress has been made by comparing multiple records from different sedimentary regimes and by using additional
Figure 34.7 The $\delta^{15}N$ of integrated N export (represented by the downward pointing arrow, "$\delta^{15}N_{export}$") versus $\delta^{15}N_{bulk}$ and $\delta^{15}N_{frustule}$, two sedimentary measurements intended to reconstruct the $\delta^{15}N$ of N export. During sinking and burial in slowly accumulating deep-sea sediments, organic N may undergo ^{15}N enrichment or depletion owing to diagenesis. The amplitude of diagenetic alteration is environmentally variable, being virtually absent in organic-rich ocean margin environments but as high as 5‰ in the less productive open ocean. The $\delta^{15}N$ of N bound within diatom frustules ($\delta^{15}N_{frustule}$) does not appear to be affected by diagenesis. However, measurements to date indicate that it is different than "$\delta^{15}N_{export}$". This difference may be due to (1) a $\delta^{15}N$ difference between diatom biomass sinking out of the euphotic zone and the bulk sinking N ("$\Delta(d\text{-}e)$"), and/or (2) a $\delta^{15}N$ difference between the organic N incorporated in diatom frustules and the bulk biomass N of the diatom ("$\Delta(f\text{-}d)$"). The amplitude of either of these $\delta^{15}N$ differences may be sensitive to changes in surface ocean conditions (e.g., because of changes in phytoplankton assemblage or in the growth conditions of diatoms). Thus, given current information, neither $\delta^{15}N_{bulk}$ nor $\delta^{15}N_{frustule}$ can be assumed equal to $\delta^{15}N_{export}$.

proxies to better constrain other environmental parameters. Indeed, many of the records generated to date show coherent variations on different spatial and temporal scales, indicating that they are undoubtedly recording meaningful signals with strong links to global climate. Here we review some of the observations to date and their current interpretations, in relation to the conceptual mechanisms outlined in Section 2.

4.1. Glacial–interglacial inventory changes

The most robust finding to arise from sedimentary N isotope records is of climatically-linked changes in $\delta^{15}N_{nitrate}$ (Fig. 34.8) near each of the major thermocline oxygen minimum zones of the global ocean: the Arabian Sea and the eastern tropical North and South Pacific (Altabet et al., 1995; Ganeshram et al., 1995, 2000; Pride et al., 1999). Although it remains possible that these signals represent changes in the degree to which ^{15}N-enriched nitrate from denitrification zones invaded the
Figure 34.8 Plots of $\delta^{15}N_{bulk}$ versus sediment age over the past 50,000 years for cores from the Mexican margin (Ganeshram et al., 1995), the Somali margin of the Arabian Sea (Ivanochko et al., 2005) and the South China Sea (Kienast, 2000). The Last Glacial Maximum (LGM) and Younger Dryas (YD) cold intervals are indicated by the blue shading. The $\delta^{15}N$ offsets among the records over the Holocene (the last ~10 kyr) are consistent with the effect of modern water column denitrification, which causes high thermocline $\delta^{15}N_{nitrate}$ along the Mexican margin and in the Arabian Sea. During the last glacial maximum, this range collapsed to roughly half that of the present day (~2‰). This appears to be due to a reduction of water column denitrification, reducing the preferential loss of ^{14}N from the oceans. The remarkable stability of the South China Sea $\delta^{15}N$ record in the face of this glacial reduction in water column denitrification supports compensatory global-scale reductions in both sedimentary denitrification and N_2 fixation.

neighboring water masses (Kienast et al., 2002), we follow here the common assumption that the records are dominated by past changes in the extent and/or activity of the thermocline denitrification zones. In addition, both the west African margin and the subarctic Pacific, which have intense thermocline O_2 minima but lack denitrification today, yield similar sediment $\delta^{15}N$ records, suggestive of water column denitrification during past periods (Galbraith et al., 2004; Lavik, 2002; Pichevin et al., 2005). We suggest three factors supporting the assumption that these records document variable denitrification in the thermocline. First, the modern thermocline denitrification zones are all associated with highly productive margin environments. As described in Section 3.3.2, the sediments from these environments have been shown to accurately record the $\delta^{15}N$ of subeuphotic zone nitrate (Altabet et al., 1999b; Thunell et al., 2004), making many of them good monitors of nearby denitrification in the thermocline. Second, the isotope

effect of water column denitrification is large, so that the isotopic signal of denitrification readily overcomes the noise of other processes (see ETNP, Fig. 34.4). Third, a number of other sediment properties (e.g., presence of laminations, redox-sensitive metal contents) corroborate regional variations in water column oxygenation that parallel the inferred denitrification changes.

All of the denitrification records show a general pattern of low $\delta^{15}N$ during glacial periods and high $\delta^{15}N$ during warm interglacial periods (Fig. 34.9). These changes are accompanied by parallel evidence of water column suboxia from trace metal concentrations (Hendy and Pedersen, 2005; Ivanochko and Pedersen, 2004; Kienast et al., 2002; McKay et al., 2005; Nameroff et al., 2004), benthic foraminiferal assemblages (Ohkushi et al., 2003) and sediment laminations (Ganeshram et al., 2000; Suthhof et al., 2001; Thunell and Kepple, 2004; van Geen et al., 2003), confirming that thermocline suboxia was expanded during periods with high $\delta^{15}N$. The inverse correlation between denitrification in the ETNP and global ice volume has been shown to have reigned throughout, at least, the past 1.8 My (Liu et al., 2005). The deglacial increase in thermocline denitrification does not appear to have been contemporaneous everywhere; in particular, records from Peru (Higginson and Altabet, 2004), Chile (De Pol-Holz et al., 2006; Robinson et al., 2007; Martinez et al., 2006) and within the core of the ETNP shadow zone (Hendy and Pedersen, 2006) show $\delta^{15}N$ rises prior to 16 kybp, while most well-dated records from near the ETNP and Arabian Sea increase rapidly after 15 kybp. Nonetheless, on a glacial–interglacial timeframe, there appear to be grossly coherent changes in integrated denitrification rates in the global thermocline, with local variability modulated by regional-scale fluctuations of circulation and productivity.

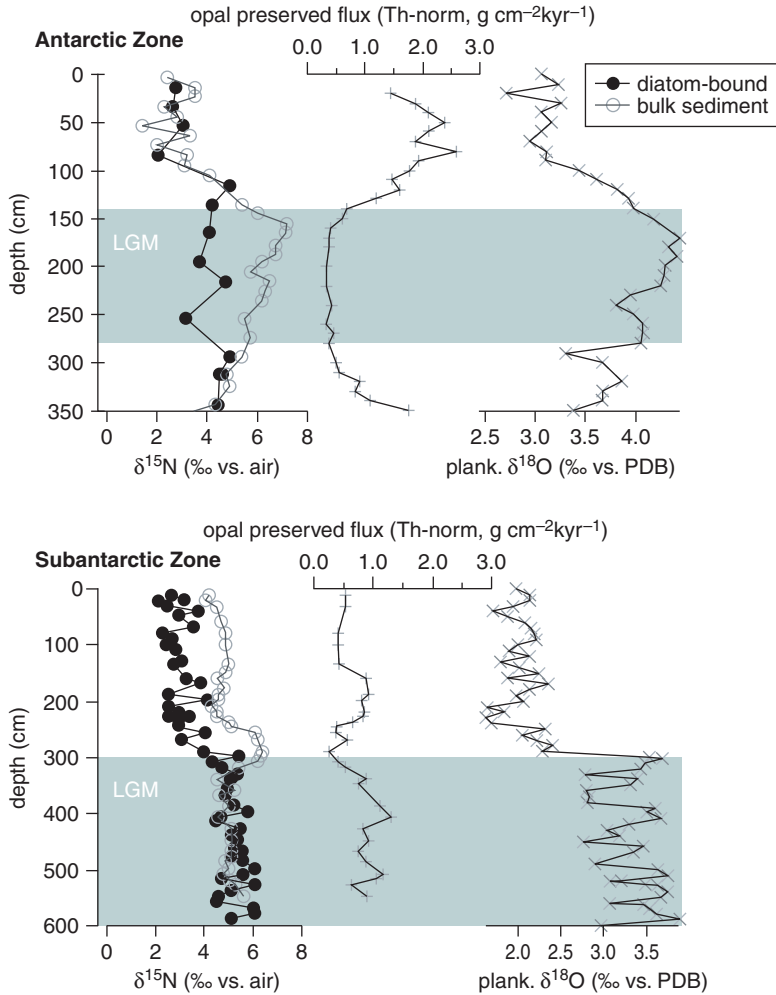
The globally recognized, millennial-timescale climate oscillations that punctuate the broader glacial cycles (Dansgaard et al., 1993) also exhibit significant changes in denitrification. For example, during the Younger Dryas, a brief return to ice-age-like conditions that interrupted the last deglaciation between 12.9 and 11.5 kybp, there was less denitrification in the ETNP (Hendy et al., 2004; Ivanochko and Pedersen, 2004) and Arabian Sea (Altabet et al., 2002; Higginson et al., 2004; Ivanochko et al., 2005; Suthhof et al., 2001). Increased oxygen concentrations at intermediate depth are corroborated by decreased sediment lamination, lower trace metal concentrations, and decreased age of intermediate waters (Ahagon et al., 2003; Behl and Kennett, 1996; Ivanochko and Pedersen, 2004; Keigwin et al., 1992; Pride et al., 1999; van Geen et al., 2003). Earlier, between 25 and 60 ky ago, the Daansgaard–Oeschger climate oscillations seem to have involved similar changes in denitrification intensity within both the Arabian Sea (Altabet et al., 2002; Ivanochko et al., 2005; Suthhof et al., 2001) and the North Pacific (Emmer and Thunell, 2000; Hendy et al., 2004). Although determining precise chronologies for sediments in this time range is difficult, the oscillations appear to be in phase with climate records from the North Atlantic, with warm conditions in the North Atlantic co-occurring with enhanced denitrification. In contrast, denitrification records in the Southern Hemisphere appear to be roughly antiphased to those of the north, so that denitrification is instead in phase with Antarctic warm events (Martinez et al., 2006; De Pol-Holz et al., 2006; Robinson et al., 2007).


Figure 34.9 Paleoceanographic records from the Antarctic (MD84–552) and Subantarctic (MD84–527) zones of the Southern Ocean. Foraminiferal $\delta^{18}O$ is shown as a proxy for global ice volume, to indicate the Last Glacial Maximum, which is shaded gray. The ^{230}Th-corrected opal flux is shown in the centre of each panel as a proxy for diatom export production, and both $\delta^{15}N_{bulk}$ and $\delta^{15}N_{frustule}$ are shown on the left (open and filled circles, respectively). During the LGM, diatom export was lower in the Antarctic Zone, and virtually unchanged in this (Indian) sector of the Subantarctic Zone. The $\delta^{15}N_{bulk}$ records appear to be affected by diagenetic alteration in this well-oxidized, low–accumulation-rate environment. However, the $\delta^{15}N_{frustule}$ shows that the $\delta^{15}N$ of diatoms was higher in both zones during the LGM. The simplest way to reconcile these data is to invoke, during the LGM, decreased upward macronutrient supply throughout the surface of the Antarctic. After Robinson *et al.*, 2004, 2005.

The dependence of water column suboxia on sinking organic matter makes variable export productivity a clear contender for control of denitrification (Altabet et al., 1995; Ganeshram et al., 1995), and there is evidence for increased export production during warm periods in oxygen-sensitive regions (Altabet et al., 1999a; Crusius et al., 2004; Ganeshram et al., 2000; Hendy et al., 2004; Ortiz et al., 2004). Such changes have been most commonly ascribed to changes in local wind-driven upwelling, although changes in thermocline preformed nutrient concentrations (Robinson et al., 2005) and the global nutrient distribution (Boyle, 1988; Schmittner, 2005, 2007) may also play an important role, which we return to in section 4.3 below. An enhanced supply of oxygen to poorly ventilated subsurface regions, through a combination of lower water temperatures (higher O_2 solubility) and accelerated circulation of thermocline water masses, would also have contributed to reducing glacial denitrification rates (Fig. 34.9, (Galbraith et al., 2004; Kennett and Ingram, 1995; Meissner et al., 2005)). A global coupled ocean–ecosystem model has shown that both reduced oxygen consumption and increased intermediate-depth oxygen supply can arise from a shutdown of NADW, as might be induced by a massive iceberg discharge to the North Atlantic region (Schmittner et al., 2007). This has the potential to explain the Dansgaard–Oeschger and Younger Dryas observations from the Northern Hemisphere, and hints that the antiphased Southern Hemisphere denitrification records might reflect correspondingly pronounced changes in the southern oceanic circulation.

Despite the large reorganization of Earth's climate system and apparent changes in thermocline denitrification, the data in hand do not suggest a clear change in mean ocean $\delta^{15}N_{nitrate}$ between the LGM and present day (Altabet and Curry, 1989; Kienast, 2000). This constraint is based on the observation of little glacial–interglacial change ($<0.5‰$) in many cores, including in the North Atlantic (Huon et al., 2002), Southern Indian Ocean (Francois et al., 1997), Sulu Sea (Horikawa et al., 2006) and South China Sea (Kienast, 2000; Tamburini et al., 2003). This is in stark contrast to marine oxygen isotopes, for example, which are overwhelmed by a global glacial–interglacial signal (Lisiecki and Raymo, 2005). The South China Sea records appear to be compromised to some degree by sedimentary processes (Kienast, 2005), which may mask a glacial–interglacial change to some degree. More importantly, all low-latitude records are highly sensitive to the opposing, dramatic isotopic signals of denitrification and N_2 fixation that permeate the thermocline (Galbraith et al., 2004); lack of variability at any given site could be due to fortuitous location at an isotopic balance point between regions of denitrification and N_2 fixation. Furthermore, as noted in Section 3.3.2, some of these deep-sea records are likely affected by diagenesis, which casts doubt on their fidelity as recorders of the glacial–interglacial change. Nonetheless, lack of an obvious global change between the LGM and Holocene is an important constraint, given that the short residence time of marine N ($\sim$3 kyr, (Codispoti et al., 2001)) requires that steady state was approached during the LGM and has been approached again since the deglaciation. Under the reigning N isotope paradigm, the global $\delta^{15}N_{nitrate}$ during the LGM could only have been similar to that of today if the ratio of water column to sedimentary denitrification during the LGM was also similar to the present day (see Section 3.2.2, Fig. 34.5). Given the strong evidence for lower water column denitrification rates during the

glacial, this implies that the global rate of sedimentary denitrification was significantly decreased as well, in agreement with the expected effect of lower glacial sea level (see Section 2.1.2). As a result, the total glacial denitrification rate must have been substantially lower than today.

Given the constraint that the LGM N budget was near steady state, we can infer that the global rate of N_2 fixation was lower, by an amount roughly equal to the aggregate decrease in denitrification. This corresponding decrease in N_2 fixation does not preclude changes in the N inventory, however; a small sustained surplus in the N budget, possibly abetted by an increased P inventory or trace-metal fertilization of diazotrophs (see Section 2.1.1), could have allowed for a greater N inventory during the glacial period, subject to the strength of the N_2 fixation self-limiting feedback (see Section 2.2.1). All things considered, it would seem likely that the glacial N inventory was somewhat higher, though a quantitative estimate is not currently possible. A tentative upper bound, provided by a numerical analysis of observed deglacial $\delta^{15}N$ patterns, constrains the glacial inventory to no more than 30% larger than the present day inventory, despite the possibility of much larger shifts in fluxes (Deutsch *et al.*, 2004). More precise quantification of the inventory change will require a more global distribution of $\delta^{15}N$ records, better understanding of the denitrification isotope effects, and numerical modeling.

It is possible that local manifestations of the deglacial acceleration of N_2 fixation left traces in sediments, and records from the Cariaco Basin provide a tantalizing candidate for this (Haug *et al.*, 1998). However, N_2 fixation within the Cariaco Basin may respond to local, as well as global changes in denitrification (Haug *et al.*, 1998; Meckler *et al.*, 2007), and no published open ocean records show a sustained Holocene decrease in $\delta^{15}N$ below LGM values. The lack of clear N_2 fixation records may result from a close physical proximity of N_2 fixers to denitrification zones (Brandes *et al.*, 1998; Sigman *et al.*, 2005; Westberry *et al.*, 2005; Deutsch *et al.*, 2007), such that the smaller isotopic signal of N_2 fixation is overwhelmed by the amplitude of the denitrification signal. Otherwise, it may be the lack of good deep-sea records from oligotrophic gyres that is hindering our view of N_2 fixation. The resolution of this issue is bound up in the current debate over where the bulk of modern N_2 fixation occurs (Capone *et al.*, 2005). We note that although clear records of nitrogen fixation from the open ocean are elusive, dramatic reductions of $\delta^{15}N$ within the organic-rich sapropels that punctuate Quaternary sediments of the Mediterranean (Calvert *et al.*, 1992) have been shown to reflect large increases in nitrogen fixation (Struck *et al.*, 2001). Similar $\delta^{15}N$ reductions within ancient organic-rich sediments have been interpreted as reflecting analogous periods of intense N_2 fixation during the Cretaceous (Kuypers *et al.*, 2004; Rau *et al.*, 1987).

Intriguingly, despite the lack of a global LGM-Holocene change, a deglacial maximum in $\delta^{15}N$ is observed in the majority of sediment records, followed by a $\delta^{15}N$ decrease during the Holocene (Bertrand *et al.*, 2000). Given the arguments for large variations in water column denitrification, the most straightforward explanation for the maximum invokes a peak in water-column denitrification rates, followed by a decrease during the Holocene. This sequence could conceivably have been driven by either an environmental change or progressive strengthening of the negative feedback

on water column denitrification through local nitrate limitation (Section 2.2.3; Deutsch *et al.*, 2004; Galbraith *et al.*, 2004). The deglacial δ^{15}N maximum is such a pervasive signal in sediment records, however, that it may reflect a transient maximum in the mean ocean δ^{15}N$_{nitrate}$ itself, caused by a maximum in the global ratio of water column to sedimentary denitrification (Deutsch *et al.*, 2004). Indeed, this could have arisen simply due to a temporal offset between early and rapid increases in water column denitrification (17–14 kybp) vs. the more gradual rise of sea level and flooding of the continental shelves (18–10 kyr). Nevertheless, the largest δ^{15}N maxima occur in sediments close to the denitrification zones, suggesting that the absolute rate of thermocline denitrification also peaked during the deglaciation and has decreased to some degree since then.

The pronounced changes in thermocline oxygenation that have accompanied glacial–interglacial climate changes also imply large changes in the marine flux of N$_2$O to the atmosphere. The production of N$_2$O in the ocean is greatly increased under low oxygen concentrations, and oxygen–poor waters broadly associated with denitrification dominate the marine source (Suntharalingam *et al.*, 2000). Given that the modern marine N$_2$O flux is approximately one third of the global source (Hirsch *et al.*, 2006), any large change in water column denitrification related to a regional change in subsurface oxygenation should have a significant impact on atmospheric N$_2$O concentrations. Rapid changes of atmospheric N$_2$O concentrations recorded in ice cores, including a sharp rise 14.6 ky ago as well as millennial-scale fluctuations during the last ice age (Fluckiger *et al.*, 1999, 2004) may have been largely caused by the same changes of thermocline oxygenation that resulted in variable denitrification rates (Suthhof *et al.*, 2001).

In summary, the globally aggregated denitrification rate was generally lower during glacial periods, oscillated on millennial timescales in concert with climate, and accelerated rapidly during deglaciations. The emergent conclusion is that the marine nitrogen budget is highly dynamic, responding to changes in the physical environment, yet its input and output terms are coupled, leading to a nearly balanced budget on timescales of centuries to millennia. Whether this coupling allows for significant changes in the ocean N reservoir is a matter of debate. As described earlier, the apparent lack of a glacial–interglacial global δ^{15}N change, and the characteristics of certain deglacial signals in the N isotope records, suggest to us that the ice age ocean N reservoir was no more than 30% greater than that of the Holocene (Deutsch *et al.*, 2004).

4.2. Glacial–interglacial changes in nutrient-rich regions

Nutrient-rich regions of the surface ocean have undergone significant changes in export production over glacial–interglacial cycles. In the Antarctic Zone of the Southern Ocean, numerous studies have converged to show that export production was lower during the ice ages than during interglacials (Anderson *et al.*, 1998; Francois *et al.*, 1997; Kohfeld *et al.*, 2005). In contrast, studies of the Subantarctic Zone generally indicate higher export production during ice ages, the inverse of the Antarctic climate cycle in productivity (Chase *et al.*, 2003; Frank *et al.*, 2000; Kumar

et al., 1995; Mortlock *et al.*, 1991). In the Equatorial Pacific, reconstructions of glacial–interglacial export productivity are conflicting, and the picture remains equivocal (Farrell *et al.*, 1995; Loubere, 1999; Loubere *et al.*, 2004; Marcantonio *et al.*, 2001; Paytan and Kastner, 1996; Pedersen, 1983), while in the subarctic Pacific, export productivity seems to have been generally lower during glacial periods (Brunelle *et al.*, 2007; Jaccard *et al.*, 2005; Kienast *et al.*, 2004; Narita *et al.*, 2002), similar to observations from the Antarctic. The observation of variable export productivity in these nutrient–rich regions prompted sedimentary N isotope studies to explore the underlying physical mechanisms, assuming that $\delta^{15}N$ variability there would be dominated by changes in the degree of relative nitrate consumption.

In the glacial Antarctic, evidence for reduced export production is accompanied by higher sedimentary $\delta^{15}N_{bulk}$ (Fig. 34.9) (Francois *et al.*, 1997), implying a greater degree of relative nitrate consumption despite the diminished export production. Although $\delta^{15}N_{frustule}$ records suggest that the glacial/interglacial change in environmental conditions was less homogeneous across the Antarctic zone than indicated by $\delta^{15}N_{bulk}$ (Robinson *et al.*, 2004; Robinson and Sigman, 2008), they remain consistent with equal or greater relative nitrate utilization during the glacial. This requires that the gross rate of nitrate supply to the Antarctic euphotic zone was reduced during glacial times. Physically, this change could be explained by reduced exchange of water between surface and deep waters, as would result from an increase of density gradients or a change in the wind–driven circulation (see Section 2.3). Similarly, increased $\delta^{15}N_{bulk}$ and $\delta^{15}N_{frustule}$ in the subarctic Pacific co–occur with decreased export production during glacial periods, mirroring the Antarctic trend (Brunelle *et al.*, 2007; Galbraith *et al.*, 2008), consistent with theories of glacial water column stratification in the polar oceans (Haug *et al.*, 1999; Jaccard *et al.*, 2005; Sigman *et al.*, 2004). Enhanced aeolian Fe supply during the glacial may have contributed to nitrate drawdown by supplementing the Fe from deep waters (Archer and Johnson, 2000; Lefevre and Watson, 1999; Parekh *et al.*, 2004), but this cannot be resolved from the current data.

Although $\delta^{15}N_{bulk}$ measurements from the Subantarctic show few systematic glacial/interglacial patterns of change (Francois *et al.*, 1997), $\delta^{15}N_{frustule}$ records from the Subantarctic reveal a coherent pattern of elevated $\delta^{15}N$ during glacial times (Fig. 34.9) (Crosta *et al.*, 2005; Robinson *et al.*, 2005). The combination of increased opal fluxes with elevated $\delta^{15}N$ is consistent with higher nutrient consumption as expected under enhanced Fe supply. Given the greater proximity of the Subantarctic Zone to potential dust sources in Patagonia, South Africa, and Australia, and the zonality of the winds, the $\delta^{15}N$ may indicate a greater susceptibility to iron fertilization during ice ages than the higher latitudes of the Southern Ocean (Robinson *et al.*, 2005).

In the equatorial Pacific, $\delta^{15}N_{bulk}$ is low during glacial episodes and elevated during interglacials (Farrell *et al.*, 1995). While this may indicate lower nitrate consumption during the ice age, there are two important caveats to consider. First, the correlation of low $\delta^{15}N_{bulk}$ with periods of rapid sediment accumulation is reminiscent of the Subantarctic records, in which $\delta^{15}N_{frustule}$ data have suggested a diagenetic origin for the $\delta^{15}N_{bulk}$ changes (Robinson *et al.*, 2005). Second, the equatorial Pacific exchanges water with the ETNP shadow zone (Higginson *et al.*,

2003; Yoshikawa *et al.*, 2005), so the apparent glacial decrease in denitrification within the ETNP may have lowered the regional $\delta^{15}N_{nitrate}$ enough to impact the $\delta^{15}N$ of glacial-age sediment in the equatorial Pacific. Thus, the nutrient status of the ice-age equatorial Pacific remains enigmatic.

4.3. Connections

Although we have presented inventory changes and nutrient utilization as separate processes, they are undoubtedly linked. Perhaps most interesting is the potential role of high latitude circulation and nutrient utilization on the nutrient content of the thermocline, a key parameter for setting the productivity of low latitude surface waters (Sarmiento and Orr, 1991; Sarmiento *et al.*, 2004; Schmittner, 2005).

The nutrient cycling scenarios presented above show the potential for Southern Ocean surface waters to become relatively nutrient-poor under alternate climate states. If such nutrient depletion did indeed occur in the glacial ocean, the net result would likely have shifted nutrients from the surface and thermocline to the deep sea (Boyle, 1988; Keir, 1988). Glacial decreases in the formation rate of North Atlantic Deep Water (NADW), intimately linked to North Atlantic surface conditions, would also have decreased the rate at which nutrients were returned from the deep ocean to the surface (Schmittner, 2005). Both of these mechanisms fit with extensive evidence from foraminiferal $\delta^{13}C$ and Cd/Ca for thermocline nutrient depletion during the last ice age, in the Atlantic (Marchitto *et al.*, 1998), the North Indian Ocean (Boyle, 1988, 1992; Kallel *et al.*, 1988), and the Pacific (Herguera *et al.*, 1991; Keigwin, 1998; Matsumoto *et al.*, 2002). The loss of nutrients from the sunlit surface ocean would have driven a decrease in low latitude export production, for which there is considerable evidence (Ganeshram and Pedersen, 1998; Loubere *et al.*, 2004; Marcantonio *et al.*, 2001; Ortiz *et al.*, 2004; Ivanochko *et al.*, 2005). This, in turn, would have reduced oxygen consumption in the thermocline at the same time as the subsurface oxygen supply was increased by physical means (Fig. 34.10). Furthermore, global variations in the nutrient richness of the thermocline would have caused sedimentary denitrification to vary in parallel with water–column denitrification, maintaining a stable global mean $\delta^{15}N_{nitrate}$ as implied by the observations. Although this general mechanism remains speculative, it offers an intriguing paradigm that is consistent with the evidence gathered to date.

Reflexively, it seems likely that changes in the subsurface nitrate $\delta^{15}N$, driven by low latitude processes, will become more apparent in high latitude records. For instance, recent work has shown that sedimentary $\delta^{15}N$ records in the subarctic Pacific represent the sum of broad, regional changes caused by denitrification in the tropical Pacific, and local nutrient utilization within the subarctic itself (Galbraith *et al.*, 2008). The Antarctic, in contrast, is more intimately connected to the deep ocean and thus may be most sensitive to $\delta^{15}N$ changes of deep nitrate. N isotopes aside, past changes in the oceanic N reservoir could have affected relative nitrate consumption in nutrient-rich regions of the ocean, as the gross nitrate supply to the surface would have changed. Given that the low and high latitude ocean regions can affect one another in these and other ways, future research will likely reveal complex relationships between the input/output budget for oceanic fixed N and its internal cycling.
Figure 34.10 Modulation of marine N budget by high latitude climate change. The colored layer indicates the ventilated thermocline, in which darker blue represents greater phosphate concentrations. Downward-pointing green arrows represent export production, which consumes subsurface oxygen, while the upward pointing blue arrows represent the upwelling of nutrients. In the upper panel, low relative nutrient utilization in high latitude source water regions produces a nutrient-rich thermocline, fuelling abundant low-latitude export production. Meanwhile, warm conditions tend to produce low initial O_2 concentrations and the waters may circulate more slowly. The high nutrient:O_2 waters maintain abundant suboxia, with widespread denitrification and, consequently, low N:P in thermocline water (i.e. waters with excess phosphate), which is subsequently upwelled to the surface. Algal growth in this upwelled water eventually yields nitrate-free, phosphate-bearing water, which drives N_2-fixation. In contrast, the lower panel shows high relative nutrient utilization in the source regions, producing a nutrient-poor thermocline that limits export production at low-latitudes. In addition, cool conditions are likely to produce high initial O_2 and more rapid thermocline circulation. As a result, thermocline suboxia and denitrification are reduced. With low nutrient:O_2 conditions inhibiting denitrification, the N:P ratio in upwelling water will be high, encouraging complete P utilization by non-N_2 fixing algae, discouraging N_2 fixation.

5. Perspectives on Progress

5.1. Looking backward

It may seem as though the current view of the past marine N cycle is highly uncertain, but this should be viewed in the context of the last several decades. The first proposition that climate change can influence the marine N cycle was made by McElroy (1983), who pointed out that the short residence time of fixed marine N (then believed to be ∼10 ky) made it a good candidate for change over glacial–interglacial cycles. The marine nitrogen budget estimates of the day appeared to

show a large deficit, so McElroy suggested that the present–day situation was part of a grand ∼100 ky cycle: during ice age inception, advancing glaciers would have bull-dozed terrestrial N into the ocean, while the erosion of continental shelves exposed by sea level drop would have flushed N-rich sediments into the deep sea, to create a glacial ocean rich with nitrogen in which phosphate was the limiting nutrient everywhere. When shelf sediments were worn down and the ice sheets reached their maximum extents, the supply of terrestrial N would have returned to something like its low, modern rate. Denitrification would have eaten away at the accumulated surplus of N, bringing us eventually to our modern-day position of a nitrogen-limited ocean with a large N deficit. This hypothesis, which was novel and fully defensible at the time, was predicated on the view of the marine N cycle as unresponsive, in that the marine fluxes of fixation and denitrification were assumed to be ineffective at compensating for changes in the external supply of N.

Over the past twenty years, modern process studies have taught us that the input and output fluxes of the marine N cycle are dominated by marine microbes, not by terrestrial inputs or sediment burial. Meanwhile, sedimentary N isotope studies have shown that extensive changes in the $\delta^{15}N$ of thermocline nitrate have occurred, with coherent connections to climate dynamics. These observations indicate that the marine nitrogen cycle responds dramatically to changes in the physical environment on timescales shorter than envisioned by McElroy, with large changes in thermocline denitrification occurring within centuries. Moreveover, the realization that the resi-dence time of marine nitrogen is only a few thousand years, coupled with the stability of global mean nitrate $\delta^{15}N$ suggested by sediment records, requires that steady state is roughly achieved on a thousand year time scale and not over tens of thousands of years. These observations are consistent with a reactive, internally stabilized nitrogen cycle, unlike the unresponsive, terrestrially controlled cycle described by McElroy.

Although quantitative interpretation of the paleoceanographic data has just begun, the insights gained thus far suggest a tightly coupled system that reacts dramatically to external forcings but is resistant to extreme inventory variations. This, in turn, requires the existence of effective stabilizing feedbacks within the marine N cycle. Thus, the remaining questions do not concern whether or not these feedbacks exist, but rather how strong they are, how tightly they constrain the system, and by precisely what mechanisms they operate.

5.2. Looking forward

Valuable information will continue to arise from measurements of the isotopic composition of bulk sediments, especially in margin environments. Expanding the network of high-resolution $\delta^{15}N_{bulk}$ records is crucial to map out patterns of changing $\delta^{15}N_{nitrate}$ in space and in time, without which mechanistic hypotheses cannot be tested. However, it is critical that we work to address the ambiguities that afflict $\delta^{15}N_{bulk}$ in open ocean records, with the ideal goal of quantifying diagenetic isotope effects so that they can be removed from the bulk records. One promising approach is the isolation and analysis of organic matter that is of known origin and protected from diagenesis, such as microfossil-bound N. The development of compound-specific techniques, such as for chlorophyll and amino acids, also holds

promise for the future, as does the coupling of compound-specific techniques with the use of microfossil-bound organic matter (Ingalls *et al.*, 2003).

The interpretation of isotopic data will become more quantitative and mechanistic. The use of numerical models with realistic circulation, coupled with the inclusion of other paleoceanographic proxies, will lead to much better-defined pictures of, for example, how water column denitrification zones have interacted with physical circulation and respiration. The inclusion of nitrogen isotope dynamics in ocean general circulation models will allow estimates of past rates of denitrification, N_2 fixation and high latitude nitrate utilization to be drawn from the expanding array of $\delta^{15}N$ records. Also, although we have limited our discussion here to the past 2 My, the number of studies exploring the nitrogen isotopic dynamics of ancient oceans is increasing rapidly, and is sure to reveal exciting insights. Together, these advances will illuminate the connections of N cycle processes to other aspects of the climate system and to each other.

This work will necessarily go hand in hand with studies to link N isotopic patterns in the modern ocean to underlying N transformations. Some important processes such as sedimentary denitrification can only be studied indirectly with available or foreseeable paleoceanographic tools. These processes should be considered critical targets for improved understanding through study of modern environments. Finally, paleoceanographic techniques that, to date, have focused mostly on open-ocean processes, can be brought to bear on the critical environment of the coastal zone. This prospect offers a wealth of unexploited avenues of research with implications for preindustrial human impacts on the environment, fisheries, and coastal zone management.

Contents

1. Evolutionary History of the Nitrogen, Carbon, and Oxygen Cycles

1.1. Nitrogen in the preoxygenated world/oceans

All organisms on Earth are composed primarily of the six light elements: H, C, N, O, S, and P. Hydrogen was created 13.7 Ga (billion years ago) in the ''Big Bang'' while the other five elements were created via fusion reactions in stars. Their relative

abundance scales, to a first order, with the inverse of their atomic mass. Hence, among these five elements in our solar system, H is the most abundant and P is the rarest (Williams and Frausto Da Silva, 1996). When our solar system was formed, *ca.* 4.6 Ga, a complement of elements was imported from supernovae and distributed among the planets and planetary bodies (e.g., moons and asteroids) and our sun. During planetary accretion, formation of dense phases caused siderophile elements (e.g. Fe metal) to move towards the core, while lighter elements tended to migrate toward the mantle or the atmosphere.

In early models of planetary accretion, the process was thought to be relatively slow, such that elements such as N and C had high probabilities of combining with H to form highly reduced molecules such as NH_3 and CH_4 (Urey, 1952). However, based on more detailed observations of how planets are formed, as well as on theoretical calculations about the rate of outgassing of H_2 to space, a much larger fraction of C and N probably existed in higher oxidized states such as CO_2 and N_2 (Holland, 1984), but almost certainly not NO_x. Chemically, N_2 is highly inert. The biologically accessible form of the element requires that it be used in dissimilatory metabolism (such as bacterial conversion from nitrate to nitrite) or react either at a lower reducing level, with H, to form NH_3, or at a higher oxidized level, NO_x, from which it can be biologically reduced to NH_3. Assuming the described initial conditions, the environment of the Archean oceans exerted a strong selection pressure for processes that could reduce N_2 to NH_3, thereby making N_2 a sink for electrons in an electron market where oxidized species are relatively rare. Under such conditions, biological reduction of N_2 could serve as a pathway for the oxidation of organic carbon under anaerobic conditions, or as a detoxyase for detoxification of cyanides, which could have been common in the ancient oceans (Fani *et al.*, 2000; Postgate, 1998). This redox couple, namely the oxidation of organic carbon and the reduction of N_2, is sensitive to oxygen, and hence the biologically-mediated geochemical cycles of the three elements, C, N, and O, are inextricably interconnected (Box 35.1).

In this chapter we examine the connections between these three elements and focus on biological nitrogen-fixation to illustrate the regulatory control of biological processes on the geochemistry of the oceans and Earth over the past 4 billion years.

1.2. Oxygenation of the early atmosphere: The influence of shelf area and nitrogen fixation rates

Geochemical evidence suggests that there were delays of several hundred million years between the rise of oxygenic photosynthesis, the oxygenation of the atmosphere, and the oxygenation of the deep ocean. Photosynthesis (evidenced by cyanobacterial microfossils and biomarkers) rose as early as 3.5 Ga (billion years before present; (Schopf, 1993)) and had been solidly established by 2.7–2.5 Ga (Brocks *et al.*, 1999; Knoll, 1996; Schopf, 1993; Summons *et al.*, 1999). Data from red beds, detrital mineral deposits, and sulfur isotopes indicate the rise of atmospheric oxygen around 2.4 Ga (Bekker *et al.*, 2004; Chandler, 1980; Des Marais *et al.*, 1992;

Box 35.1 Links Between Oceanic Nitrogen and Oxygen Cycles

The oceanic cycles of nitrogen and oxygen are intimately linked through the processes of nitrification and denitrification. These processes constitute the key source and sink of fixed nitrogen in the ocean and control its global budget. The coupling of the nitrogen and oxygen cycles has implications for the long-term chemical evolution of the ocean and the atmosphere, variations in the oceans' nitrogen budget, and the nitrogen limitation of marine ecosystems over centennial to very long timescales.

During photosynthesis nutrients, including nitrogen, are assimilated into organic matter and molecular oxygen is produced, depicted schematically by

$$106CO_2 + 16NO_3 + H_2PO_4 + 122H_2O \leftrightarrow C_{106}H_{263}O_{110}N_{16}P + 138O_2 \qquad (35.1)$$

Here we assume a source of fixed nitrogen in the form of nitrate. Alternatively, diazotrophs can fix their own nitrogen, reducing N_2 gas to the level of ammonium in order to be assimilated for protein synthesis. Ammonium may be oxidized by nitrifying bacteria to produce nitrite and nitrate and consuming molecular oxygen:

$$NH_4 + 2O_2 \leftrightarrow NO_2 + 2H_2O. \qquad (35.2)$$
The sequence of nitrogen fixation and nitrification is a source of fixed nitrogen and a sink of dissolved oxygen in the ocean. Aerobic respiration of organic material by heterotrophic bacteria also consumes oxygen and releases nitrogen to the dissolved inorganic pool; the reverse of (35.1).

Under very low oxygen conditions, denitrification, resulting from the anaerobic reduction of nitrate by heterotrophic bacteria, consumes fixed nitrogen in the form of nitrate, ultimately regenerating N_2 gas (Froelich *et al.*, 1979).

$$C_{106}H_{263}O_{110}N_{16}P + 84.8HNO_3 \rightarrow 106CO_2 + 42.4N_2 + 16NH_3 + H_3PO_4 + 148.4H_2O$$
$$(35.3)$$
Hence, the sources and sinks of dissolved inorganic nitrogen and dissolved oxygen in the ocean are intimately linked and their global cycles coupled.

Farquhar *et al.*, 2000; Holland and Rye, 1997; Knoll, 1996; Summons *et al.*, 1999). The deep ocean appears to have remained anoxic at least until the disappearance of banded iron formations at 1.8 Ga (Holland, 1984), and possibly as late as 0.8 Ga (Arnold *et al.*, 2004; Canfield, 1998; Canfield and Teske, 1996).

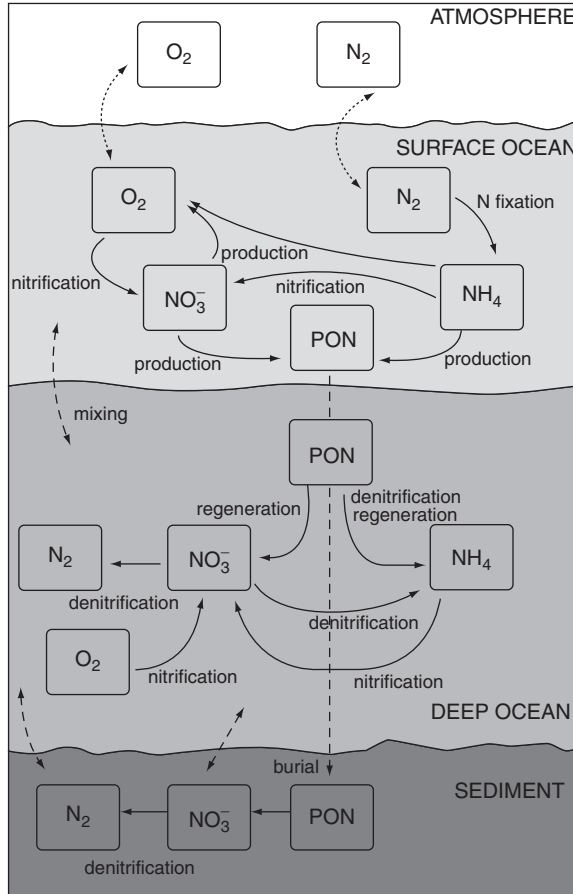
It is likely that oxygen feedbacks on N and C cycles substantially delayed the rise of atmospheric oxygen. This hypothesis is supported by box model calculations, incorporating ocean circulation and ocean–atmosphere gas-exchange with the geochemical cycles of C, N, and O (Fennel *et al.*, 2005; Fig. 35.1). The model has four ocean boxes (high and low latitude surface, deep ocean and shelf seas) coupled to a single atmospheric reservoir and represents the nitrogen and oxygen cycle interactions excluding the sedimentary processes (Fig. 35.1). Application of this model shows that, when initialized with anaerobic conditions, ammonium is originally stable in the reduced


Figure 35.1 Schematic depiction of the coupled, global ocean nitrogen and oxygen cycles. Dissolved inorganic nitrogen and nitrogen fixation fuel oxygenic photosynthesis in the surface ocean, helping to sustain atmospheric and deep ocean oxygen levels. In the deep ocean, oxygen is typically consumed during the microbial respiration of organic matter, producing dissolved inorganic nitrogen. However, in low oxygen waters and sediments, denitrification fuels the oxidation of organic matter, ultimately removing dissolved inorganic nitrogen from the water column. In the early ocean, initial oxygenation of the water column may have inhibited the build up of nitrate which would have been quickly consumed as the oxidant of organic matter.

deep ocean. Yet, as free oxygen becomes available in the ocean, ammonium is converted to nitrate, which can be rapidly reduced to N_2, thus decreasing the pool of fixed inorganic nitrogen. Hence, the interaction between N, C, and O during a transition from an anaerobic to aerobic ocean leads to a strong negative feedback. During this low–nitrogen stage, which can last several 100 million years in our simulations, export production is severely attenuated. Unless some exported carbon is buried, oxygen cannot accumulate in the upper ocean or atmosphere.

The net rate of oxygen production during the low (fixed)-nitrogen stage at the anoxic/oxic transition depends on several factors, including the burial of organic matter and the rate of oxygen consumption during nitrification. In our model studies, the oxygenation of the ocean and atmosphere critically depend on the presence of shallow continental shelf seas (Fennel *et al.*, 2005). The burial of organic matter is much more efficient in shallow continental shelves than in the deep ocean (Hartnett *et al.*, 1998) hence, rates of organic matter burial and net oxygen production should increase as a function of the relative area of continental shelves and shallow seas (Berner, 1984). The relationship between the area of continental shelves, carbon burial, and oxygen production highlights the fundamental role of tectonic processes, especially seafloor spreading, in controlling eustatic sea level and the area of shallow seas (Miller *et al.*, 2005), and in determining the rate of oxygen evolution. The model also demonstrates that an increase in the oceanic phosphate inventory will enhance the net rate of oxygen production owing to higher export. In a fully oxidized ocean, it also potentially leads to an increased inventory of fixed inorganic nitrogen. Furthermore, the rate of net oxygen production is very sensitive to the N_2 fixation rate, which suggests that the initial increase of oxygen had an additional negative feedback on oxygen production by compromising nitrogenase activity both directly and through trace metal limitation (Anbar and Knoll, 2002; Falkowski, 1997) (see below and Fig. 35.2)

An extended period of severe nitrogen limitation and low productivity during the Proterozoic is consistent with the $\delta^{13}C$ record of carbonates, which indicates large variations at the beginning and end of the Proterozoic, but not in the intervening period (Des Marais *et al.*, 1992). Our model studies suggest that during the enhanced tectonic activity at the end of the Proterozoic, changes in the global shelf area or in the oceanic phosphate inventory could have triggered the oxygenation of the deep ocean.

2. NITROGEN-FIXATION, NITROGENASE, AND OXYGEN. EVOLUTIONARY CONSTRAINTS, ADAPTATIONS OF CELLULAR PATHWAYS AND ORGANISMS, FEEDBACKS TO GLOBAL NITROGEN, CARBON, OXYGEN CYCLES

2.1. Evolutionary constraints for nitrogen fixation and adaptive strategies

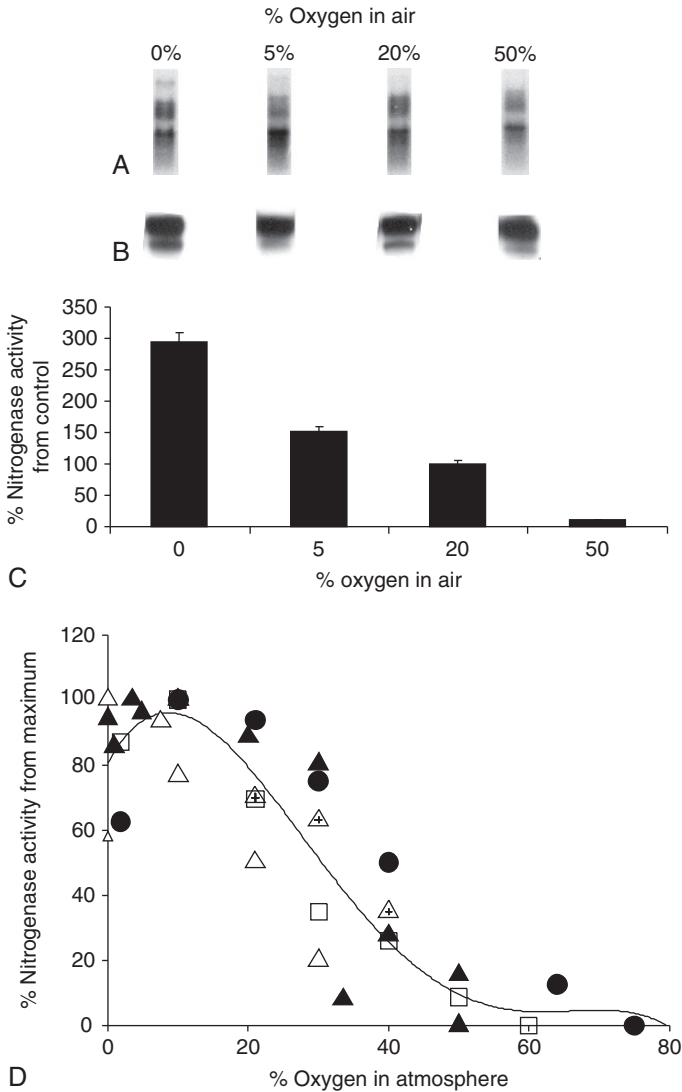
Over a 200 million year period, centered around 2.3 billion years ago (Bekker *et al.*, 2004), the partial pressure of oxygen (pO_2) rose from $<4 \times 10^{-6}$ atm to >0.03 atm (Pavlov and Kasting, 2002; Rye and Holland, 1998). This emerging environment especially challenged diazotrophic cyanobacteria, the only diazotrophs capable of oxygenic photosynthesis, yet having to contend with the innate sensitivity of the nitrogenase enzyme to molecular oxygen. Diazotrophic cyanobacteria provide an elegant case-study of how the interplay between the N, C and O cycles influenced the adaptation of key metabolic processes, and how these cellular processes feed back


Figure 35.2 (A) Northern blots of *nif* HDK transcript abundance for *Trichodesmium* IMS101 cultures bubbled with nitrogen (0% oxygen), 5%, 20%, and 50% O_2 for 5 h. (B) Western blots of nitrogenase protein abundance (challenged with universal Fe–protein polyclonal antibodies) for the above experiment (C) Nitrogenase activity (presented as % of air-control) measured by acetylene reduction for the above experiment 1 h after induction of bubbling. (D) Relationship between O_2 concentrations and nitrogen fixation (% from maximum rates) for *Trichodesmium* IMS101 and other diazotrophs. Filled triangles: experimental data from our cultures of *Trichodesmium* IMS101; empty triangles with cross—*Trichodesmium* NIBB1067 (Ohki and Fujita, 1988), empty triangles—*Trichodesmium* spp. field populations (Mague *et al.*, 1977; Saino and Hattori, 1982), black circles—*Anabaena cylindrical* (Gallon *et al.*, 1993), black squares—*Gloeothece* (Nageli) (Gallon *et al.*, 1993). Short-term (1–2 h) anaerobic incubation yields maximum nitrogenase activity for aerobic diazotrophs (C). On longer time scales, respiratory requirements will yield maximum activity (*in vivo*) at microaerobic oxygen concentrations (D).

into the aquatic and global systems. In this section we focus on the evolutionary constraints on nitrogen-fixation in cyanobacteria. We then discuss how these biological controls feed back into the geochemical cycles.

The evolutionary roots of nitrogen fixation, inferred from molecular phylogenetic analyses of *nifH* genes, suggest that the genes encoding for nitrogenases are ancient and underwent horizontal gene transfer, gene duplication, recruitment and fusion (Raymond *et al.*, 2004). Indeed, phylogenic analyses do not rule out the possibility that nitrogenase was present in the last universal common ancestor (LUCA) and, therefore predates the divergence of the archaea and bacteria (Fani *et al.*, 2000; Raymond *et al.*, 2004; Woese, 1998), or if it evolved in methanogenic archaea and was subsequently transferred to a primitive bacterium (Raymond *et al.*, 2004). In either scenario, the catalytic subunits of the enzyme complex clearly indicate that the original enzyme existed long before the oxygenation of Earth's atmosphere (Broda and Pesheck, 1983) and that trace elements such as Fe, Mo, and V additionally modulated its evolutionary trajectory.

The influence of required trace elements on the evolution of nitrogenase has been discussed by several authors (Anbar and Knoll, 2002; Kustka *et al.*, 2003; Raven, 1988; Raymond *et al.*, 2004). The availability of iron influences N_2 fixation in diazotrophic cyanobacteria, from its direct effect on Fe-rich protein synthesis such as nitrogenase, to effects on photosynthesis, growth, and global productivity (Berman-Frank *et al.*, 2001, 2007; Falkowski, 1997; Kustka *et al.*, 2003; Mills *et al.*, 2004; Paerl *et al.*, 1994; Reuter *et al.*, 1988). In the anaerobic environments of the Archean oceans, Fe would have been found predominantly in its reduced form (FeII) rather than FeIII (Anbar and Knoll, 2002 and Table 1 in Berman-Frank *et al.*, 2003). The necessity for nitrogen selected for nitrogenase, while the availability of reduced iron selected for the metal complement of nitrogenase. Both laboratory studies (Berman-Frank *et al.*, 2001; Berman-Frank *et al.*, 2007, Shi *et al.*, 2007; Kupper *et al.*, 2008) and field simulations (Mills *et al.*, 2004) show a direct link between the availability of nitrogen fixation rates in environmentally important diazotrophs (see Section 3.1). Thus, diazotrophy and subsequent primary production were predicted and found to be limited in the iron deficient regions of the subtropical and tropical oceans, such as the contemporary South Pacific (Moutin *et al.*, 2008; Raimbault and Garcia, 2008).

Molybdenum (Mo) is another essential metal co-factor of nitrogenase. Mo, a rare trace element is much more abundant in the contemporary ocean than under the anaerobic conditions prevailing when nitrogenase first evolved, and is also required in the bacterial reduction of nitrate to nitrite (Williams and Frausto Da Silva, 2002). In the anoxic, asulfidic Archean oceans, up to 90% of the Mo would have been complexed in relatively insoluble sulfide minerals in igneous rocks (Anbar and Knoll, 2002; Falkowski, 2001; Williams and Frausto Da Silva, 1996). Limited availability of Mo may have been exacerbated in the mid-Proterozoic, where weathering, under a moderately oxidizing atmosphere, would have enhanced the delivery of sulfate (SO_4^{2-}) and molybdate to the deep ocean. Combined with primary production in the surface waters, this would have resulted in extremely high H_2S concentrations and removal of Mo via increased precipitation and formation of active thiomolybdate (MoS_4^{2-}) (Anbar and Knoll, 2002; Arnold *et al.*, 2004).

Whereas alternative, older nitrogenases exist, in which Fe or V were replaced by Mo, these forms are catalytically less efficient. Interestingly, Mo-independent nitrogenases have been found only in heterocystous diazotrophs (phylogenetically the most recently diverging group—see discussion below) but not in non-heterocystous species (Bergman et al., 1997).

Past depletions in dissolved inorganic phosphate may have also limited nitrogen-fixation and primary production due to high adsorption of phosphate by iron-rich minerals. Indeed, based on adsorption isotherms in banded iron formations, sea-water phosphate concentrations in the Archean have been suggested to have been more than ten fold lower than the present values (0.15–0.6 µM versus the modern value of 2.3 µM) (Bjerrum and Canfield, 2002). Thus, present restrictions of phosphate on N_2 fixers in some oligotrophic areas such as the western subtropical Atlantic (Mills et al., 2004) and in the tropical Pacific (Moutin et al., 2007) may have correlations in the paleoceanographic records of the late Archean eon.

Nitrogen fixation is metabolically costly, requiring relatively large inputs of energy, reducing power, ancillary antioxidant enzymes and metal co-factors such as iron and Mo (Raven, 1988; Kustka et al., 2003). A priori, the nitrogenase enzyme is notorious for its sensitivity to molecular oxygen and for the irreversible damage to the the the Fe_4S_4 clusters, in-vitro (Burgess and Lowe, 1996). Moreover, high oxygen stress causes proteolysis of nitrogenase subunits (Durner et al., 1996), suppresses nitrogenase synthesis, and leads to a shortage of respiratory substrates and reductants necessary for nitrogen fixation and assimilation (Gallon, 1992). Inhibitory effects of moderate oxygen levels, or short exposure times, in-vivo may be reversed, leading to an increase in nitrogen fixation rates (Gallon, 1992; Ludden and Roberts, 1995; Pan and Vessey, 2001; Prosperi, 1994; Yakunin et al., 2001) and, in some diazotrophs, to post-translational modification of the Fe protein from an inactive to active form (Ernst et al., 1990; Jouanneau et al., 1983; Ohki et al., 1991; Sweet and Burris, 1982; Zehr et al., 1993).

The fundamental constraint of the two conflicting processes has led to several adaptations including spatial (e.g. heterocystous cyanobacteria) and temporal separation of photosynthesis and N_2 fixation (e.g. unicellular species such as Cyanothece), or a combination of both (e.g. in the non-heterocystous colonial forms such as Trichodesmium). The oxygen protection mechanisms have been the focus of several reviews examining molecular, phylogenetic, physiological, morphological, regulatory, and evolutionary adaptations in cyanobacteria (Adams, 2000; Bergman et al., 1997; Berman-Frank et al., 2003; Bohme, 1998; Fay, 1992; Gallon, 1992, 2001; Tuli et al., 1996). The various strategies to overcome the inherent conflict between oxygenic photosynthesis and nitrogen fixation reflect the wide-ranging flexibility and niches occupied by cyanobacteria: from anaerobic sediments to pelagic waters saturated with oxygen. Molecular phylogenies, of N_2 fixers using the nifH gene and small subunit ribosomal RNA sequences, showed no correlation between the phylogenetic relationships and the type of N_2 fixation (Raymond et al., 2004; Turner et al., 2001). This lack of correlation suggests multiple gains and/or losses of N_2 fixation among the different cyanobacteria (Raymond et al., 2004; Turner et al., 2001). The loss of cyanobacterial nif genes implies that different strategies arose early in the evolution of the clade, where some organisms

were able to adapt to an oxic world, while others were not (e.g. *Oscillatoria*). Commonly, many phylogenies show the most recent phylogenetic branching (both for *nifH* and RNA trees) in filamentous species where complete segregation of N_2 fixation and photosynthesis was achieved with the evolution of heterocystous cyanobacteria (Wolk *et al.*, 1994).

Heterocystous cyanobacteria are predominantly terrestrial, fresh water and coastal species, inhabiting eutrophic or brackish environments (e.g. the Baltic Sea), with a few epiphytic and symbiotic representatives in the marine environment (Paerl and Zehr, 2000) (see Chapter 4, Carpenter and Capone, this volume). Very few heterocystous free-living species are found in the pelagic oceans, though a novel species was found, designated *Anabaena gerdii* (Carpenter and Janson, 2001). The heterocyst glycolipid envelope may confer an advantage for cyanobacteria inhabiting temperate brackish and fresh waters. These waters are characterized by an increase in O_2 flux by $\sim$25% from that in sea water, and thus the thick glycolipid layer can help decrease diffusion of oxygen into the heterocysts (Staal *et al.*, 2003a). At higher temperatures, typical of tropical waters, the glycolipid envelope of the heterocyst does not provide additional protection against oxygen, which may explain the paucity of heterocystous free-living bacteria in such environments (Staal *et al.*, 2003a).

In addition to specialized niche selection and avoidance strategies, whereby nitrogen fixation is spatially or temporally separated from photosynthesis, oxygen concentrations influence transcription, translation, and changes in nitrogenase activity of cyanobacteria. We demonstrate this with results from the bloom-forming cyanobacterium *Trichodesmium* IMS101, which contributes significantly to nitrogen fixation in the tropical and sub-tropical oceans. Sequence and structural analyses of its nitrogenase are similar to those of other diazotrophic organisms (Zehr *et al.*, 1997), and there is a post-translational modification between the active and non-active form of the protein under natural and induced conditions (Ben-Porath *et al.*, 1993; Ohki *et al.*, 1991). The abundance of *nifH* transcripts and its corresponding gene product were assayed in *Trichodesmium* cultures incubated for 5 h with 0, 5, 21 (present atmospheric level—PAL), and 50% O_2 (Fig. 35.2A). The results indicate that extracellular O_2 does not significantly influence transcription or translation of *nifH* on this time scale (Fig. 35.2A and B). In contrast, nitrogenase activity was strongly depressed by O_2; at 50% O_2 >90% of the nitrogenase activity was inhibited within 1 h (Fig. 35.2C).

Post-translational modification of activity appears relatively common in diazotrophic cyanobacteria and operates at much lower concentrations of oxygen then those required for repression of *nif* genes (Dominic *et al.*, 1998; Tuli *et al.*, 1996). A compilation of published data on the response of nitrogen fixation to varying ambient O_2 concentrations suggests a general relationship that is consistent with both the short-term response of the enzyme to O_2 and the organisms' longer evolutionary adaptations where O_2 is used as sink for electrons in respiration (Fig. 35.2D). On average, 20–30% of the enzymatic activity is inhibited at present atmospheric oxygen concentrations of 21% (Fig. 35.2D).

In *Trichodesmium* spp., maximum nitrogen fixation occurs at oxygen concentrations of 2.5–5% PAL. Under truly anaerobic conditions, the Embden–Myerhof

(glycolysis) pathway apparently cannot supply sufficient substrates through fermentative reactions to meet the demands of nitrogen fixation. Hence, *in vivo,* the activity of the enzyme declines. As oxygen concentrations increase above 5%, the enzyme activity is inhibited, with only ~70–80% activity measured at atmospheric oxygen concentrations of 21%. At oxygen concentrations greater than 30%, a sharp drop in activity reduces fixation efficiency (potential) to <10% within minutes. This pattern of an inefficient nitrogenase is corroborated in data from other aerobic cyanobacteria such as in the heterocystous *Anabaena* and in the unicellular *Gloeothece* (Fig. 35.2D). In these cyanobacteria, lowering the oxygen below atmospheric concentrations also enhances relative nitrogenase activity at short durations. However, at very low oxygen concentrations, lack of respiratory production of energy and substrates ultimately affects nitrogen fixation. Thus, in *Trichodesmium* for example, low oxygen stress caused faster mortality and biomass crashes after ~48 h (Berman-Frank, unpublished).

2.2. Adaptive strategies. Oxygen consumption—The Mehler reaction

In cyanobacteria, oxygen is potentially consumed through aerobic respiration and two light-dependent reactions, the oxygenase activity of RubisCO (photorespiration) and the photosynthetic reduction of O_2, termed pseudocyclic photophosphorylation or the Mehler reaction (Box 35.2). In contrast to terrestrial C3 plants, which have relatively high rates of photorespiration, photorespiration of oceanic phytoplankton is usually low when dissolved inorganic carbon concentrations in seawater are at equilibrium (~2 mM) with the atmosphere. Moreover, cyanobacteria operate a CO_2 concentrating mechanism (CCM) which raises the CO_2 concentration in the vicinity of RubisCO and inhibits oxygenase activity (Kaplan and Reinhold, 1999).

The Mehler reaction is a photochemical reduction of O_2 to H_2O_2 or H_2O in photosystem I (Box 35.2). Mehler activity is thought to be a mechanism for energy dissipation under high light intensities or when carbon fixation is limited by supply

Box 35.2 The Mehler reaction (pseudocyclic photophosphorylation)

In 1951, the late Alan Mehler (1951) observed that chloroplasts can use oxygen as an electron acceptor. The reaction sequence is

$$H_2O + 2O_2 \rightarrow 2O_2 + 2H^+ + \tfrac{1}{2}O_2,$$

$$2O_2 + 2 H^+ \rightarrow H_2O_2 + O_2$$
and, in the presence of catalase:

$$H_2O_2 \rightarrow H_2O + \tfrac{1}{2}O_2.$$
Net gas exchange is absent since the overall electron transport reaction which involves both Photosystems II and I is:

$$H_2O + 2O_2 \rightarrow H_2O + 2O_2$$
of inorganic carbon (Helman *et al.*, 2003). Since the products of O_2 reduction are often superoxide and hydrogen peroxide (with superoxide dismutase catalyzing the reduction of superoxide to peroxide), Mehler activity has been hypothesized to be a metabolic defect rather than an adaptive strategy (Patterson and Myers, 1973). However, in the cyanobacterium *Synechocystis* sp. (PCC 6803), superoxide is reduced directly to water without a hydrogen peroxide intermediate (Helman *et al.*, 2003). This single step reduction of superoxide to water is catalyzed by A-type flavoproteins; two of which (flv1, flv3) were identified as essential for this activity (Helman *et al.*, 2003). Examination of the genome of *Trichodesmium*, identifies homologous genes to flv1 and flv3 with 62% and 67% sequence identity, respectively (Milligan *et al.*, 2007).

Mehler activity is generally considered a process which can only consume photosynthetically derived O_2, and it cannot cause net consumption of O_2 because PSI activity relies on photosynthetically derived electrons (Kana, 1993). Yet, the shared-arrangement of photosynthetic and respiratory electron transport chains in cyanobacteria allows electrons from respiratory derived NAD(P)H to feed into the plastoquinone pool of the photosynthetic electron transport chain and reduce PSI (Schmetterer, 1994). Through the translocation of reductant (i.e. glucose 6-phosphate) from cells with functional PSII, Mehler activity can result in a net consumption of O_2 in cells (or heterocysts) which have no PSII activity and in which nitrogen is fixed (Fig. 35.3).

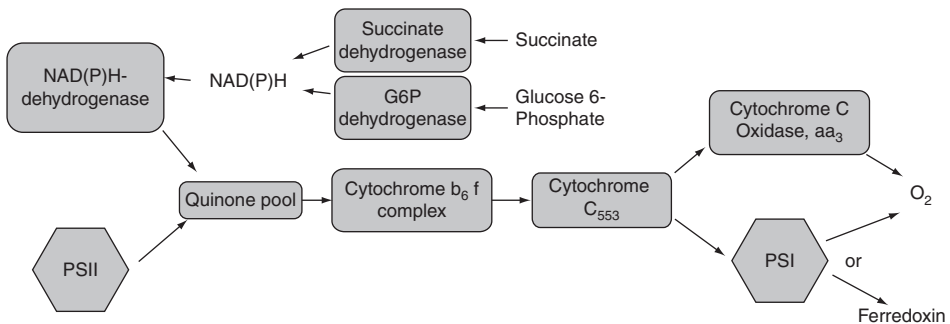
Results from *Trichodesmium* provide an example of the Mehler pathway's role in modulating oxygen and facilitating nitrogen-fixation. In this species, under nitrogen-fixation conditions, approximately 50% of gross O_2 production is consumed through Mehler activity (Fig. 35.4); this is about twice the rate reported for *Synechococcus* ($\sim$25% of gross O_2 production) exposed to photoinhibitory irradiances (Kana, 1992). Mehler activity is dependent both on the time of day and the nitrogen source (Fig. 35.4). The period of maximum N_2 fixation is coincident with a decline in the net production of O_2 and a rise in the consumption of oxygen via Mehler activity, which is consistent with the hypothesized role of this pathway as a mechanism to protect nitrogenase from O_2 damage. In nitrate-grown *Trichodesmium*


Figure 35.3 Photosynthetic and respiratory electron transport chains in cyanobacteria showing the shared electron carriers of each pathway (based on Schmetterer, 1994).
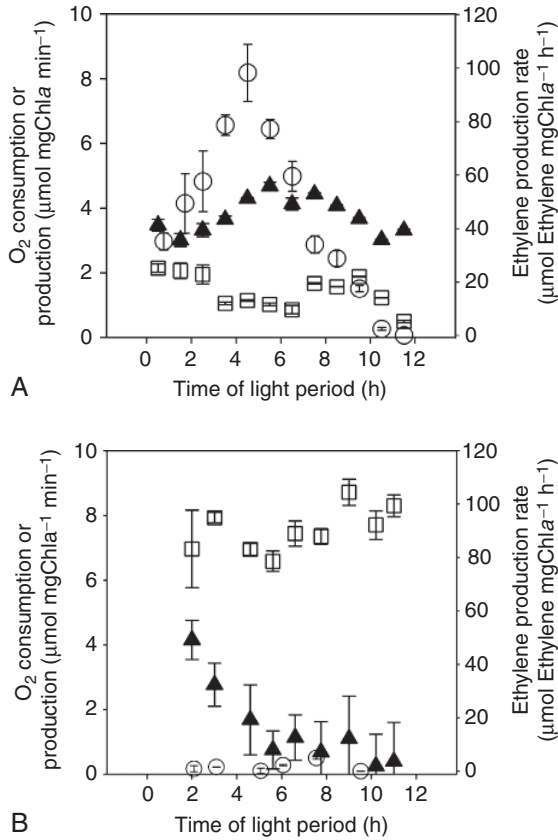

Figure 35.4 Time course of oxygen production (□), consumption (▲) and acetylene reduction (○) during the photoperiod in *Trichodesmium* sp. IMS 101 grown with N_2 (A) and nitrate (B) as nitrogen sources. Error bars are ±1 standard deviation.

cultures (with negligible nitrogen-fixation), Mehler activity increases with light induction, but quickly drops to low and constant rates (10% of gross production) through the rest of the photoperiod (Fig. 35.4).

In *Trichodesmium*, Mehler activity is essential, as *Trichodesmium* relies on short term regulation of PSII and nitrogenase activities to separate these functions within a trichome (Berman-Frank *et al.*, 2003). PSII activity is regulated on time scales of 10–15 min and appears to involve the association/disassociation of the light harvesting complex (LHC II) from PSII (Küpper *et al.*, 2004). Nitrogenase activity is also regulated on similar time scales when incubated at different oxygen concentrations, with transcriptional and translational regulation requiring longer time-scales and higher concentrations of exposure (Fig. 35.2). While PSII activity is repressed in N_2 fixing cells, the activity of PSI is responsible for net O_2 consumption relying on the translocation of reductant for the donor side of PSI and the flux of photons driving the oxidation. Cultures of *Trichodesmium* grown under low (5%) oxygen showed some nitrogenase activity during the night; this

activity was absent in controls (21%) and in high (50%) oxygen cultures (Küpper *et al.*, 2004). The lack of Mehler activity at night in the controls (21%) and in the high oxygen cultures may thus reduce the total possible oxygen consumption and prevent nitrogenase activity. At lower O_2 concentrations, N_2 fixation can proceed in darkness because the respiratory rates are sufficient to consume O_2.

2.3. Biological feedbacks to the global nitrogen, carbon, and oxygen cycles

Oxygen-consuming pathways, including the Mehler reaction, deliver a positive feed-back to nitrogenase and nitrogen fixation by reducing the concentrations of molecular and reactive oxygen that inhibit the enzyme. Yet the presence of oxygen is essential as respiratory pathways provide the required substrates for subsequent nitrogen assimilation. Thus, oxygen concentrations will exert both a positive and negative feedback towards adaptations at the organism-scale, which reflect a compromise of opposing metabolic requirements. At the molecular/biochemical scale, oxygen concentrations impose an upper limit on the nitrogenase enzyme for all types of cyanobacterial diazotrophs. Whether the regulation is at the level of transcription, translation, or metabolic activity, depends on the concentration and duration of inhibition by oxygen. Chronic inhibition of nitrogenase at PAL of O_2 imposes a metabolic inefficiency that reflects an extraordinarily slow tempo of evolution for this critical biogeochemical process. The high conservation within the primary sequence of *nif* genes suggests that the evolutionary risks associated with modifying nitrogenase outweigh the costs of its production. Nitrogenase is analogous to other core metabolic proteins, such as the reaction center protein of photosystem II, D1 and ribulose 1,5 bisphosphate carboxylase/oxygenase (Rubisco), which also operate at a fraction of their capacities under ambient atmospheric conditions or undergo extremely high rates of turnover as a result of post-translational damage. The inhibition of all of these proteins, either directly by elevated O_2, or indirectly through reactive oxygen species, potentially exerts a strong biological control on the upper bound of the concentration of the gas in Earth's atmosphere, leading to metabolic and biogeochemical inefficiency in N_2 fixation. The inefficiency imposes a major elemental taxation on diazotrophic cyanobacteria, both in the costs of protein synthesis and in the scarce trace elements, such as iron, which has, in turn, led to a global limitation of fixed nitrogen in the contemporary oceans (Falkowski, 1997).

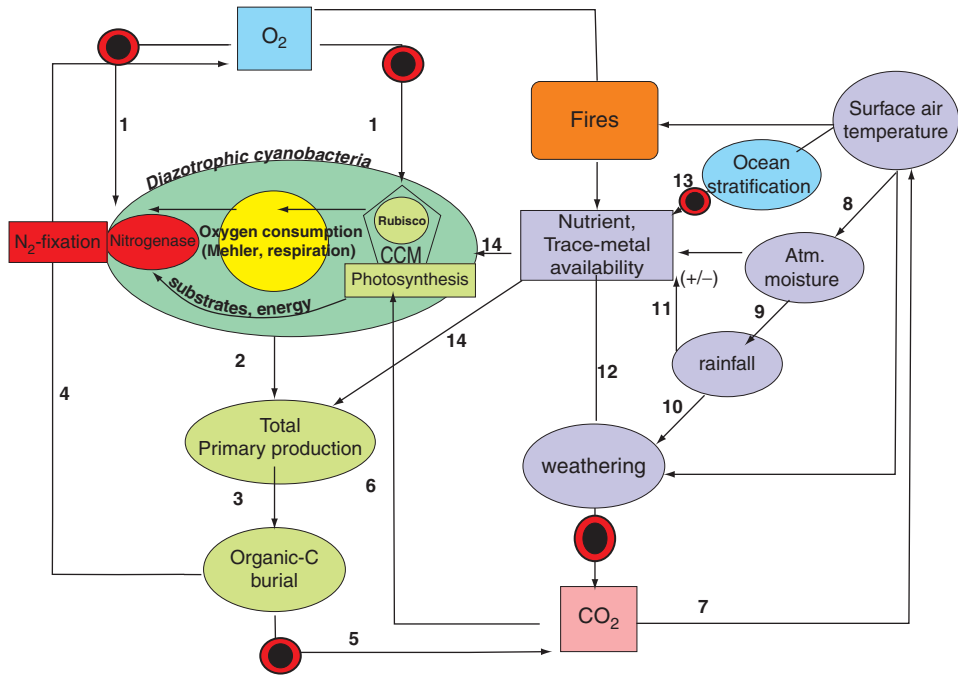
We extended and applied the systems-analysis based approach of Beerling and Berner (Beerling and Berner, 2005) to the feedbacks between (aquatic) nitrogen fixation and the cycles of carbon and oxygen (Fig. 35.5). While the role of sustained forest fires in maintaining PAL of oxygen (Lenton and Watson, 2000; Watson *et al.*, 1978) is currently debated (Wildman *et al.*, 2004) (Fig. 35.5), nitrogen fixation (via the evolutionary sensitivity of nitrogenase) acts as an additional control, limiting the upper concentration of oxygen in the atmosphere. The reduction of nitrogen-fixation due to high oxygen concentrations could lead to a decline in both diazotrophic and total aquatic primary productivity (with parallel declines in the terrestrial biomass due to higher photorespiration under high oxygen), and to reduced rates of organic burial (Fig. 35.5 path 1–2–3). Lower burial rates would lead to a decrease in oxygen and an


Figure 35.5 Simplified systems analysis diagram of the feedbacks between nitrogen fixation (mainly by aquatic cyanobacterial diazotrophs) and the oxygen and carbon cycles. Plain arrows show direct responses while arrows with bull's-eyes illustrate inverse effects. The $+/-$ indicates feedbacks could go in either direction depending on conditions. The feedback loop is designated by numbers adjacent to path. Note that the processes and feedbacks operate at different time-scales (from hours (e.g. N–fixation and photosynthesis) – to millenia (e.g. global O_2, CO_2 concentrations). Diagram modified from Beerling and Berner (2005).

increase in atmospheric CO_2 (Fig. 35.5 paths 1-2-3-4, 1-2-3-5). If oxygen concentrations are maintained at PAL or slightly lower (see Fig. 35.2D), nitrogen fixation may be sufficient to drive high total primary production and higher burial rates, and a negative feedback to both C and O concentrations (Fig. 35.5).

3. SENSITIVITY OF THE NITROGEN, CARBON, AND OXYGEN CYCLES TO CLIMATE CHANGE

Biological feedbacks into the global nitrogen and oxygen cycles are intricately dependant on climate patterns and oceanic circulation which also influence trace metal availability in the upper ocean (Fig. 35.5). In this section we explore future scenarios in the oceanic nitrogen, carbon and oxygen cycles due to shifts in aeolian iron availability, variations in climate, and ocean circulation.

3.1. Aeolian iron and stratification of the surface mixed layer in the future

The major source of Fe in the surface waters of several large ocean regions is the aeolian dust transported from the continents (Duce and Tindale, 1991; Fung *et al.*, 2000; Jickells *et al.*, 2005). Yet the evidence for the relative importance of aeolian sources versus *in situ* iron supply by upwelling waters from depths is unclear (Coale *et al.*, 1996). The distribution of aeolian Fe varies strongly with the seasons and from one ocean region to another. The predominant fraction of the Fe inputs enters the oceans in the Northern Hemisphere, where the high Fe fluxes are primarily concentrated in low and mid-latitudes (Gao *et al.*, 2001). These are characterized by disproportionate seasonal flux rates, with summer Fe fluxes approximately twice those of winter fluxes (Gao *et al.*, 2001). This non-uniform distribution feature is largely reflected by the distribution of dust sources (Ginoux *et al.*, 2001; Zender *et al.*, 2003). The current estimate of the total Fe deposition to the ocean is $\sim 14 \times 10^{12}$ g year^{-1}, which includes substantial uncertainties. The major processes that control the delivery of aeolian Fe to the ocean are dry deposition by gravitational settling of particles, turbulence in the surface layer of the atmosphere, and wet deposition through precipitation scavenging. Any variation in the strength and distribution of dust sources, and removal processes caused by climate change and land use, could affect dust emissions (Tegen *et al.*, 2004) and consequent delivery of aeolian iron to the ocean (Fig. 35.5 path 8-13).

One example is the increasing concentrations of atmospheric CO_2 and enhanced global temperatures which have altered the global hydrological cycle. This is reflected by changes in precipitation patterns that may have profound impacts on dust emissions and subsequent deposition to the oceans. Over the past century there has been a global increase in rainfall over land (Dai *et al.*, 1997). Enhanced precipitation over desert regions, in particular, has been considered as a negative feedback to desertification (Miller *et al.*, 2004). The increased rainfall could directly impact the emissions of dust through altering soil moisture (aridity) in the source regions and dust burden in the atmosphere and, consequently, affect the concentrations of dust over the oceans. Observations made at Barbados in the tropical North Atlantic indicate that variations in dust concentrations from 1965 to 1998 were inversely correlated with rainfall in the Soudano-Sahel region in Africa (Prospero and Lamb, 2003). This finding suggests that atmospheric dust loading over the ocean is sensitive to the strength of precipitation in the dust source regions; therefore, any increases in precipitation and rising concentrations of atmospheric CO_2 may contribute to decreased aridity and a possibly less dusty atmosphere in the future (Mahowald and Luo, 2003) (Fig. 35.5 path 7-8-9-11 inverse effect).

Increased precipitation over the oceans may increase the supply of a more "bioavailable," dissolved aeolian Fe via wet deposition (Fig. 35.5 path 8-9-11 direct effect). During long range transport, dust particles undergo heterogeneous reactions at gas-solid-liquid interfaces involving pollution-derived substances that may lead to the increased solubility of aeolian Fe (Dentener *et al.*, 1996; Meshidzke *et al.*, 2003; Underwood *et al.*, 2001). Photochemical reduction in more acidic cloud waters and precipitation promote dissolution of Fe in dust, leading to the production

of soluble Fe (II) (Siefert et al., 1999; Zhu et al., 1997; Zhuang et al., 1992). These natural processes potentially increase the amount of dissolved Fe in precipitation beyond the Fe solubility of a few percent directly measured from leaching of dry dust particles. Gao et al. (2003) suggest that the annual input of dissolved Fe by wet deposition accounts for 4–30% of the total aeolian Fe fluxes to the ocean. Hand et al, (Hand et al., 2004) reported that soluble iron associated with aerosols over the Atlantic and Pacific ranged from 0–45% in the $PM_{2.5}$ mode (particulate mass less than 2.5 µm diameter) and 0–87% in the coarse mode. These findings reveal that soluble iron could be a significant fraction of the total aeolian Fe entering the surface seawaters. Thus, increasing the supply of soluble aeolian Fe in the oceans through wet deposition may cause natural iron fertilization and induction of blooms by diazotrophic and other Fe-limited photosynthetic populations (Fig. 35.5 path 8-14). As such, variations in precipitation distributions, or changes in hydrological cycles caused by global warming, could alter carbon cycles in the ocean and contribute to the future climate change. The non-linear response of critical environmental factors over the land and oceans has restricted the characterization and predictive power of how precipitation and land–use patterns influence dust generation and subsequent aeolian Fe deposition to the oceans.

Changes in ocean stratification may further affect the degree of aeolian Fe demand by marine biota and the subsequent CO_2 fluxes (Le Quere et al., 2003). Intensified stratification in the upper ocean due to global warming could become more resistant to mixing by surface wind and prevent the flux of nutrients from deep waters to the surface layer (Sarmiento et al., 1998) (Fig. 35.5 path 13-14). This weakened mixing could also reduce the amount of recycled Fe brought from the deep ocean to the surface layer and, consequently, the supply of aeolian Fe to production in the surface ocean could be more critical in the future. This situation may occur both in the high-nutrient low-chlorophyll (HNLC) waters and also in the oligotrophic gyres, where there may be co-limitation of production by iron and phosphorous (Mills et al., 2004). In the eastern subtropical North Atlantic, where the impact of Saharan dust input is strong, utilization of nitrate supplied from dust deposition could be enhanced in the strongly stratified mixed layer during the late summer-fall period, thereby promoting phytoplankton growth (Neuer et al., 2004). Although primary productivity in the Sargasso Sea is often suggested to be phosphorus-limited, as the concentrations of dissolved inorganic phosphate in the surface waters are low (Wu et al., 2000), results from nutrient-addition bioassays in the tropical North Atlantic indicate that nitrogen fixation in this region is co-limited by iron and phosphorus (Mills et al., 2004). This finding suggests that even in a region where dust deposition is high and the amount of aeolian Fe should be sufficient, the rates of nitrogen fixation by high-Fe demanding organisms such as Trichodesmium spp. are still controlled by the supply of iron.

The combined effects of warming air temperatures and of enhanced stratification in the upper ocean may thus promote the dissolution of iron in dust and its subsequent bio-availability in the surface seawaters, possibly enhancing nitrogen fixation and export production. Future aeolian Fe input to the ocean may increase due to desertification enhanced by human activities or decrease by altered hydrological cycles (Fig. 35.5). These interactions and feedbacks could certainly play important roles in future nutrient and carbon cycles in the ocean.

3.2. Interactions of the oxygen and nitrogen cycles: Nitrification and denitrification

Changes in the ocean nitrogen budget linked to climate change have been discussed by several authors (Altabet *et al.*, 1995; Broecker and Henderson, 1998; Falkowski, 1997; Ganeshram *et al.*, 1995; Galbraith *et al.*, Chapter 34 this volume). The coupling of the nitrogen and oxygen cycles via nitrification and denitrification has implications for the long-term chemical evolution of the ocean and atmosphere, the variations in the oceans' nitrogen inventory, and the nitrogen limitation of marine ecosystems over centennial and longer timescales. Yet, the interactions and feedbacks of the coupled nitrogen and oxygen cycles are not clearly understood. Consider a reduction of nitrogen fixation leading to a global decline in the fixed nitrogen budget of the ocean, increasing nitrogen limitation and reducing total export production. In response, deep ocean respiration decreases and the low oxygen zones shrink along with the integrated rate of denitrification. While there is the possibility for a stabilizing feedback (Codispoti, 1989; Deutsch *et al.*, 2007), the processes of nitrogen fixation and denitrification are spatially (and temporally) disconnected; the former occurs predominantly in the surface, subtropical oceans while the latter occurs in the low oxygen zones of the water column and sediments (Fig. 35.1). Thus the rate of accumulation or the loss of nitrogen in the ocean must also be regulated by the processes of physical transport by which these regions are connected. In the modern ocean, the transport timescale between the subtropical Atlantic, a region of significant nitrogen fixation, and the low oxygen waters of the mid-depth Pacific basin, is on the order of hundreds of years leading to the potential for delayed responses in the feedback loop (e.g. Gruber, 2004; see Chapter 1, Gruber, this volume) and even to oscillatory behavior. A highly idealized box model of the coupled nitrogen and oxygen cycles (Fennel *et al.*, 2005) suggests complex interactions (see following section) and illustrates how these interactions were likely critical in the development of global biogeochemical cycles on the early Earth. Factoring in possible links to the carbon pumps, climate and the global iron cycle suggests even richer, and more complex, possibilities for interactions of climate and biogeochemical cycles (e.g. (Falkowski, 1997).

3.3. Ocean circulation and the global ocean cycles of nitrogen, oxygen and carbon

Ocean models forced by warmer atmospheric climates and coupled climate models in global warming scenarios suggest that weakened atmospheric temperature gradients and increased hydrological cycle might weaken the ventilation of the deep ocean (e.g. Zhang *et al.*, 2001) and expand the regions of well-stratified, subtropical surface waters (e.g. (Sarmiento *et al.*, 2004). Consider the oceanic nitrogen cycle as represented simply in Fig. 35.6. Nitrogen is supplied to the surface ocean by ocean circulation, from depth, or by fixation in the surface. Depending upon the nature of the ecosystem and its efficiency at recycling, some fraction, N_{bio}, of the deep ocean nitrogen, N_d, is brought to depth through biological export of organic matter and remineralization. The remaining fraction, or the pre-formed nitrogen N_{pre}, is brought to depth by physical advection or mixing from the surface layer. In regions
Figure 35.6 Simplified schematic views of the oceanic nitrogen and oxygen cycles. N_d and O_{2d} are the deep ocean dissolved inorganic nitrogen and dissolved oxygen concentrations respectively, N_{pre} and O_{2pre}, are the preformed nitrogen and oxygen concentrations, and N_{bio} and O_{2bio} are the contributions to deep ocean concentrations due to the remineralization of exported organic matter. N_s and O_{2s} are the concentrations of dissolved inorganic nitrogen and dissolved oxygen in the surface mixed-layer of the ocean. Exported organic matter (really export of "oxygen demand"—indicated by the minus sign) is respired in the deep ocean, providing a source of dissolved inorganic nitrogen and a sink of dissolved oxygen.

of low oxygen (including pore waters), denitrification and subsequent processes ultimately lead to a return to dinitrogen gas, and to nitrogen loss from the oceans.

The warming of the surface ocean will weaken the overturning circulation leading to shallower mixed-layer. Slower overturning suggests a longer residence time for waters in the surface, perhaps increasing the role of biological export relative to physical transport, favoring N_{bio} over N_{pre}. In addition, a coincident warming of the surface waters and reduction of turbulent mixing in the surface mixed-layer might favor diazotrophs such as *Trichodesmium* (Capone, 2001; Karl *et al.*, Chapter 16 this volume), enhance nitrogen fixation and work to increase the oceanic nitrogen budget, perhaps relieving nitrogen limitation. Consider, however, the coupled oxygen cycle. Shallower mixing and warming of the surface waters will reduce the physical supply of oxygen to the deep ocean and decrease the solubility of oxygen in the ventilated waters (O_{2pre} decreases) (which may further enhance nitrogenase activity and nitrogen-fixing species but will reduce productivity of other phytoplankton). Consequently, deep ocean oxygen concentrations, O_{2d}, will likely decrease under such conditions, increasing the extent of regions of very low oxygen concentration in the water column (Zhang *et al.*, 2001) and pore waters. In consequence, the global flux of denitrification is also likely to increase in response. The net effect of such a climate change on the oceanic nitrogen budget and productivity is not yet clear.

We examined the steady state response of the fully dynamic ocean nitrogen and oxygen cycles in our box model (see section Ib, Fennel *et al.*, 2005) and an atmospheric mixing ratio of oxygen at 20% to prescribed variations in the ocean overturning, efficiency of nitrogen fixation and mean ocean phosphate loading. Starting from modern ocean conditions under which the oceanic N:P ratio is close to 16, varying the rate of overturning between 10 and 30 Sverdrups does little to the ocean nitrogen

inventory, or N:P, though the timescale for adjustment increases as overturning decreases. Changing the efficiency of nitrogen fixation, perhaps interpreted as reflecting changes in upper ocean stratification, has some interesting and counter-intuitive consequences; since the modern ocean has an N:P ratio close to 16, increasing the efficiency of nitrogen fixation does not significantly enhance the nitrogen budget, as the model assumes diazotrophs are not competitive unless nitrogen is limiting. However, for conditions where oceanic N:P is somewhat lower than 16, *increasing* nitrogen fixation can *decrease* the fixed nitrogen inventory of the deep ocean by enhancing export production, reducing deep ocean oxygen and increasing the rate of denitrification. Increasing the oceanic phosphorus inventory above today's values also reduces N:P through a similar mechanism. These model explorations suggest there are critical non-linear interactions of between the C, N, O and P cycles which remain to be elucidated.

3.4. Implications for the global carbon cycle

What are the implications of such changes in the nitrogen cycle for the global carbon cycling and atmospheric pCO_2? A biologically mediated *net* exchange of CO_2 between the atmosphere and ocean can be brought about by changing the oceanic inventory of one or more limiting nutrients (Falkowski *et al.*, 2003). If fixed inorganic nitrogen is limiting, then how sensitive is the atmospheric exchange of CO_2 with the ocean to a change in the inventory of fixed inorganic nitrogen. To do this, we examined the effect of changing the nitrogen inventory (through biological fixation) in a coupled biogeo-chemical model. Following the treatment of the nitrogen and oxygen concentrations in the deep ocean, we may describe the ocean reservoir of dissolved inorganic carbon (DIC_d) as the sum of preformed (DIC_{pre}) and biological components (DIC_{bio}):

$$DIC_d = DIC_{pre} + DIC_{bio} \qquad (35.4)$$

Here, the preformed pool includes contributions from the saturation concentration and the degree of disequilibrium at the point of subduction. The biological fraction has contributions from both soft-tissue and carbonate pumps (Volk and Hoffert, 1985). Following Brewer (Brewer, 1978) we may, as a first approximation, interpret the soft-tissue contribution to be related to the biological fraction of nitrogen by a fixed, Redfieldian stoichiometry:

$$DIC_{bio} = R_{CN} N_{bio}.$$

If the ocean-atmosphere loading of carbon is fixed then, given these simplistic assumptions, enhancing the oceanic nitrogen budget and export production would lead to an enhancement of the oceans biological carbon pool at the expense of the atmosphere, reducing atmospheric pCO_2 in proportion to the change in DIC according to the buffer factor, B:

$$dpCO_2/pCO_2 \sim B\, dDIC/DIC \qquad (35.5)$$

(e.g. Bolin and Erickson, 1959) where $B \sim O(10)$.

Accordingly, let us consider some climate change process which leads to an increase in fixed inorganic N by 1 μmol L^{-1} in the ocean interior, N$_d$. Studies of the contemporary ocean suggest that the biological contribution N$_{bio} \sim 0.3$ N$_d$. Assuming this fraction stays constant and $R_{CN} \sim 6$, this implies a corresponding 2 M increase in DIC$_d$. The buffering relationship (2.5) suggests a modest associated decrease in atmospheric pCO$_2$ (relative to 280 ppmv) of about 3 ppmv in the steady state (see Ito and Follows, 2004) for a more detailed analysis). If all of the extra nitrogen is in the biological fraction, the sensitivity of atmospheric CO$_2$ to the mean ocean nitrogen concentration could be as much as 10 ppmv per micromole, relative to the pre-industrial state. It should be noted that this argument assumes no impact on the preformed component, DIC$_{pre}$. It also assumes a fixed ocean–atmosphere carbon budget. However, modifications of the deep ocean carbonate system will ultimately lead to interactions with the sedimentary calcium carbonate reservoir, dampening the impact on atmospheric pCO2 (e.g. Bolin and Eriksson, 1959).

4. SUMMARY AND CONCLUSIONS

The history of Earth can be broadly divided into two "super eons." The first 2.2 billion years were marked by biological innovation and experimentation, during which time all the major metabolic pathways evolved in prokaryotes. One of these pathways, oxygenic photosynthesis, would subsequently, over the second half of Earth's history, give rise to aerobic metabolism, and ultimately permit the evolution of multicellular eukaryotes. The shift from mildly reducing to strongly oxidizing conditions was, beyond doubt, the most profound transition since the origin of life itself. Our analysis suggests that feedbacks between C, N, and O cycles helped prevent the oxidation of Earth in the Paleoproterozoic. This stabilizing feedback, which was ultimately over-ridden, led to the contemporary nitrogen cycle where nitrate, rather than ammonium, was the stable form of fixed inorganic nitrogen in the oceans. Barring some minor changes in the trace element composition in nitrogenases, the core proteins remained essentially unchanged following the transition to an oxidized atmosphere. In the contemporary ocean, approximately 20—30% of nitrogenase activity is inhibited at any moment in time by O$_2$. This inhibition results in a negative feedback which constrains the upper level of O$_2$ on Earth (Figs. 35.2 and 35.5).

Three central aspects of cyanobacterial nitrogen fixation remain curious. First, although some trace elements have been altered in the evolution of nitrogenases, the core proteins have remained virtually unchanged. In effect, nitrogenase, like RuBisCO, is a "frozen metabolic accident" (Shi *et al.*, 2005). Either there is no substitute for the basic iron–sulfur cluster motif, or protein–protein interactions have severely constrained the evolutionary trajectory of this enzyme complex, or both. Whatever the reason, all nitrogenases are irreversibly inhibited by oxygen—and cyanobacteria are the only oxygenic photoautotrophs that contain the gene. Second, while there is abundant evidence of lateral transfer of nitrogenase genes between prokaryotes, in the endosymbiotic appropriation of cyanobacteria into heterotrophic hosts to photosynthetic eukaryotes, nitrogenases were lost. Indeed, there is no known eukaryote that contains an endogenous functional nitrogenase. It is not apparent whether this deficiency is

genetically insurmountable, but it is clear that (under present conditions) it made most aquatic eukaryotes dependent on cyanobacteria for fixed inorganic nitrogen. In oligo-trophic subtropical and tropical oceans large chain–forming diatoms are found in association with the endosymbiotic heterocystous cyanobacterium, *Richelia intracellularis* that contribute significant amounts of fixed N to some systems (Capone *et al.*, 1997; Carpenter *et al.*, 1999; Foster and O'Mullan, Chapter 27, this volume; Janson *et al.*, 1999; Venrick, 1974)(see Carpenter and Capone, Chapter 4, this volume). Yet, given the above dependency, the low diversity and limited biomass of endosymbiotic nitrogen fixing cyanobacteria harbored in eukaryotic host cells seems curious. Third, although free-living heterocystous cyanobacteria are abundant in lakes and brackish water eco-systems, they appear to be rare in the open ocean (Carpenter and Janson, 2001). Heterocysts are advantageous at lower temperature and salinities compared to *Tricho-desmium* types, which dominate in the tropical oceans (Staal *et al.*, 2003b). Yet, it is not clear why this, or some other biological innovation which facilitates nitrogen fixation under relatively high oxygen concentrations, is rare in temperate and polar oceanic ecosystems.

Clearly these issues will be the focus of research efforts over the next few decades because they lie at the heart of a fundamentally applied problem: why have we not been able to genetically engineer plants that feed and serve humans with the capability of fixing their own nitrogen? Should we overcome that major hurdle, we will have made a major transition in the impact of humans on the chemistry of Earth and its oceans.

Nitrogen Fluxes from Rivers to the Coastal Oceans

Elizabeth W. Boyer *and* Robert W. Howarth

Contents

1. Introduction

Human activities, largely associated with food production and fossil-fuel combustion, have greatly modified biogeochemical cycles of nitrogen in terrestrial and aquatic ecosystems throughout much of the world (Galloway *et al.*, 2004; Smil, 2001; Vitousek *et al.*, 1997). Fifty years ago, the vast majority of reactive nitrogen on the land surfaces of the Earth was created naturally through biological nitrogen fixation, but the rate of formation of reactive nitrogen stemming from human activities now roughly matches this (Table 36.1, Galloway *et al.*, 2004). A significant quantity of this nitrogen is transported in rivers from the continental landscape to the coastal ocean zones (Boyer *et al.*, 2006). The major change in the global nitrogen cycle has been the creation of synthetic nitrogen fertilizers to fuel the green revolution, although the release of reactive nitrogen during fossil-fuel combustion has also been a factor (Fig. 36.1).

Notwithstanding unequivocal benefits associated with the acceleration of the global N cycle in terms of satisfying societal demands for food and fuel, the negative environmental consequences to estuaries and coastal seas caused by over-enrichment of nitrogen are significant (Howarth and Marino, 2006; Rabalais, 2002). For example, two-thirds of the coastal rivers and bays in the United States are moderately to severely

Table 36.1 The rate of formation of reactive nitrogen on the land surfaces of Earth in 1950 and in 2000 from natural and human-controlled processes (Tg N year^{-1})

	1950	2000
Natural processes		
Biological nitrogen fixation	100–200	100–200
Lightning	5	5
All natural processes	105–205	105–205
Human-controlled processes		
Synthetic fertilizer production	5	110
Nitrogen release during fossil-fuel combustion	5	25
Biological nitrogen fixation in agroecosystems	24	33
All human-controlled processes	34	168
Total rate of creation of reactive nitrogen	139–239	273–373

Rates of nitrogen fixation in natural ecosystems are from Cleveland *et al.* (1999). Data on notrogen creation from human-controlled processes are from Galloway et al. (2004), assuming no major loss of natural ecosystem fixation since 1950.
Figure 36.1 Human activities have greatly altered the global nitrogen cycle, increasing reactive nitrogen inputs to the terrestrial landscape, shown below. Major sources of reactive nitrogen to the environment include industrial processes that produce nitrogen fertilizers, cultivation of leguminous crops that host nitrogen-fixing bacteria, and combustion of fossil fuels. Coastal eutrophication problems worldwide have been largely attributed to this increase of reactive nitrogen in the environment (as indicated by the gray bar). Figure modified from Boesch (2002), Galloway *et al.* (2004).

degraded from nutrient pollution, and nutrients are now considered the largest pollution problem in the coastal zone of the country (NRC, 2000). Environmental problems in the coastal oceans associated with nitrogen pollution are global in scope (Diaz, 2001; Rabalais, 2002) and are likely to increase as population increases and as use of

inorganic fertilizers and fossil fuels continues to intensify (Galloway *et al.*, 2004; Glibert *et al.*, 2006). As we present below, the geographic variation in the problem is large.

We estimate current inputs from rivers to the coastal zone as approximately 48 Tg N year^{-1} (Boyer *et al.*, 2006; Galloway *et al.*, 2004). In comparison, net inputs from atmospheric deposition in excess of volatile losses from the oceans are estimated as approximately 30 Tg N year^{-1} and biological nitrogen fixation in the oceans is estimated as approximately 120 Tg N year^{-1} (Galloway *et al.*, 2004). Although there is considerable uncertainty in all of these terms, riverine inputs of nitrogen to the coastal zone as of the 1990s represented roughly one quarter of all the nitrogen inputs to landscape. Much of the nitrogen delivered from rivers to coastal waters is subsequently consumed by denitrification on the continental shelves. Shelf sediments are a very large sink for nitrogen, thus only a small fraction of nitrogen inputs reach the open ocean (Nixon *et al.*, 1996; Seitzinger and Kroeze, 1998; Seitzinger *et al.*, 2006). However, nitrogen input to offshore oceanic waters may be significant from very large rivers that can transport water and nitrogen across the continental shelves, or from rivers that discharge into coastal waters where the continental shelves are narrow. The major influence of riverine nitrogen on ecological functioning in the oceans is in estuaries and waters on the continental shelves themselves. In many estuaries, inputs from rivers are by far the largest source of nitrogen (Nixon *et al.*, 1996; Seitzinger *et al.*, 2006). Nonetheless, the importance of nitrogen from rivers in the nitrogen budgets of continental shelf regions varies greatly, with much of this variation related to differences in the extent of advection of nitrate-rich bottom waters onto the continental shelves (Table 36.2; Howarth, 1998).

In this chapter, we review information from previous studies regarding nitrogen inputs to landscapes and the associated delivery of nitrogen to coastal waters around the world. We focus on fluxes of total nitrogen rather than dissolved inorganic nitrogen (DIN, typically including nitrate, nitrite, and ammonium), since most of the organic nitrogen added to the oceans in rivers is likely converted to DIN on ecologically meaningful time scales; that is, terrestrially derived organic nitrogen in marine sediments is only a very small proportion of the inputs (probably $< 6\%$, assuming that all nitrogen in deltaic sediments represents terrestrially derived organic nitrogen; Galloway *et al.*, 2004). Several models have been developed to estimate nitrate fluxes to the global ocean (see for example Dumont *et al.*, 2005; Seitzinger and Kroeze, 1998, Seitzinger *et al.*, 2002; Smith *et al.*, 2003); these generally yield estimates of nitrate fluxes that are one-third to one-half of global estimates for total nitrogen fluxes in rivers. However, in considering the role of human activities, it is important to note that the nitrate fluxes represent a much higher proportion of the anthropogenically-increased nitrogen fluxes (Boyer *et al.*, 2002; Galloway *et al.*, 2004; Howarth *et al.*, 1996). Though ammonium fluxes are generally much lower than nitrate fluxes in streams and rivers, they also may represent a substantial proportion of the increased fluxes resulting from anthropogenic activities, such as in some urban areas with inputs of wastewater (Paul and Meyer, 2001; Shuiwang *et al.*, 2000).

There are many complimentary approaches presented in the recent literature for considering fluxes of total nitrogen in rivers at regional and global scales, all of which

Table 36.2 Sources of nitrogen to the continental shelves in major temperate-zone water regions of the North Atlantic Ocean

Major water region of the North Atlantic Ocean	N delivered from rivers and estuaries Tg N year^{-1}	N from direct atmospheric deposition Tg N year^{-1}	N delivered from deep ocean Tg N year^{-1}	N flux due to human activities (%)
North Canada rivers	0.16 (0.16)	0.10 (0.03)	0.77	7
St. Lawrence basin	0.34 (0.11)	0.13 (0.01)	1.26	25
NE coast of US	0.27 (0.03)	0.21 (0.01)	1.54	28
SE coast of US	0.13 (0.03)	0.06 (0.01)	1.36	11
Gulf of Mexico	2.10 (0.50)	0.28 (0.03)	0.14	275
Nort Sea and NW Europe	0.97 (0.14)	0.64 (0.02)	1.32	98
SW European Coast	0.11 (0.04)	0.03 (0.001)	0.20	40

Nitrogen fluxes (in Tg N year^{-1}) are reported for contemporary conditions, with estimates under pristine conditions indicated in parentheses. Flux of nitrogen delivered from rivers and estuaries is the direct input of rivers that discharge onto the continental shelf plus the riverine input into estuaries, minus nitrogen consumed in estuaries. Atmospheric nitrogen deposition estimates in this table are those directly onto the waters of the continental shelf and do not include deposition onto the landscape (which is part of the flux from rivers and estuaries). The flux from the deep ocean represents the advection of nitrate-rich deep Atlantic water onto the continental shelf. Data in this table are from Howarth (1998).

rely on relatively simple descriptors of nitrogen sources (such as fertilizers, deposition, fixation, manure, sewage) and landscape characteristics (such as data on climate, soil properties, land use, and river routing) to estimate fractions of nitrogen inputs to landscapes that are ultimately discharged to rivers; calibrating or evaluating the models with information on nitrogen fluxes observed in world rivers (such as the GEMS/GLORI compendium of riverine nitrogen fluxes synthesized by Meybeck and Ragu, 1995). For example, Seitzinger *et al.* (2005) use a spatially-explicit empirical approach to predict riverine nitrogen fluxes as a function of nitrogen inputs, land use, hydrology, and other factors. Green *et al.* (2004) use aggregate measures of basin temperature and hydraulic residence times of water in soils and river reach networks to characterize transport and transformations of nitrogen inputs from landscapes to river basins with a statistical approach. Van Drecht *et al.* (2003) and Bouwman *et al.* (2005) take a more mechanistic approach, describing the fate and transport of nitrogen inputs explicitly (e.g., ammonia emissions, denitrification in soils and waters, leaching and groundwater transport) as they are transported along various hydrologic pathways.

These approaches all provide admirable first approximations at how to characterize disproportionate impacts of nitrogen inputs to a heterogeneous landscape, though they also point out a vast number of assumptions and challenges associated

with characterizing the complex factors controlling nitrogen retention and release at this scale (Bouwman *et al.*, 2005; Green *et al.*, 2004; Van Drecht *et al.*, 2003, 2005). For example, limitations are imposed by: (1) the coarse resolution of spatial databases describing point- and non-point sources of nitrogen (e.g., deposition, fertilizers, human waste, animal manure, crop uptake and fixation); (2) land characteristics and associated assumptions about their hydraulic characteristics (e.g., soils, land cover, geology); (3) characterization of nitrogen transformation processes (e.g., assumptions about in-stream retention based on physical flow regime or time-of-travel that do not aim to consider the complexity of chemical and biological conditions that influence microbial activity); and (4) estimates of riverine nitrogen loads that are based on sparse observations that are not always representative of mean annual flow conditions, and are synthesized from large numbers of literature sources with differences in measurement methods, sampling frequencies, and length of period covered by the measurements (Bouwman *et al.*, 2005).

In the face of these uncertainties, we assert that simple empirical methods remain useful for exploring broad-scale linkages among nitrogen inputs and exports at regional scales. In their original application providing a comprehensive analysis of nitrogen export from large water regions to the North Atlantic Ocean, Howarth *et al.* (1996) presented a nitrogen budgeting approach for regional watersheds, and found a very strong positive correlation between net anthropogenic nitrogen inputs per unit land area and nitrogen delivery per area to coastal waters (Fig. 36.2). This method is similar to the approaches outlined above in that it uses information on the spatial and temporal variability of nitrogen sources on the landscape to predict riverine nitrogen exports, and suggests that fates of residual nitrogen inputs (e.g., retention and gaseous losses) are controlled by a variety of factors related to functioning of terrestrial and aquatic ecosystems. Applications of nitrogen
Figure 36.2 Nitrogen fluxes per area of watershed to the coastal ocean as a function of net anthropogenic nitrogen inputs to the landscape per unit area. Reprinted from Howarth *et al.* (1996).

budget models have set forth the conceptual notion that nitrogen fluxes in surface waters are controlled to a large degree by inputs of nitrogen to their watersheds, a basic fact which underlies most of the more complex modeling approaches and underpins management strategies to mitigate nitrogen pollution problems in surface waters.

Though the nitrogen budget method is subject to the same suite of limitations described for the approaches outlined above, it has been widely adapted given its simple structure. It is particularly useful because it provides a method to quantify and assess the relative importance of the various sources of nitrogen within and among regions and their associated riverine nitrogen responses; and allows systematic comparisons of regions over space and time. In a comparison of 6 large watershed models for estimating either total nitrogen or DIN fluxes, Alexander *et al.* (2002) found that the nitrogen budgeting approach of Howarth *et al.* (1996) compared very favorably, with one of the lowest factor-related biases of any of the models and the greatest precision of all, although it tended to under-predict fluxes (by ∼15% on average). Further, nitrogen budget models were found to be very robust when extended to watersheds of many different sizes and to world regions in both temperate and tropical settings (Alexander *et al.*, 2002; Bashkin *et al.*, 2002; Borbor *et al.*, 2006; Boyer *et al.*, 2002, 2006; Filoso *et al.*, 2006; Howarth *et al.*, 1996; Xing *et al.* and Xhu, 2002) For these reasons, a modified version of the nitrogen budgeting method was chosen to estimate global riverine nitrogen transfers to the coastal zone for the International Nitrogen Initiative's current global assessment of nitrogen cycles: past, present, and future (Galloway *et al.*, 2004). Regardless of the method used, quantifying the changing nitrogen inputs to world regions is critical for mitigating problems associated with nitrogen pollution.

As a basis for contrasting the contemporary distribution of nitrogen fluxes around the world, we present results from various applications of the nitrogen budget method in this chapter, and compare predictions of nitrogen fluxes to coastal waters from this method to other methods reported in published studies. In addition to consideration of global nitrogen fluxes, we emphasize regional differences, given that most reactive nitrogen cycles at spatial scales far smaller than global. Since the distribution of newly created reactive nitrogen is not uniform, some regions have seen massive increases in reactive nitrogen, while other regions have seen little change (Fig. 36.3). Associated with fossil-fuel combustion, atmospheric nitrogen deposition (Fig. 36.3A) yields nitrogen inputs to landscapes, with hot spots in the heavily developed regions (Dentener *et al.*, 2006). Associated with food production, cultivated land areas (Fig. 36.3B, showing areas in which at least 30% by area of the landscape is cultivated in a given year) result in large inputs of nitrogen to landscapes from the use of fertilizers and manure, and from biological fixation in cultivated leguminous crop lands. In 2000, heavily cultivated systems used for crop production, livestock production, aquaculture and agroforestry covered nearly 25% of the land surface (MEA, 2005).

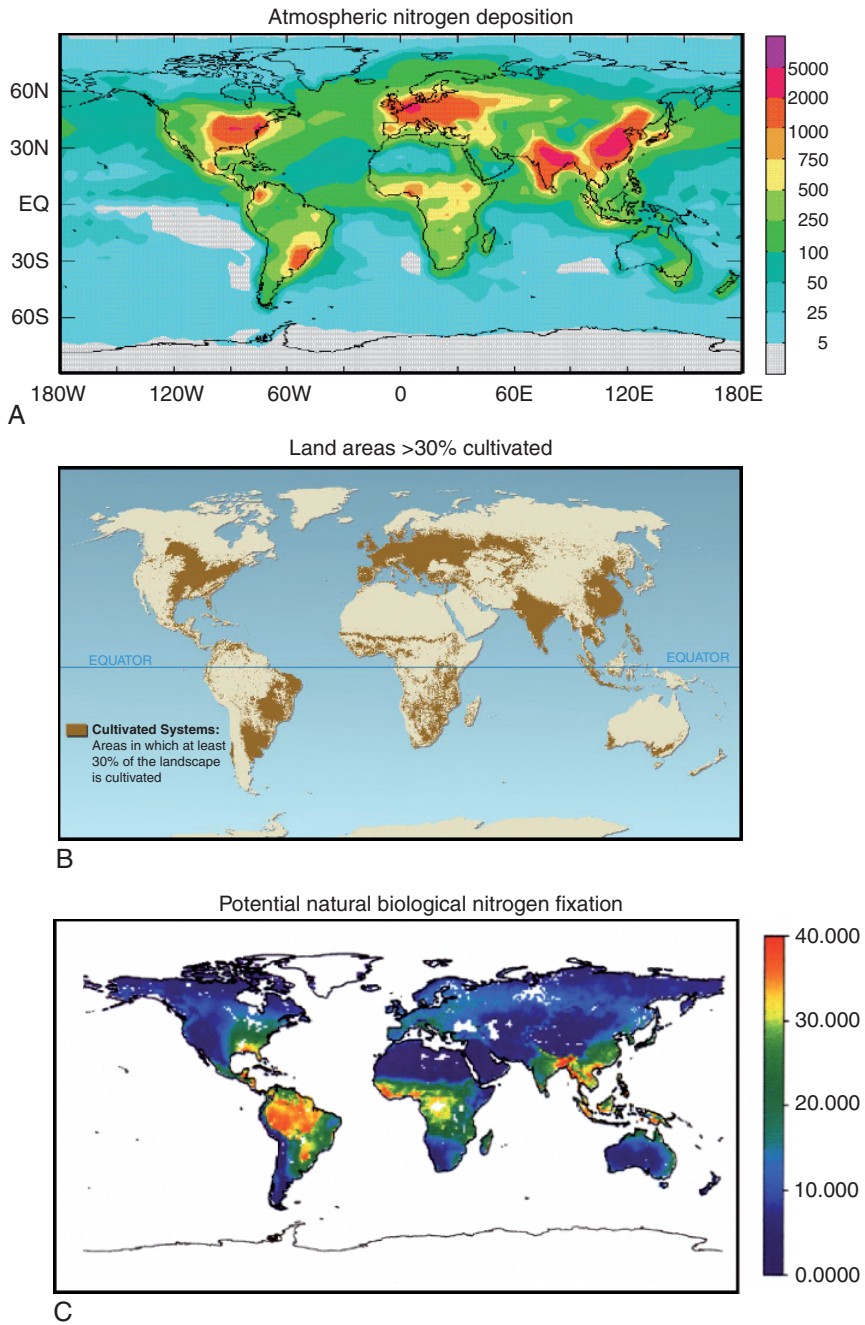
Note that the greatest intensity of use of nitrogen by humans is often in regions where the natural rates of biological nitrogen fixation are low (Fig. 36.3C). Where natural biological nitrogen fixation tends to be highest—in the tropics—human inputs of nitrogen still tend to be relatively low in many regions, although rapid


Figure 36.3 Contemporary nitrogen inputs to the landscape are unevenly distributed across the world. (A) Inputs of nitrogen to landscapes from atmospheric deposition (kg/km^2/year). Data from Frank Dentener, Reprinted from Galloway *et al.* (2004). (B) Significant inputs of nitrogen from use of fertilizers and manure and from biological nitrogen fixation occur in cultivated regions of the landscape. This map showing the extent of cultivated systems, which cover 24% of the earth's surface in 2000, is reprinted from the Millennium Ecosystem Assessment (2005). (C) Potential biological nitrogen fixation by natural ecosystems (kg/ha/year), if lands were not cultivated or otherwise converted. Reprinted from Cleveland *et al.* (1999).

future growth in nitrogen use is anticipated (Downing *et al.*, 1999; Matson *et al.*, 1999).

2. Nitrogen Budget Method

Our approach to modeling nitrogen fluxes with budgeting methods has been described extensively in our earlier publications (Boyer *et al.*, 2002, 2004; Galloway *et al.*, 2004; Howarth *et al.*, 1996, 2002A, 2006). In brief, the method involves assembling spatial and temporal data on nitrogen sources from available synoptic databases, tallying nitrogen inputs to each watershed or region from multiple sources, and developing relationships between these inputs and riverine nitrogen export. Nitrogen flux terms in the budgets are typically calculated using multiple years of data to avoid short-term climatic influences, and are typically expressed in units of mass per time (Tg N year^{-1}) or mass per unit area of watershed per time (kg N km^{-2} year^{-1}). For readers who are more accustomed with other units, 1 Tg N = 1 million metric tons N = 10^{12} gN, and 100 kg N km^{-2} year^{-1} = 1 kg N ha^{-1} year^{-1}. The goal is not to quantify the entire distribution of nitrogen in the landscape, but rather to quantify and sum the *new* inputs of reactive nitrogen to each watershed or water region from anthropogenic and natural sources. "New" inputs refer to inputs that are either fixed within a region or transported into a region. Anthropogenic nitrogen sources include fertilizer, biological nitrogen fixation in cultivated cropland, net imports of nitrogen in human food and animal feedstuffs (where a negative net import term indicates a region that is a net exporter of food and feed), and atmospheric NO$_y$-N deposition from fossil-fuel combustion. Natural nitrogen sources include biological nitrogen fixation in natural (non–cultivated) land and nitrogen fixation by lightning.

An important distinction among various implementations of the nitrogen budgeting method is how specifically the inputs are quantified. The net anthropogenic nitrogen inputs (NANI) approach considers nitrogen inputs from just the anthropogenic sources, while the net total nitrogen inputs (NTNI) approach includes natural in addition to the anthropogenic sources. Regardless of whether nitrogen inputs are tallied as NANI or NTNI, animal waste (manure) and human waste (sewage) are not considered *new* nitrogen inputs because they are recycled within a region; the nitrogen in these wastes originated either from synthetic nitrogen fertilizer, nitrogen fixation in agricultural lands, or nitrogen imported in food or feedstocks. It is important to note that nitrogen from human and animal waste sources is represented in the NANI and NTNI budget approaches, as they are included implicitly as part of the calculation of nitrogen inputs in food and feed.

Similarly, deposition of ammonium is not considered a new input, as this is largely recycled nitrogen volatilized from animal wastes within the same region or large watershed (Howarth *et al.*, 1996; Boyer *et al.*, 2002). Approximately 90% of ammonia in the global atmosphere comes from agricultural sources (Dentener & Crutzen, 1994), with major emissions coming from animal wastes (manure) and lesser contributions from volatilization of fertilizers. Because ammonia is short-lived

in the atmosphere, with residence times ranging from hours to a few weeks, ammonia may re-deposit within the same region from which it was emitted (Prospero *et al.*, 1996). The volatilization and deposition cycle is likely to be complete over the scale of a large region, such as the large water regions used in this analysis. Therefore, most nitrogen budgets computed over large spatial scales simply assume that ammonia deposition reflects local recycling and ignore it as a new input (Howarth *et al.*, 1996; Jordan and Weller, 1996). However, it is unlikely that this recycling is complete over shorter distances, and nitrogen budgets applied at smaller catchment scales have taken this into account (Boyer *et al.*, 2002).

Further, the budgeting approach assumes that the nitrogen status of soils is in steady state, and that the rate of soil nitrogen mineralization equals the rate of nitrogen immobilization on an annual basis, at least on average over a multiple year period (Howarth *et al.*, 2002B). Soil mineralization at the scale of a large watershed or region is a very big term (McIsaac *et al.*, 2001), and if mineralization were to be significantly greater than or less than immobilization, this would have a profound influence on the nitrogen budget for the region. When virgin lands are converted to agricultural use, there is a large net release of nitrogen due to mineralization in excess of immobilization. However, over a period of decades, the soil nitrogen is likely to come to a quasi- steady state (David *et al.*, 1997; McIssac *et al.*, 2001). Much of the inorganic nitrogen fertilizer added to a field is immobilized by bacterial action and only becomes available to crops in a subsequent year through mineralization (David *et al.*, 1997). That this mineralization is dependent upon the fertilizer input does not violate assumptions of steady state conditions in nitrogen budgeting approaches (Howarth *et al.*, 2002B).

The relationship between nitrogen inputs to watersheds (expressed either as NANI or NTNI) and the associated nitrogen issuing from these regions in rivers has been shown to be an excellent integrator of the human effects on nitrogen cycling at large scales (Bashkin *et al.*, 2002; Boyer *et al.*, 2002; Galloway *et al.*, 2004; Howarth *et al.*, 1996, 2002B, 2006; Jordan and Weller, 1996; McIsaac *et al.*, 2001; NRC, 2000; Quynh *et al.*, 2005; Sferratore *et al.*, 2005; Xing and Xhu *et al.*, 2002).

3. Relationship between Nitrogen Inputs to Watersheds and Riverine Outputs

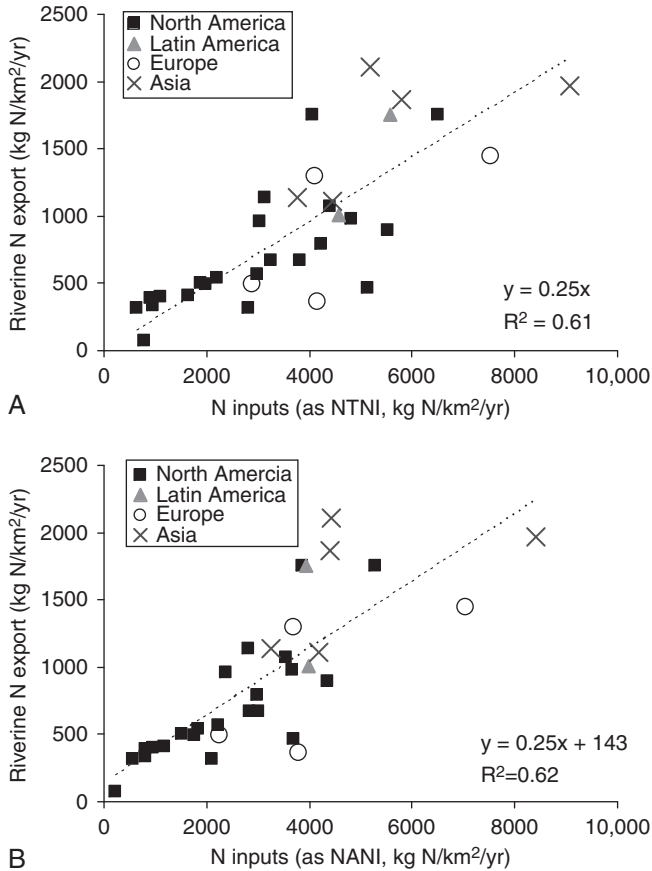
We assembled data from published nitrogen budget studies that were conducted around the world, including countries draining into the North Atlantic Ocean (Howarth *et al.*, 1996), the northeastern United States (Boyer *et al.*, 2002; Howarth *et al.*, 2006), Ecuador (Borbor *et al.*, 2006), Brazil (Filoso *et al.*, 2006), Korea (Bashkin *et al.*, 2002), and China (Xing and Xhu *et al.*, 2002). All of these studies quantified nitrogen inputs to large regions or watersheds from multiple important nitrogen sources. Then, we compared total net nitrogen inputs to the watershed landscape with nitrogen fluxes leaving the watersheds in riverine fluxes of total nitrogen (in dissolved, organic, and particulate forms). The input and output data from these studies are based on monitoring data that represent conditions in


Figure 36.4 Relationship between nitrogen inputs and riverine N fluxes from watersheds spanning multiple scales and biomes of the world. Nitrogen inputs are expressed as: (A) net total nitrogen inputs; and (B) net anthropogenic nitrogen inputs. Modified from Boyer *et al.* (2006).

the mid–1990s, consistent with the timeframe of our nitrogen input data at the continental scale shown in Fig. 36.4. We aggregated data from these studies and augmented them with additional data on nitrogen sources when necessary to make all of the studies directly comparable, in order to represent nitrogen inputs as defined by our NTNI and NANI methods (Boyer *et al.*, 2006). In both cases, there is a direct, linear relationship between nitrogen inputs and the total nitrogen fluxes in these watersheds which suggests that, on average, 75% of the nitrogen inputs are retained in the landscape (that is, stored in soils and vegetation, or lost via volatilization and denitrification), while 25% of the nitrogen inputs are exported to rivers (Fig. 36.4). Note that the intercepts vary between the two plots, with the NTNI one having an intercept near zero and the NANI plot having an intercept of 143 kg N km^{-2} year^{-1}. The intercept for the NANI plot indicates that some nitrogen will be exported from watersheds even when there are no nitrogen inputs from human activities, with this nitrogen reflecting losses from natural inputs. It is

encouraging that for the NTNI plot — where natural nitrogen inputs are also included — that the intercept is approximately zero. That is, no nitrogen can be exported from a watershed that has absolutely no nitrogen inputs, considering both natural and anthropogenic sources. The positive intercept in NANI plots of this sort (see also Fig. 36.2) have been used before to estimate a baseline for nitrogen export from a "pristine," non–human impacted landscape under current climate conditions (Howarth *et al.*, 2002A, 2005; NRC, 2000).

While nitrogen inputs to a region are a good predictor of nitrogen export from the region, there is scatter in the relationships, with R^2 values ranging between 0.61 and 0.73 (Figs. 36.2 and 36.4). Regardless of the percentage of inputs transported to rivers, the strong relationship between watershed-scale nitrogen inputs and the associated losses of nitrogen in riverine export suggests that decreasing nitrogen inputs (e.g., via policy or management approaches) will improve nitrogen pollution problems in surface waters. One might expect the scatter to be even greater, given both the quality of the data and the large number of other factors that might be expected to affect nitrogen fluxes in rivers, such as topography, soils, geology, climate, and land use. In fact, a surprisingly large amount of the variation appears to be related to climate. In a detailed study of 16 watersheds in the northeastern United States, we observed that percentage of the human-controlled inputs of nitrogen (NANI) that was exported in rivers varied from approximately 10% to over 40%. This percent export was highly correlated with both average precipitation and average discharge in the watersheds (Howarth *et al.*, 2006). The combined influences of NANI and precipitation could explain 87% of the variation in riverine nitrogen flux from these watersheds. The percentage of the nitrogen inputs that was exported was greater in the watersheds where precipitation and riverine discharge were higher, perhaps suggesting less time for denitrification in riparian wetlands and low-order streams (Howarth *et al.*, 2006). Similarly, in their studies of minimally disturbed watersheds in Lewis *et al.* (1999) and Lewis (2002) found that nitrogen yields are not strongly related to watershed area but are very strongly related to runoff, when both discharge and nitrogen flux are expressed per area of watershed. This relationship, illustrating the importance of climatic controls on nitrogen exports, held true in both temperate areas (Lewis *et al.*, 2002) and tropical areas (Lewis *et al.*, 1999).

4. Comparison of Global Estimates of Contemporary Riverine Nitrogen Fluxes to the Oceans

The NTNI modeling approach yields a global estimate for the input of nitrogen to the oceans from rivers of 48 Tg N year^{-1} as of the early to mid 1990s (Boyer *et al.*, 2006; Galloway *et al.*, 2004). In addition to the flux of nitrogen in rivers to the oceans, some nitrogen transported from rivers flows to landlocked inland waters and never reaches the coast, or to inland regions that don't actively transmit significant fluxes of water to the coasts because they are too cold or arid. The NTNI model indicates endoreic fluxes of approximately 11 Tg N year^{-1}, so the total global flux
Figure 36.5 Comparison of global estimates of total riverine N export (Tg N year^{-1}) during the early to mid 1990's from studies reported in the literature. Note that these estimates include loadings to inland regions that don't reach the oceans in addition to the coastal loadings. For the Boyer *et al.* study, riverine nitrogen flows to the coasts represent 80% of the total global riverine nitrogen fluxes. Modified from Boyer *et al.* (2006).

of nitrogen in rivers is estimated as 59 Tg N year^{-1} (Boyer *et al.*, 2006). Several other recent studies present global riverine loading estimates based on different methodologies that are comparable (Fig. 36.5). A total nitrogen flux of 40 Tg N year^{-1} was predicted by Green *et al.* (2004) with an empirical model relating watershed characteristics to nitrogen export, which uses export coefficients based on basin temperature and hydraulic residence times in soils, rivers, lakes and reservoirs to transport nitrogen loads to river mouths. Van Drecht *et al.* (2001, 2003) and Bouwman *et al.* (2005) use various versions of a conceptual model based on point- and non-point sources of nitrogen coupled with mechanistic hydro-ecological models describing their fate and transport in the landscape, producing global estimates of total nitrogen fluxes of 54 Tg N year^{-1} (Van Drecht *et al.*, 2001, 2003) and 46 Tg N year^{-1} (Bouwman *et al.*, 2005). MacKenzie *et al.* (2002) use the Terrestrial Ocean Atmosphere Ecosystem Model, a biogeochemical model representing couplings among the major element cycles, to estimate a total riverine N flux of 46 Tg N year^{-1} in dissolved, particulate, and organic forms (MacKenzie *et al.*, 2002). Seitzinger *et al.* (2005) use an empirical regression approach to quantify nitrogen exports as a function of anthropogenic inputs (including sewage, fertilizers, deposition, manure, and biological nitrogen fixation), and variables influencing nitrogen retention and loss, yielding total riverine N fluxes of 66 Tg N year^{-1}, with 25 Tg N year^{-1} in dissolved inorganic forms (DIN), 12 Tg N year^{-1} in dissolved organic forms (DON), and 30 Tg N year^{-1} in particulate forms (PN). Several other global studies present estimates nitrogen fluxes to surface waters at regional scales, considering only fractions of total nitrogen export. For example, in their regression approaches put forth earlier in the literature, Seitzinger and colleagues estimated riverine N fluxes of 21 Tg N year^{-1} as DIN (Seitzinger and Kroeze, 1998) and 23 Tg N year^{-1} as PN (Seitzinger *et al.*, 2002). Similarly, Smith *et al.* (2003) used an empirical regression approach to quantify inorganic nitrogen fluxes as a function of population density and runoff, and use a statistical clustering procedure yielding estimates of global riverine DIN fluxes ranging between 19 and 23 Tg N year^{-1}, but do not estimate fluxes as DON or PN.

All of these approaches are useful for thinking about past, current, and future scenarios, because in all cases changes in riverine nitrogen flux are driven by changes in the magnitude and distribution of the nitrogen source inputs. The differences in the estimated riverine nitrogen fluxes at regional and global scales highlight large uncertainties stemming from data quality and resolution, scaling issues, and model approaches (Van Drecht et al., 2005).

5. DISTRIBUTION OF NITROGEN FLUXES IN RIVERS BY CONTINENT AND OCEAN BASIN

The use and release to the environment of nitrogen by humans varies greatly among continents (Figs. 36.6 and 36.7). Note that we used boundaries as defined by the Food and Agriculture Organization of the United Nations (FAO, 2003), so Europe is combined with the portions of Asia that were in the former Soviet Union ("FSU"), including all of Siberia. Biological nitrogen fixation in natural ecosystems dominates the nitrogen budgets in Africa (74%), Oceania (77%), and Latin America (68%) (Fig. 36.6; Boyer et al., 2004; Galloway et al., 2004). In contrast, anthropogenic nitrogen sources dominate the nitrogen budgets in Asia (76%), North America (63%), and Europe/FSU (61%) as of the 1990s. In each of the continents where human activity dominates the nitrogen cycle, the single largest source of new reactive nitrogen is synthetic fertilizer (Fig. 36.6). As is true with the pattern globally (Table 36.1, Fig. 36.1), this domination by human activity generally and by synthetic fertilizer in particular is a very recent phenomenon, particularly in Asia. For example, between the early 1960s and the late 1990s, the use of synthetic nitrogen fertilizer increased 3.6-fold in the United States and more than 20-fold in Asia (Howarth et al., 2002a; Zheng et al., 2002).

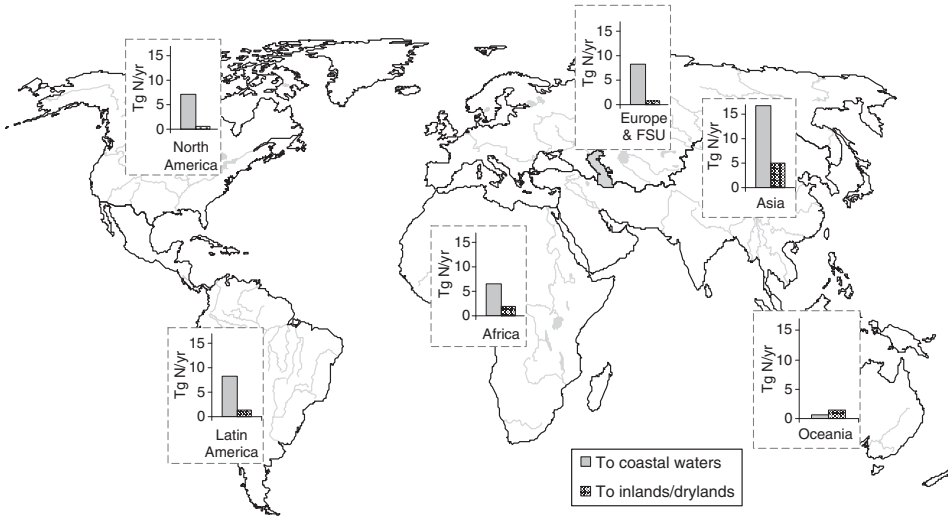
For all of the continents except Oceania, most of the nitrogen flux in rivers is delivered to the oceans rather than to landlocked inland waters (Fig. 36.7). However,
Figure 36.6 Net reactive N inputs (Tg N year^{-1}) to continental world regions during the mid-1990s, from anthropogenic and natural sources. Anthropogenic sources include N fertilizer use, N fixation in cultivated lands, net N imports in food and feed, and atmospheric N deposition from fossil–fuel combustion. The natural sources include biological N fixation in non–cultivated vegetated lands and N fixation by lightning. Modified from Boyer et al. (2004).


Figure 36.7 Riverine fluxes of total N from continental land masses to receiving waters during the mid-1990's. Significant N loads are transported in fluvial systems to coastal receiving waters. However, some N ends its journey inland as it is transported to landlocked endoreic watersheds, or originates in cold or arid regions that do not have enough throughput of water to transmit significant fluxes to the coastal zone. Data from Boyer *et al.* (2006).

in Oceania, more nitrogen is transported to inland receiving waters/drylands (1.5 Tg N year^{-1}) than is transported to the coastal zone (0.7 Tg N year^{-1}). This is because apart from Antarctica, Oceania is the driest continent globally, with deserts or semi-arid landscapes covering most of mainland Australia. Asia also has a significant percentage of its riverine nitrogen flux delivered to inland receiving waters or drylands, although the riverine flux to the oceans dominates (Fig. 36.7).

The global total riverine nitrogen flux parallels the total nitrogen inputs to the continents from both natural and anthropogenic sources. Thus, the total fluxes are comparable in North America, Latin America, Europe & FSU, and Africa at approximately 8 −10 Tg N year^{-1} each (Fig. 36.7). The flux from Asia is substantially higher and that from Oceania substantially lower, as is true for the nitrogen inputs to the landscape (Fig. 36.6). These fluxes are driven primarily by natural processes in Africa, Oceania, and Latin America and by anthropogenic nitrogen inputs in North America, Europe & FSU, and Asia.

Understandably, nitrogen fluxes from the continental land masses have the potential to impact the world's coastal zones. We quantified total nitrogen fluxes from the portions of each continent flowing to the major oceans based on data presented in Boyer *et al.*, 2006, and compare them to other published estimates (Fig. 36.8). The comparison among the ocean basins is fairly robust regardless of the modeling approach used, though it provides a glimpse into uncertainties associated with regional estimates of fluvial fluxes. All of the approaches are in consensus that the fluvial loadings from the continents to the coasts are tightly linked to human activities associated with food and fuel consumption. Data from Boyer *et al.* (2006)

indicate that the coastal Atlantic Ocean is one of the most significant receptors of nitrogen loadings, with approximately two-thirds of its fluxes contributed from the north Atlantic region, primarily from the highly developed land masses of eastern North America and western Europe. However, nitrogen fluxes to the north Pacific Ocean are also highly significant and are changing rapidly, largely influenced by the acceleration of the nitrogen cycle in Asia (Boyer *et al.*, 2004). As the region with the highest population and the most intensive and extensive agricultural practices, it also receives the highest N deposition rates globally (Galloway *et al.*, 2004). Unlike the United States and Europe which have seen rather stable rates of population growth in recent decades, East Asia continues to see very rapid increases in population, agriculture, and industrial activity, and will continue to play a major role in the global nitrogen budget in the future (Bashkin *et al.*, 2002; Bouwman *et al.*, 2005; Boyer *et al.*, 2006; Galloway *et al.*, 2004; Howarth *et al.*, 1996, Xing and Xhu *et al.*, 2002).

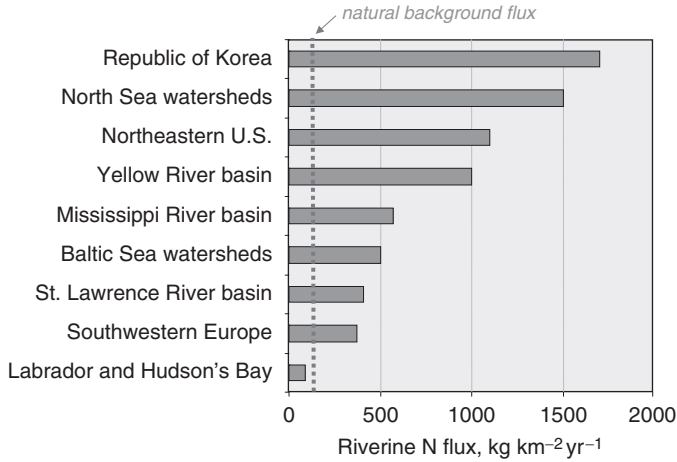
There is a great deal of variation in nitrogen fluxes off the landscape in rivers at scales smaller than the continents (Fig. 36.9). For example, within North America contemporary fluxes of nitrogen in rivers per area of watershed are estimated as 76 kg km^{-2} year^{-1} in Labrador and the Hudson's Bay area, as 566 kg km^{-2} year^{-1} in the Mississippi River basin, and as 1070 kg km^{-2} year^{-1} in the northeastern United States from Maine southward through Virginia (Howarth *et al.*, 1996; Fig. 36.10). At finer scales yet, more variation is observed: within the major watersheds in the northeastern United States, the riverine nitrogen flux per area varies from a low of 317 kg km^{-2} year^{-1} in the Penobscot River basin to 1755 kg km^{-2} year^{-1} in the


Figure 36.9 Fluxes of nitrogen (kg per km^2 of watershed area per year) from the landscape to coastal oceans in rivers for contrasting regions of the world in the temperate zone. The "natural background flux" is based on the intercept of plots of nitrogen export vs. NANI (such as shown in Figs. 36.2 and 36.4B). Data from Howarth *et al.* (1996, 2002); Bashkin *et al.* (2002).

both the Charles and Schuylkill River basins (Boyer *et al.*, 2002). Again, these variations in fluxes largely reflect the variation in nitrogen inputs to the landscape per unit area, although there is some influence of climate (Howarth *et al.*, 2006). For most of the regions shown in Fig. 36.9, the riverine flux of nitrogen is far greater—up to 15-fold greater—than is the expected natural background flux that would occur in the absence of human activity. Thus, while human activity may have roughly doubled the rate of creation of reactive nitrogen on the landscape of the planet, the distribution of this new nitrogen is far from uniform, and some regions have seen more than others an increase in the delivery of nitrogen to their coastal zones. Much of this increase has probably occurred during the last half century, since this is the time of global increase in the formation of reactive nitrogen (see Fig. 36.1).

6. DEVELOPMENT OF POLICY AND MANAGEMENT STRATEGIES FOR REDUCING COASTAL NITROGEN POLLUTION

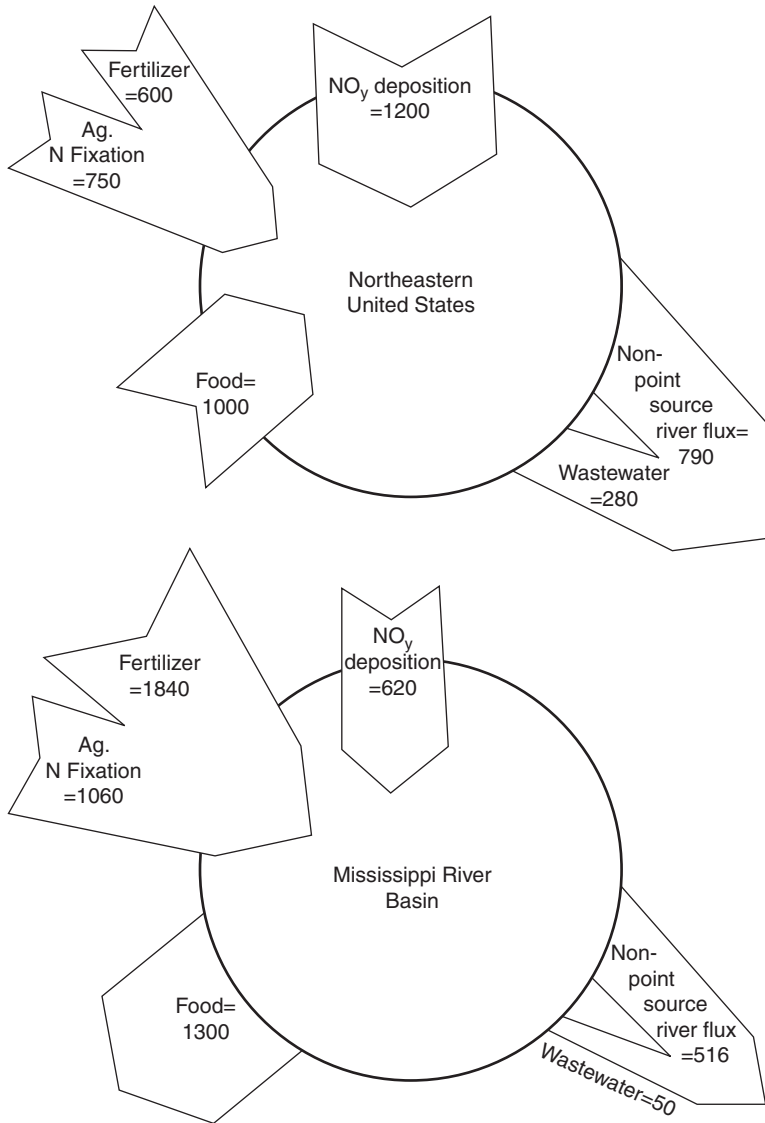
The marine science community has long recognized that eutrophication in coastal systems is usually driven by nitrogen inputs (Boynton *et al.*, 1982; Graneli *et al.*, 1990; Howarth, 1988; Nixon *et al.*, 1986, 1995; NRC, 2000). Nonetheless, while nitrogen fluxes to coastal systems have increased dramatically over the past 30 to 40 years, management actions over much of this time were disappointing. In both the United States and Europe, national strategies for dealing with eutrophication did not distinguish between lakes and coastal marine ecosystems, and therefore focused primarily on phosphorus control, throughout the 1970s and 1980s and in fact well into the 1990s (Howarth, 2005; Howarth *et al.*, 2005; Howarth and


Figure 36.10 Comparison of anthropogenic nitrogen inputs and associated riverine N exports (kg per km^2 of watershed area per year) in two contrasting water regions of the USA: The northeast USA and the Mississippi River basin. Modified from NRC (2000) based on data from Howarth *et al.* (1996).

Marino, 2006; NRC, 1993, 2000). At the national scale, policy makers and water-quality managers often did not consider or accept the evidence for nitrogen control of eutrophication in coastal marine ecosystems, in part because of the political legacy left from heated debates in the 1960s and 1970s over whether phosphorus or carbon caused eutrophication in lakes (Howarth and Marino, 2006; NRC, 2000). Some

progress was made during the 1990s at removing nitrogen from wastewater treatment plants, notably in Tampa Bay (Florida, USA), Himmerfjorden (Sweden), and to a lesser extent, Chesapeake Bay (USA) (Elmgren and Larsson, 2001; NRC, 2000). However, the majority of the nitrogen inputs to most coastal marine ecosystems come from non-point sources rather than from wastewater, and to date there has been little success in significantly reducing nitrogen pollution from non-point sources in either the United States or in most of Europe (Howarth *et al.*, 2005; NRC, 2000). The fact that progress can be made was illustrated in Denmark, where strong regulatory programs and deliberate, policy-based nutrient control strategies have led to substantial reductions in non-point source nitrogen pollution (Carstensen *et al.*, 2006; Grant *et al.*, 2006). Another notable reversal of nitrogen pollution from both point and non-point sources was unintentional: nitrogen loading to the Black Sea decreased greatly as the use of synthetic nitrogen fertilizer plummeted and point sources inputs were greatly reduced after the collapse of the former Soviet Union (Boesch, 2002; Garnier *et al.*, 2002).

National-scale efforts at controlling non-point source nitrogen inputs to coastal waters in most countries only began in the 1990s and are still largely not implemented (Howarth *et al.*, 2005). In the United States the Congress in 1990 for the first time addressed the problem of non-point source nitrogen pollution in coastal marine ecosystems when the Coastal Zone Act was reauthorized (Melillo and Cowling, 2002). This was largely a planning exercise, and states were required by 1995 to submit plans for nitrogen reduction to the federal government. Actual implementation of the first phase of nitrogen reduction was not scheduled until 2004 (Melillo and Cowling, 2002), and this has not yet in fact started as of 2006. The first efforts to control non-point sources nitrogen pollution by the European Union also began in the 1990s with the Nitrate Directive, a plan for better management of nitrogen from agricultural sources that was driven largely by concerns over drinking water quality (Chave, 2001). The Water Framework Directive replaced the Nitrate Directive and other water pollution directives in 2001, substituting a watershed based approach for managing phosphorus and nitrogen in all surface and ground waters (Chave, 2001).

The good news is that many technical solutions for reducing nitrogen pollution exist, and generally at reasonable cost, at least as viewed from the perspective of developed nations (NRC, 2000; Howarth, 2005; Howarth *et al.*, 2005). This provides hope that, as national strategies for nitrogen control become fully implemented, they may be effective. Unfortunately, though past experience constrains our optimism. Regional-scale efforts to reduce nitrogen pollution in Chesapeake Bay (target of 40% reduction set in 1987), in the North Sea (target of 50% reduction set in 1987), and in the Baltic Sea (target of 50% reduction set in 1990) had come nowhere near meeting their targets by 2000 despite 10 years or more effort (Boesch *et al.*, 2001; Elmgren and Larsson, 2001; OSPAR Commission, 2000). One possible reason is delays between management action and the resulting decrease in riverine nitrogen fluxes, due to storage in aquifers and soil organic matter (Grimvall *et al.*, 2000). However, the analysis of McIsaac *et al.* (2001) for the Mississippi River basin suggests that the time lag between nitrogen use in the landscape and nitrogen flux down the river is relatively short, with most nitrogen transported downstream within a few years of its introduction to the landscape. Also, the recovery of the Black Sea following the collapse of the

former Soviet Union occurred within a few years, and a large decrease in nitrogen flows to the system was observed in less than 1 year (Boesch, 2002).

The failure to adequately control non-point source nitrogen pollution to date – in the few cases where such controls have been attempted — probably lies in structural problems with the application of the control strategies (Boesch *et al.*, 2001; Boesch, 2002; Howarth, 2005; Howarth *et al.*, 2005; NRC, 2000). An analysis of some problems with the Chesapeake Bay case is illustrative:

1. The major sources of nitrogen inputs to Chesapeake Bay remain uncertain (NRC, 2000; Howarth *et al.*, 2002b). Management decisions have been based on the source estimates of the Chesapeake Bay model, which is a highly complex and largely unverified model (NRC, 2000). This model suggests that agriculture is the largest source of nitrogen to the Bay, but other lines of evidence suggest that atmospheric deposition may equal or even exceed the agricultural sources (Howarth, 2006). Management efforts have focused largely on the agricultural sources.
2. There has been little or no monitoring of the effectiveness of management practices that have been implemented (Boesch *et al.*, 2001; NRC, 2000). For example, the watersheds of Chesapeake Bay have had some of the most extensive efforts at repairing streams and riparian wetlands of any area in the United States, but these efforts have been among the least monitored of all projects in terms of their effectiveness (Bernhardt *et al.*, 2005; Palmer *et al.*, 2005). Similarly, the effectiveness of best management practices as applied in the watersheds of the Chesapeake has received little or no assessment.
3. The best management practices that have been applied to agriculture may be less effective than assumed (Howarth, 2005). For example, while the Chesapeake Bay model suggests that no-till agriculture is an effective approach for reducing nitrogen losses from fields, this has not been demonstrated in most field studies (Randall and Mulla, 2001). On the other hand, winter cover crops and switching to perennial crops are an extremely effective approach to reducing nitrogen pollution (Staver and Brinsfield, 1998; Randall and Mulla, 2001). Water quality managers in the past often have failed to distinguish between the effectiveness of practices for phosphorus pollution and for nitrogen pollution (Howarth, 2005).
4. Climate variation and change may be aggravating efforts to reduce nitrogen pollution. Watersheds in the northeastern United States that have more precipitation and higher freshwater discharge export a higher percentage of their nitrogen inputs (Howarth *et al.*, 2006). A generally wetter climate with greater freshwater discharge to Chesapeake Bay during many years in the 1990s compared to the 1980s may have partially counteracted management efforts at nitrogen control (Boesch *et al.*, 2001).

Clearly, management strategies to decrease the flow of nitrogen pollution to coastal marine ecosystems must be grounded in policies that adequately consider the sources of nitrogen pollution, that allow for uncertainty in analysis, that monitor the effective of control strategies, that consider the greater mobility of nitrogen than phosphorus in the environment, and that understand the potential consequences of climate change and variability.

Silicon:Nitrogen Interactions in the Marine Environment

Raphael M. Kudela

Contents

1. Introduction

A central challenge of environmental research is to understand the feedbacks that connect elemental cycling with ecosystem structure and function. This challenge has become of increasing importance as human activities continue to change the elemental ratios (Turner *et al.*, 2003b) and eutrophy the coastal ocean (Galloway and Cowling, 2002; Chapter 11 by Paerl and Piehler, this volume) and elevate atmospheric carbon dioxide concentrations, with subsequent changes to the terrestrial and marine environments (Houghton *et al.*, 2001). Phytoplankton are the link between physical, chemical, and atmospheric changes in the oceanic environment. The carbon cycle is driven by phytoplankton photosynthesis and nitrogen, phosphorous, silica, and iron are all potentially limiting nutrients for phytoplankton.

The efficiency of the "biological pump" has also been proposed as the mechanism by which atmospheric CO_2 levels are regulated on glacial/interglacial time scales (e.g., Martin, 1990). Ice core records show that for the last 420,000 years atmospheric CO_2 has oscillated between low levels (~180 ppm) during glacial periods and higher levels (~280 ppm) during interglacials (Petit et al., 1996). Thus long-term changes in the efficiency of nutrient use by marine phytoplankton, especially in those areas that have a high nutrient, low chlorophyll (HNLC; Minas et al., 1986) character in the present-day ocean, may be a key link connecting surface water geochemistry, oceanic biology, atmospheric CO_2, and global climate.

Diatoms are ubiquitous in the world's aquatic systems, including both benthic and pelagic marine ecosystems, freshwater lakes and streams, and in sea ice (Garrison et al., 1986), and are the most species-rich of all algae (Mann, 1999). Because of this ubiquity, diatoms account for a large fraction of the total carbon fixation in the modern oceans (Tréguer and Pondaven, 2000). Diatom productivity has been estimated to account for as much as 40% of the annual ocean carbon fixation, or approximately 15–20 Pg C year^{-1} (Field et al., 1998). The importance of this productivity to the global carbon cycle has been equated to the contribution of grasses to terrestrial productivity (Raven and Waite, 2004), or the total impact of the terrestrial rain forests (Field et al., 1998). This productivity forms the basis for the short, efficient transfer of energy supporting the economically and ecologically important fisheries that dominate in coastal upwelling systems (Ryther, 1969).

These unicellular, photosynthetic eukaryotes evolved relatively recently, appearing ca. 180–250 million years ago as evidenced by both the fossil record and molecular techniques, with a major expansion occurring in the Cretaceous (Falkowski et al., 2004; Raven and Waite, 2004). Diatoms have an absolute requirement for silicon (Lewin, 1962). Although there are other marine organisms which utilize silica (and nitrogen) in the marine environment, including silicoflagellates, radiolaria, and many sponges (Siever, 1991), the rise of the diatoms fundamentally altered the marine silica cycle (Harper and Knoll, 1975; Maliva et al., 1989; Racki and Cordey, 2000), and diatoms are the dominant organisms in the modern ocean which utilize both silicon and nitrogen (but see Maldonado et al., 2005). This dominance of the biogeochemical cycling of Si by diatoms in the modern ocean is so complete that each atom of Si derived from the weathering of terrestrial rocks is recycled an average of 39 times by diatoms before burial in the ocean, with an estimated residence time of 400 years in surface waters (Tréguer et al., 1995).

Although diatoms and Si cycling have long been of interest to oceanographers (e.g., Simpson and Volcani, 1981), this interest was rekindled when sediment-trap data from a variety of ocean habitats showed strong temporal correlation between the downward fluxes of particulate organic carbon (POC) and diatom opal, implying that diatoms are the autotrophic source of much of the sinking POC. Diatoms are known to play a major role not only in carbon fixation, but also in the export flux of biogenic material to depth (Dugdale and Wilkerson, 1998; Goldman, 1988; Goldman, 1993; Goldman et al., 1992; Nelson et al., 1995; Ragueneau et al., 2000; Tréguer et al., 1995; Villareal et al., 1993), including the vast regions of Fe-limited, HNLC oceans (Boyd, et al., 2007, Boyd, 2004; Boyd et al., 2000; Coale et al., 1996,

2004; Tsuda *et al.*, 2003). Fast rates of NO_3 uptake and high *f*-ratios are generally caused by a dominance of larger phytoplankton, which on death sink faster and are considered to be the major contributors of export (or new) production (Buesseler, 1998), thus providing diatoms with another key role in controlling climate (Tréguer and Pondaven, 2000). Because of their key role in the biogeochemistry of the oceans, diatoms are important components for the cycling of carbon (C), nitrogen (N), silicon (Si), phosphorous (P), and iron (Fe).

Because of the key role that diatoms play in global productivity, their dominance in regulating export flux of biogenic material, the ubiquity and diversity of diatom species, and their role in food web dynamics, diatoms as a group have been well studied, and there are many excellent review articles focusing on diatoms and their physiology, biogeochemistry, and evolution (e.g., Falkowski *et al.*, 2004; Kristiansen and Hoell, 2002; Lewin, 1962; Martin-Jézéquel *et al.*, 2000; Ragueneau *et al.*, 2000; Raven and Waite 2004; Round *et al.*, 1990; Siever, 1991; Tozzi *et al.*, 2004; Yool and Tyrrel 2003). The focus of this review is on the less well-documented interactions between silicon and nitrogen in the marine environment across a variety of scales. Towards that end, this review of Si:N interactions focuses primarily on diatoms, starting with newly available genomic information (Armbrust *et al.*, 2004), and continuing on to a review of cellular Si-metabolism, emphasizing interactions with other cellular constituents. This leads naturally to a discussion of physiological and ecophysiological Si:N interactions, with an emphasis on the (un)coupling of Si-metabolism from photosynthesis and C:N assimilation, as well as the modulating effects of trace-metal interactions such as Fe and Zn. The role of Si:N interactions in controlling export production and biogeochemical cycling, both in the modern and paleo ocean is then discussed, followed lastly by anthropogenic changes in Si:N ratios and their consequences.

2. Cellular Processes

2.1. Molecular ecology of diatoms

Although molecular techniques have been used in oceanographic studies for many years, it is only recently that the ready availability of genomic information for algae has flourished (Grossman, 2005). Of relevance to this review of Si:N interactions, nitrogen metabolism by diatoms has been reasonably well described at the molecular level, particularly with the full genome sequencing of the diatom *Thalassiosira pseudonana* (Armbrust *et al.*, 2004) and *Phaedactylum tricornutum* (*http://genome.jgipsf.org/Phatr2/Phatr2.home.html*), and the availability of many partial sequences and expressed sequence tags (ESTs) for other diatoms (Grossman, 2005), particularly *P. tricornutum* (Montsant *et al.*, 2005). This molecular information has provided the characterization of several potentially rate-limiting steps such as nitrate and nitrite transport (Armbrust *et al.*, 2004; Hildebrand and Dahlin, 2000), silicic acid transport (Armbrust *et al.*, 2004; Hildebrand and Wetherbee, 2003; Hildebrand *et al.*, 1997, 1998; Thamatrakoln and Hildebrand, 2005), glutamine synthetase (e.g., Robertson *et al.*, 1999, 2001; Takabayashi *et al.*, 2005), and nitrate reductase (Allen *et al.*, 2005),

while many other functional genes not listed here have also been characterized (e.g., review by Ward, 2005).

Molecular approaches have been especially useful in the characterization of nutrient transporter genes. Transporters are of particular interest since they are typically highly regulated, interact with specific nutrients, and are key to the environmental response of diatoms in the natural environment. Besides the silica class of transporters (SITs; Hildebrand *et al.*, 1997, 1998; Thamatrakoln *et al.*, 2006), Hildebrand and Dahlin (2000) have isolated a nitrate transporter (NAT), and more recently, Hildebrand (2005) cloned and isolated a class of ammonium transporters (AMT), while the whole–genome sequencing of *T. pseudonana* has identified multiple NAT and AMT genes, a single nitrite transporter, and transporters for other inorganic nutrients and metals (Armbrust *et al.*, 2004).

Once these transporter genes have been identified, it is possible to combine more traditional physiological experiments with molecular methods to elucidate the response, regulation, and biochemical pathways for various nutrients in diatoms. As an example, recent work has focused on the development of a "molecular *f*-ratio" by examining the genes encoding for nitrite, nitrite, and ammonium assimilation directly. Hildebrand and Dahlin (2000) showed that NAT genes are strongly induced by N starvation, but repressed in the presence of NH_4 (even NH_4NO_3); in contrast, the AMT genes are less regulated by the presence or absence of N, but are always active (Hildebrand, 2005). Further along in the biochemical pathway, Takabayashi *et al.* (2005) have shown that the gene *glnII* isolated from the diatom *Skeletonema costatum*, which encodes glutamine synthetase (GS), the isoenzyme linking C and N metabolism in the cell, is up regulated in response to external NO_3, but not NH_4. These results provide intriguing evidence for both the molecular basis for the apparent preference of NH_4 versus NO_3, as well as functional assays for "new" versus "regenerated" production (sensu Dugdale and Goering, 1967).

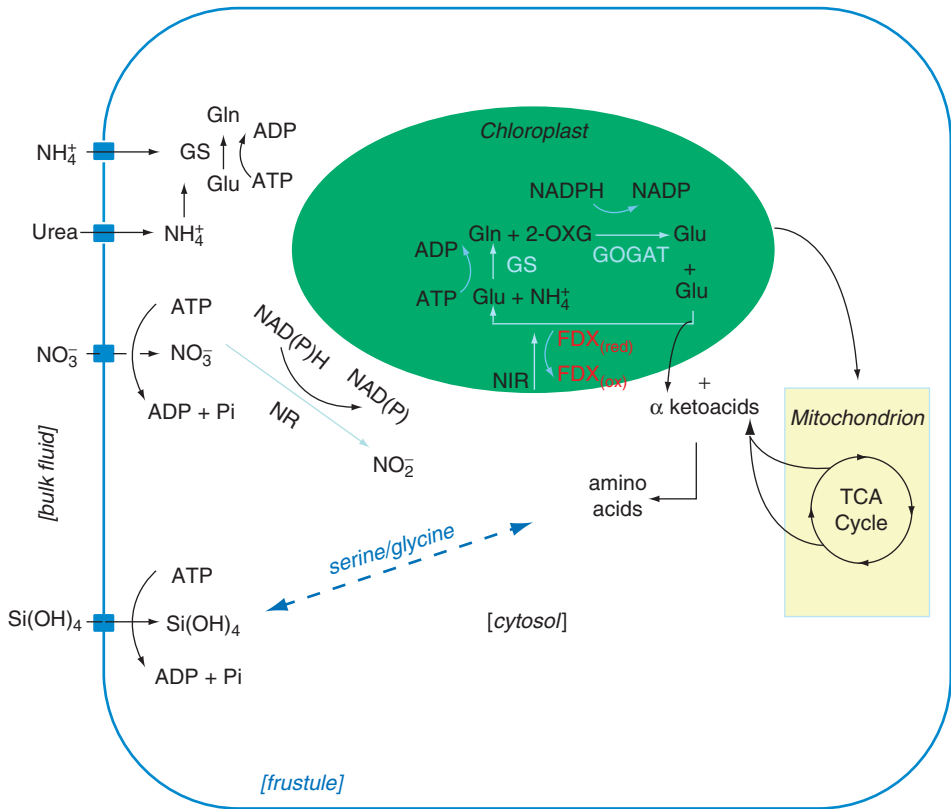
Despite the rapid development of molecular approaches for algal ecophysiology, much work remains to be done. For example, until the completion of the *T. pseudonana* genome, it was not known that this diatom, at least, contains a complete urea cycle, similar to animals, while about half the genes sequenced from *T. pseudonana* have no known function (Armbrust *et al.*, 2004). It is also not clear how representative a genome from a single species is; using an example relevant to this review, recent evidence shows disparate copy numbers for AMT in the diatoms *T. pseudonana, Thalassiosira weissflogii*, and *Cylindrotheca fusiformis*, which may be related to physiological function (Hildebrand, 2005), while structural differences (suggesting differences in transporter mechanisms and/or regulation) have been found in the SIT class of genes from centric and pennate diatoms (Thamatrakoln *et al.*, 2006). Using the genome for *T. pseudonana* and the EST libraries for *P. tricornutum* (the two best characterized diatoms at a molecular level), Montsant *et al.* (2005) also reported differences between pennate and centric diatoms for several other metabolic pathways, including carbon-concentrating mechanisms, cytosolic acetyl-Coenzyme A production, and fructose-1,6-biphosphate metabolism.


Figure 37.1 A simplified schematic of the major biochemical pathways involved in Si and N metabolism by diatoms. Metabolic steps are represented by arrows. Dashed arrow indicates a proposed, but undocumented, interaction between serine and glycine amino acid pools, Si–transport and deposition, and Rubisco. Adapted from figures and content in Armbrust *et al.*, 2004; Falkowski and Raven, 1997.

Although genomic methods have only begun to characterize the apparently wide diversity of diatoms, a general understanding of how Si and N interact at the molecular and biochemical level has emerged (Fig. 37.1). Both Si and N are actively transported across the cell membrane, although N is much more closely linked to the light reactions of photosynthesis, while Si-transport is driven by respiration (see below). Once taken up, both Si and N can efflux from the cell (Azam *et al.*, 1974; Syrett, 1981), and there is a direct coupling of Si and N metabolism due to the requirement for amino acids (particularly serine and glycine) in the formation of the cytoskeleton (see review by Martin-Jézéquel *et al.*, 2000). The evolutionary role for Si is still debated (Raven and Waite, 2004), but it has been suggested that Si–metabolism may originally have been involved in DNA synthesis (e.g., Medlin *et al.*, 2000; Okita and Volcani, 1978). Additional genome sequencing will undoubtedly refine our understanding of Si:N interactions at the molecular level in the near future.

2.2. Nutrient transport kinetics

Laboratory studies have suggested that there are three modes of transport for silicic acid (reviewed by Martin-Jézéquel *et al.*, 2000): first, silicic acid may be rapidly transported across the cell membrane, following ''surge uptake'' kinetics. This occurs primarily in Si-starved cells with cell quotas (Droop, 1968, 1973) near minimal values. Second, silicic acid uptake can be controlled internally, presumably due to regulation of silica precipitation and deposition (e.g., Hildebrand *et al.*, 1997). Third, silicic acid uptake may be controlled externally due to substrate limitation.

Under substrate limitation, silicic acid uptake is expected to follow Michaelis–Menten kinetics, and numerous laboratory and field experiments have demonstrated this to be true for both silicate and the various nitrogen species in diatoms (Azam *et al.*, 1974; Eppley *et al.*, 1969; Goering *et al.*, 1973; McCarthy, 1972; MacIsaac and Dugdale, 1969; Paasche, 1973a,b):

$$V = V_{max}[S]/(K_s + S) \tag{37.1}$$

where V is the specific uptake rate (t^{-1}), S is the substrate (N or Si in this case; μM), V_{max} is the substrate-saturated uptake rate, and K_s is the half-saturation constant, or the concentration of S at which uptake is half of V_{max}.

Although the biochemistry of silicon metabolism within the diatom is still not completely understood, multiple silicic acid transporter (SIT) genes have been characterized for various diatom species (Armbrust *et al.*, 2004; Hildebrand *et al.*, 1997, 1998), with multiple SIT genes expressed in the same organism at different times and under different environmental conditions (Hildebrand *et al.*, 1998). It is likely that these multiple SIT genes encode transporters with varying affinities for silicic acid. This strongly suggests that multi-phase kinetics should be observed for a given species, and is consistent with experimental observations. Previous investigators (e.g., Brzezinski *et al.*, 2005; Conway and Harrison, 1977; De La Rocha *et al.*, 2000; Jacques, 1983; Leynaert *et al.*, 2004) have demonstrated that the half-saturation constant (K_s) for silicic acid is highly variable ($K_s = 0.2$–55 μM), and may increase with increasing ambient concentrations, while Sullivan (Sullivan, 1977) showed that K_s and V_{max} varied as a function of the stage of cell wall biosynthesis. Similar to silicic acid, nitrogen transport also exhibits both surge uptake (Conway and Harrison, 1977) and multiphasic kinetics (see review of Collos *et al.*, 2005).

Although phytoplankton (including diatoms) commonly grow at non-Redfield proportions for C:N when either N or light is limiting (e.g., Geider and LaRoche, 2002; Goldman *et al.*, 1979; Falkowski, 2000), with few exceptions (Azam and Chisholm, 1976; Dortch and Whitledge, 1992; Dugdale, 1972; Dugdale and Wilkerson, 1998; Dugdale *et al.*, 1995; Nelson and Tréguer, 1992; Sommer, 1986, 1994a,b; Turner *et al.*, 2003a; White and Dugdale, 1997) nitrogen (*cf.*, Carpenter and Capone, 1983) and iron (Martin, 2002) have generally been assumed to be more broadly limiting in the modern ocean than Si.

Under optimal conditions, diatoms assimilate Si and N in approximately equimolar ratios (Brzezinski, 1985), essentially extending the Redfield ratio (Redfield *et al.*, 1963) to include Si. However, unlike N, many diatom species exhibit

markedly different half-saturation constants for uptake (Michaelis–Menten kinetics) versus growth (Monod, 1942), where Monod kinetics are described as in Eq. (37.1), but with the substitution of μ (specific growth rate; t^{-1}), $\mu_{\max}$, and K_μ:

$$\mu = \mu_{\max}[S]/[K_\mu + S] \qquad (37.2)$$

Although uptake (Michaelis–Menten) kinetics for silicic acid typically range from 0.2 to 55 μM, with most values <10 μM, half-saturation kinetics for Si-limited *growth* (K_μ) are substantially lower, ranging from *ca.* 0.04 to 1.5 μM (Martin-Jézéquel *et al.*, 2000; Nelson and Dortch, 1996; Ragueneau *et al.*, 2000). As a result, many, if not most, diatoms can maintain near maximal growth rates despite external limitation of Si in the media or environment. This is accomplished by allowing the frustule to become thinner, effectively reducing the per-cell concentration (quota) of Si and allowing the C:Si and N:Si ratios to increase (Brzezinski *et al.*, 1990; Claquin *et al.*, 2002; Nelson and Dortch, 1996; Paasche, 1973a).

2.3. Silica to nitrogen ratios energetics

Once Si or N substrates have been transported across the cell membrane, the substrates must be incorporated into the cell via a variety of biochemical processes. Much of this is beyond the scope of this review (see Chapter 7 by Mulholland and Lomas and Chapter 32 by Berges and Mulholland, this volume); here I will focus on the similarities and differences in the assimilation of N versus Si, and the role of photosynthetic energy.

Ultimately, photosynthetic organisms derive their energy from the conversion of sunlight. After carbon, nitrogen uptake and assimilation is the primary sink for photosynthetic reducing power, requiring a minimum of 288 kJ mol^{-1} of NH$_4^+$ (the form of nitrogen required with carbon skeletons to form amino acids; (Syrett, 1981) if the initial substrate is NO$_3^-$ (Falkowski and Raven, 1997). It is not surprising, then, that C and N metabolism, and therefore photosynthesis, are closely linked in algae (*cf.* Falkowski and Raven, 1997).

N-limitation frequently manifests as a decoupling of C and N responses to irradiance, resulting in dark-uptake of N compounds (e.g., Clark *et al.*, 2002), although dark-uptake is also influenced by diel cycles (e.g., Cochlan *et al.*, 1991a; Fisher *et al.*, 1988; Miyazaki *et al.*, 1987; Shiomoto and Matsumura, 1993). In many cases, however, particularly for coastal waters, there is a direct correspondence between irradiance and both C and N uptake rates, with a positive uptake-irradiance response for both elements (e.g., Cochlan *et al.*, 1991b; MacIsaac and Dugdale, 1972; Kanda *et al.*, 1989; Kudela and Cochlan, 2000; Kudela *et al.*, 1997). This can be mathematically described as either a Michaelis–Menten type curve with the addition of a dark-uptake value (V_D, h^{-1}), or using a photosynthesis versus irradiance (P vs E) model such as proposed by Platt and Gallegos (Platt and Gallegos, 1980), modified to account for dark uptake (Cochlan *et al.*, 1991b):

$$V = V_D + V_{\max}(E/E_K + E) \qquad (37.3)$$

$$V = V_s(1 - e(-\alpha \bullet E/V_s))(e - \beta \bullet E/V_s) + V_D \qquad (37.4)$$

where E is irradiance (μmol photons m^{-2} s^{-1}), E_K is the half-saturation value for irradiance, alpha and beta are the light-limited and light-inhibited slopes of the uptake–irradiance curve, and V_s is the uptake rate in the absence of inhibition. Thus, it is possible to describe both C and N responses to irradiance using the same mathematical models, and to extend this concept to (for example) calculation of quantum efficiency and yield for N independent of the quantum yield for carbon (Kudela and Chavez, 1997).

At the biochemical level, N-limitation manifests as a loss of chlorophyll a, and an increase in nonphotochemical carotenoid compounds (Herzig and Falkowski, 1989; Geider *et al.*, 1993). It also results in a direct reduction in the efficiency of photosystem II (PSII), primarily due to decreasing thermal efficiency (Berges *et al.*, 1996; Geider *et al.*, 1993; Kolber *et al.*, 1988). This is readily assayed by measuring the ratio of variable to maximal fluorescence (F_v/F_m), which decreases with increasing N-stress (Beardall *et al.*, 2001; Berges *et al.*, 1996; Kolber and Falkowski, 1993; Kolber *et al.*, 1998). C and N uptake and assimilation, then, are directly linked at the level of photosynthesis because of the direct coupling of C and N metabolism and the requirement for photo-reductant.

In contrast to C and N, Si-metabolism is metabolically inexpensive; for a given cell size, a silicon frustule requires *ca.* 1/10 the total metabolic energy of an equivalent cell wall composed of carbon compounds (Raven, 1983). Si-metabolism is also not directly coupled to photosynthesis. Si-transport and deposition are driven by oxidative phosphorylation (Blank and Sullivan, 1979; Blank *et al.*, 1986; Sullivan, 1976), while serine and glycine, the amino acids which provide the main fraction of the protein matrix for Si-deposition (Werner, 1977), are terminal substances produced during photorespiration (Burris, 1977). Si-metabolism is instead linked to the regulation of cell division (Fig. 37.2) and growth rates (Brzezinski *et al.*, 1990; Martin-Jézéquel *et al.*, 2000; Volcani, 1981).

The cell cycle is typically divided into four phases, G1, S, G2, and M, corresponding to DNA replication (S), mitosis and cell division (M), and two "gaps" (G1, G2) when growth occurs (Mitchison, 1971). Si-uptake and assimilation occurs predominantly just before G2 and during M (Brzezinski, 1992; Brzezinski *et al.*, 1990; Martin-Jézéquel *et al.*, 2000; Schmid, 1994). Because cell division can occur in both the light and dark, Si-metabolism remains largely independent of irradiance, with the difference between light/dark uptake most often attributed to the synthesis or activation of a transient compound in the light required for Si-transport. Blank and Sullivan (1979) demonstrated that silicic acid transport requires ATP, a byproduct of photosynthesis. They also reported, however, that it takes >6 h for transport to degrade, and that it does so fairly slowly. The implication is that silicic acid utilization is only weakly controlled by the availability of photosynthate and is essentially uncoupled from ambient irradiance, unlike C and N assimilation, which are strongly dependent on light.

Despite the potentially complex interactions between C, N, Si, irradiance, and growth stage in diatoms, progress has been made towards developing generalized mechanistic models of diatom physiology (e.g., Claquin *et al.*, 2002; Flynn and Martin-Jézéquel, 2000). Although cell division and growth rate have the most direct impact on Si-metabolism (*cf.*, Martin-Jézéquel *et al.*, 2000), light, temperature,
Figure 37.2 A simplified schematic view of cell cycle progression in diatoms, with critical arrest points and dominant processes indicated. Most diatoms arrest at the G1/S boundary, but a secondary arrest point can occur during the G2/M phase. M: mitosis; S: DNA replication (synthesis); G1 and G2: gap phases.

and both macronutrient (N, P) and micronutrient (Zn, Fe) concentrations also affect growth rate, and therefore indirectly, Si-metabolism. Recent genomic analysis of T. pseudonana suggests that the link between Fe and Si metabolism may also be more direct, with a set of 84 genes showing an inducible response to both Si and Fe limitation (Mock et al., 2008). Conversely, Si is strongly regulated by the cell cycle, as are some components of nitrogen metabolism (Claquin et al., 2004; Hildebrand and Dahlin 2000; Olson et al., 1996; Vaulot et al., 1987). Under nutrient limitation, the cell cycle can be prolonged, or even halted. For example, N stress prolongs G1 as well as G2 (Olson et al., 1996), and previous authors have identified the G2+M phase in diatoms as an ''arrest point'' for cell division under various conditions (Brzezinski et al., 1990; Claquin et al., 2002; Martin-Jézéquel et al., 2000). When this occurs, Si-uptake continues so long as Si-substrate limitation does not occur, but cell division is halted, resulting in increased per-cell Si content and frustule thickness. Conversely, under Si-limitation, cell division is also halted but there can be increased cell quotas of C, N, P, and chlorophyll (Harrison et al., 1977).

Although any stressor that slows growth in diatoms can result in a shift in the elemental composition of diatoms (e.g., Claquin et al., 2002; Harrison et al., 1977), the shift towards higher values in the Si:C and Si:N ratio has frequently been used as a diagnostic indicator for impaired growth due to Fe-limitation (e.g., Firme et al., 2003; Hutchins and Bruland, 1998; Takeda, 1998). When diatoms are stressed for Si rather than some other environmental factor, cell growth is also halted at the end of G1 and G2 (Brzezinski et al., 1990), although obviously there is no accumulation of Si in the cell. Intriguingly, a recent study by De La Rocha and Passow (2004)

suggests that diatoms, by arresting growth in the G2+M stage under Si-limitation, may obtain a competitive advantage relative to cells limited by N (but see discussion in Martin-Jézéquel *et al.*, 2000; Raven and Waite, 2004). This is because Si-starved cells can accumulate excess C and N, giving these cells a head start when rate-limiting nutrients are resupplied. Diatoms that are N-starved often exhibit lower cell quotas for C, chlorophyll, proteins, and amino acids (Dortch, 1982; Harrison *et al.*, 1977), thus making rapid recovery upon nutrient resupply more difficult. De La Rocha and Passow (2004) further demonstrate via the use of a model simulation that descendents of N-starved cells would never catch up to descendents of Si-starved cells under a pulsed nutrient scenario such as occurs in upwelling regions (see Chapter 17 by Wilkerson and Dugdale, this volume).

Despite this decoupling of C, N, Si, and irradiance (or the occurrence of a much more complicated interaction precluding a direct relationship), there is evidence in the field and laboratory for a direct relationship between Si-metabolism and irradiance under some conditions. As an example, Fig. 37.3 presents the results of simultaneous tracer measurements for carbon (^{14}C), nitrogen (^{15}N), and silica (^{32}Si) from a diatom-dominated natural assemblage during a typical spring upwelling event (described in more detail by Brzezinski *et al.*, 1997; Kudela and Chavez, 1997). All of the substrates demonstrate a positive uptake versus irradiance response, which is not in Redfield proportions over the short (*ca.* 4 h) duration of the experiment. These results are similar to a field study in the Hudson River estuary by Malone *et al.* (1980), who found carbon assimilation and Si-metabolism to be coupled, with strong diel periodicity evident. Despite the overall pattern of uncoupling between C (light) and Si-metabolism, some field studies have also shown a decrease in Si-uptake near the bottom of the photic zone (e.g., Brzezinski *et al.*, 1997, 2001; Leynaert *et al.*, 2001; Smith *et al.*, 1999), suggestive of, at minimum, Redfield-ratio coupling of metabolism.

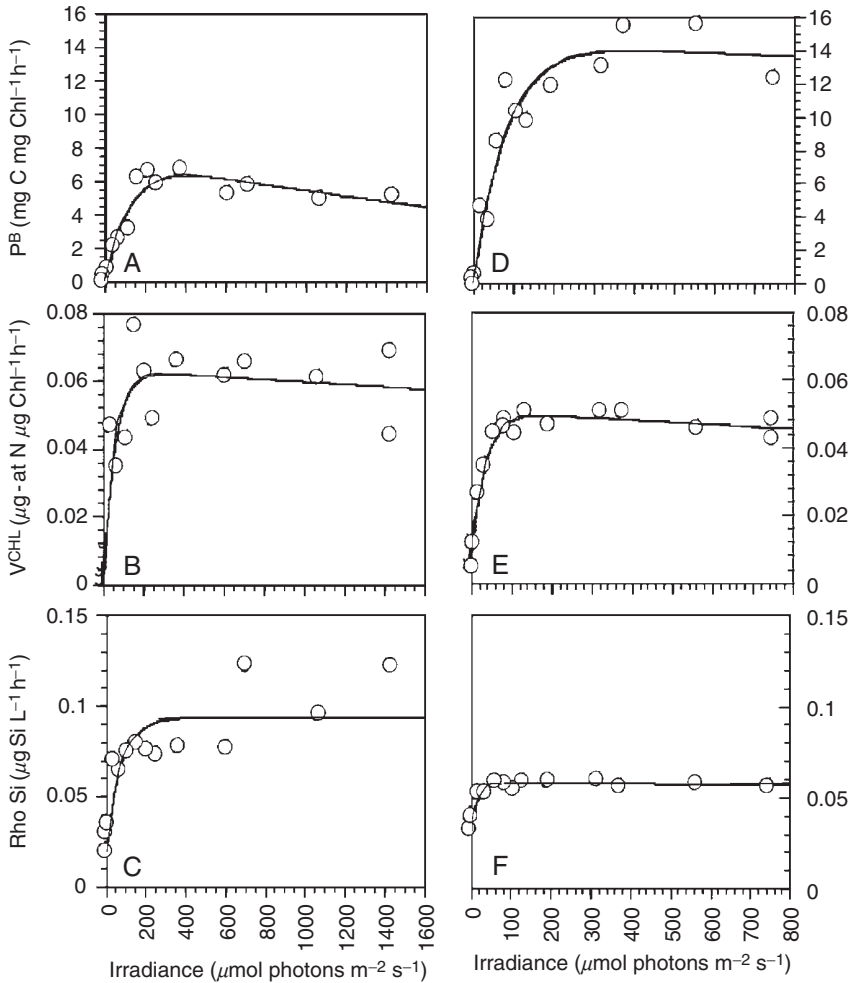
There is also evidence for a feedback-mechanism between Si and photosynthetic performance, contrary to expectations. Lippemeier *et al.* (1999) found that in batch culture, the diatom *T. weissflogii* decreased photochemical efficiency in response to Si-limitation as measured by a pulsed amplitude modulation (PAM) fluorometer. This response looks functionally like Fe-limitation, with a decrease in photosynthetic performance under increasing Si stress; as with Fe-limitation, this inhibition is readily and rapidly (20 min) reversible with the addition of $Si(OH)_4$, followed by a prolonged (18 h) recovery to full health, as determined by changes in variable fluorescence. More recently, Claquin *et al.* (2004) demonstrated that photosynthetic capacity in *C. fusiformis* is highest during G1, directly linking Si-metabolism and photosynthetic competency to changes in the cell cycle. We have extended the results of Lippemeier *et al.* (1999) to Si-limited chemostats and batch cultures using the toxic diatom *Pseudo-nitzschia multiseries* (Fig. 37.4), grown under either Si or N-limitation, at a range (16–100% of maximal) of growth rates and constant light (Kudela *et al.*, 2002). The quantum efficiency of PSII (variable fluorescence: F_v/F_m) declined from the theoretical maximum (*ca.* 0.7) at 100% growth rate to *ca.* 50% of maximum at 16% growth rate. The decrease in F_v/F_m indicates that decreases in photochemical efficiency are regulated under both quasi-steady-state (chemostat) as well as nonsteady-state (batch) conditions, and have been confirmed for a second species (*P. australis*). As with *T. weissflogii*, the initial recovery upon re-addition of Si occurred nearly instantaneously, but the duration to full health (as indicated by


Figure 37.3 Uptake versus irradiance plots for two stations from Monterey Bay, California showing carbon (A, D) nitrate (B, E) and silicate (C, E) uptake estimated using stable (^{15}N) and radiotracers (^{14}C, ^{32}Si). The first station (A–C) was collected from freshly upwelled surface waters; the second station (D–F) was collected downstream, *ca.* 4 days from the source of upwelling. Experiments were conducted at ambient temperature for ca., 4 h at midday, as detailed in (Brzezinski *et al.*, 1997; Kudela and Chavez, 1997). Data were fitted to a PE relationship using Eq. (37.3).

F_v/F_m) depended on the amount of time the cells were left in Si-starved media. Recovery in fluorescence parameters was similar to recovery times seen for other nutrients such as N, P, and Fe (Berges *et al.*, 1996; Geider *et al.*, 1993). The rapid recovery (minutes) rules out the recovery of photochemical efficiency by a coupling to protein synthesis, which occurs on the order of hours (Werner, 1977), while the decoupling of F_v/F_m and optical density (division rates) suggest that the changes are not directly attributable to a reinitiating of the cell cycle.
Figure 37.4 Replicate *Pseudo-nitzschia multiseries* cultures were grown under 24 h light (100 μmol photons m^{-2} s^{-1}) at 15 °C for 4 days as an auxostat (chemostat with growth limited by pump rate) with Si-limited f/2 media. On day −4, the pumps were turned off, forcing the cultures into Si-limitation. On days 0, 4 Si-spikes (10 μM) were added. On day 5, trace-metals (f/2 stock) was added, with no apparent response. Optical density (cell abundance) and variable fluorescence were determined from a PAM fluorometer and are plotted versus time (dashed vertical lines indicate additions of unenriched seawater; dashed horizontal line indicates maximal F_v/F_m values in healthy cells). A rapid decline and recovery of variable fluorescence indicates impaired photosynthetic performance, and functionally mimics the response of Fe-limitation, with recovery times dependent on the length of time spent in Si-deprived conditions.

The results of these field and laboratory experiments imply that Si-metabolism is more tightly linked to photosynthesis than previously thought. It is not clear what mechanism is responsible for this interaction; Lippemeier *et al.* (1999), posited that there was an inhibitory feedback on the assimilatory enzyme ribulose bisphosphate carboxylase/oxygenase (RubisCO). Under Si-limitation, a buildup of the internal pools of the amino acids serine and glycine, which are used as part of the protein matrix during Si-deposition, results in a down-regulation of RubisCO, and to a decrease in photosynthetic efficiency caused by a change in the electrochemical gradient of the chloroplast (details are provided in Lippemeier *et al.*, 1999). In our study we saw no evidence for a change in the ratios of serine and glycine relative to other amino acids, nor a pronounced increase in the free amino acid pools necessary for this mechanism (Smith, unpublished data).

Another potential connection between Si-metabolism and photosynthetic competency has been proposed by Milligan and Morel (2002). Those authors demonstrated that biogenic silica provides good buffering capacity in seawater, and could potentially be used as a proton donor. Specifically, Milligan and Morel suggest that to enhance the activity of RubisCO, which is undersaturated for CO_2 at ambient

seawater conditions, diatoms employ external carbonic anhydrase (CA) as a carbon concentrating mechanism. CA activity requires a proton buffer, the diatom frustule. Those authors further speculate that other biochemical processes may also benefit from a proton buffer, giving diatoms a competitive advantage relative to other microalgae. Regardless of the underlying mechanism, it is clear that there is the potential for direct coupling of photosynthesis and Si-metabolism, and hence a more direct relationship between C, N, and Si via photosynthesis in diatoms.

3. Ecological Interactions

3.1. Diatoms versus coccolithophores

Diatoms tend to dominate the phytoplankton community whenever conditions are optimal for phytoplankton growth, and provide a disproportionate fraction of the total and export primary production in the world's oceans, including the oligotrophic tropical oceans (Leynaert *et al.*, 2001). Sediment-trap data from a variety of ocean habitats showed strong temporal correlation between the downward fluxes of POC and diatom opal, implying that diatoms are the autotrophic source of much of the sinking POC (Armstrong *et al.*, 2002; Klass and Archer, 2002). Fast rates of NO_3 uptake and high *f*-ratios are generally caused by a dominance of larger phytoplankton, which on death sink faster and are considered to be the major contributors of export (or new) production. Small plankton sink relatively slowly (or not at all) and are recycled primarily within the euphotic zone by microzooplankton predation, even in systems where they are the dominant primary producers (Michaels and Silver, 1988; Probyn, 1992). Studies of natural assemblages using size-fractionation and ^{15}N tracers have demonstrated that small phytoplankton use relatively higher proportions of NH_4 and urea for growth, resulting in lower *f*-ratios (e.g., Kudela and Dugdale, 2000; Probyn, 1985; Sahlsten, 1987). Thus, diatoms also have a disproportionate influence on marine biogeochemical cycles and global climate (e.g., Field *et al.*, 1998; Raven and Waite, 2004).

Diatom dominance in the modern ocean tends to occur whenever there is more than *ca.* 2 µM Si, regardless of time of year, and over a range of environmental conditions (e.g., Egge and Aksnes, 1992). Diatom dominance includes spring blooms, coastal upwelling, equatorial upwelling, river plumes, decay of ocean eddies and transient open ocean wind events, and Fe-perturbations (see review by Ragueneau *et al.*, 2000). Diatoms are particularly well adapted to conditions favoring large cells (Chisholm, 1992). Diatoms have low surface to volume ratios, and are dominant in high-nutrient, turbulent conditions (e.g., Margalef, 1978). In addition to size-specific effects, diatoms are also well adapted to growth under low light conditions (Goldman, 1993), and there is evidence that the large capacity for dark-uptake of nitrogen by diatoms may provide a competitive advantage over other organisms such as flagellates (Clark *et al.*, 2002), while diatoms may also utilize N assimilation as an electron sink when rapidly transferred from low to high light conditions (Lomas and Glibert, 2000; Lomas *et al.*, 2000). As a result, so long as

silicic acid and other nutrients are nonlimiting, diatoms tend to exhibit higher maximum growth rates and dominate the algal assemblages (e.g., Egge and Aksnes, 1992; Furnas, 1990; Wilkerson *et al.*, 2000).

The influence of marine phytoplankton on global climate depends not only upon total primary productivity, but also on the taxonomic composition of algal assemblages. Planktonic photosynthesis contributes significantly to the oceanic uptake of anthropogenic CO_2, (Sarmiento and Le Quéré, 1996; Sarmiento and Toggweiler, 1984), but certain phytoplankton play a disproportionate role, by modifying the elemental fluxes to the deep ocean. The net effect of phytoplankton on the oceanic carbon cycle and climate is thus determined by the relative rates of photosynthesis and calcification in surface waters, and by the efficiency of organic C and calcite transport (the ''biological'' and ''carbonate'' pumps) to the deep ocean.

Ocean organic carbon storage by the biological pump is disproportionately driven by a few algal groups such as large diatoms relative to other ecologically dominant but smaller-celled taxa (Boyd and Newton, 1999; Chisholm, 1992; Michaels and Silver 1988; Wilkerson *et al.*, 2000), and by the incorporation of dense coccolithophorid calcite into sinking particles (François *et al.*, 2002; Klaas and Archer, 2002). Although diatoms tend to dominate the large phytoplankton size classes in the modern ocean, they are not the only phytoplankton cells that produce mineral ballast with correspondingly fast sinking rates and the potential for enhanced carbon export to the deep ocean. For instance, diatom nitrate reductase activity declines rapidly at elevated temperatures, potentially favoring the growth of competing species (Lomas and Glibert, 1999). Indeed, shipboard experiments in the subarctic Pacific demonstrate a shift from diatoms towards coccolithophorids at increased temperatures, and unprecedented recent *Emiliania huxleyi* blooms in the Bering Sea have been linked to changing climate regimes, including increased temperature (Napp and Hunt, 2001; Stockwell *et al.*, 2001; Sukhanova and Flint, 1998) as well as to enhanced ammonium concentrations, while silicic acid and Si:N ratios appeared not to be controlling community structure (Shiomoto, 1999). Estimates of global export production are also closely coupled to sea surface temperature via changes in community structure, and a warmer ocean may be expected to result in dramatically lower export of carbon with the Laws, 2000.

Coccolithophores produce external platelets (coccoliths) of calcium carbonate ($CaCO_3$) whose density is similar to that of SiO_2 and thus enhances the sinking of cells and their remains. In the North Atlantic Bloom (NAB), a typical succession pattern includes an initial dominance by diatoms giving way to later communities dominated by nanoplankton, especially coccolithophorids (Lochte *et al.*, 1993). This pattern has been attributed to silicate depletion during the early diatom-dominated bloom phase (Sieracki *et al.*, 1993), and *E. huxleyi* also appears to be adapted to low phosphate and high light (Tyrrell and Taylor, 1996). *E. huxleyi* has been reported to resist Fe-limitation when grown on ammonium, rather than nitrate (Muggli *et al.*, 1996); although iron is unlikely to be limiting in the North Atlantic, laboratory data on *E. huxleyi* (Sunda and Huntsman, 1995) have demonstrated that they can grow at near optimal rates with $10–100\times$ less iron than coastal diatoms, which have a high iron requirement and are easily stressed by low Fe conditions (Bruland *et al.*, 2001). Sunda and Huntsman (1995) have shown that *E. huxleyi* has a significant cobalt

requirement and concluded that variations in the Co:Zn ratios in the ocean "could influence the relative growth of diatoms and coccolithophores." They suggested that high $[Zn^{2+}]:[Co^{2+}]$ ratios may initially inhibit *E. huxleyi* growth in freshly upwelled water through an antagonism of Co uptake and nutrition. All of these factors may be part of a more general response to stratification-induced nutrient depletion favoring coccolithophores over diatoms (e.g., Tozzi *et al.*, 2004).

From a modeling perspective, understanding the processes that control the proportion of primary production carried out by diatoms versus coccolithophores can influence the marine C cycle very strongly. For example, Harrison (2000) proposed that changes in $Si(OH)_4$ supply may have influenced the relative success of diatoms and coccolithophores on glacial/interglacial time scales, and that those floristic changes may have been a key to the well known glacial/interglacial transitions in atmospheric CO_2. Experimentally, studies in mesocosms with semi-continuous nutrient additions have shown that the coccolithophore *E. huxleyi*, and other flagellates, are out competed by diatoms when silicic acid is $>\sim 2$ μM and P, N, and Fe are present in nonlimiting concentrations (Egge and Aksnes, 1992). More recently, a comparison of Si-limited, but warmer, versus Si-enriched, but colder, waters north and south of the Antarctic Polar Frontal Zone during the Southern Ocean Iron Fertilization Experiment (SOFeX) demonstrated that total productivity may be enhanced in warmer waters, despite a net decrease in diatom growth (but with a net increase in nanoflagellate growth); the resulting export of carbon was greater than Redfield predictions, resulting from differential remineralization of C and N and the effects of ballasting (Coale *et al.*, 2004). However, Arrigo *et al.* (1999) and DiTullio *et al.* (2000) demonstrated that diatoms have less potential for export of carbon and nitrogen relative to *Phaeocystis* in the Southern Ocean, due to enhanced N recycling by diatoms (relative to *Phaeocystis*).

Superimposed on these physiological and taxonomic shifts during blooms are corresponding changes in nutrient assimilation patterns. Although it is often convenient to invoke Redfield ratios, natural assemblages are rarely assimilating nutrients at Redfield proportions, such that time-integrated assimilation ratios may not be in Redfield proportions, even when averaged over reasonably long time periods (Klausmeier and Litchman, 2004). As a result, export flux is also not necessarily in Redfield proportions, which can in turn lead to variable (or unpredictable) carbon sequestration (e.g., Arrigo *et al.*, 1999; Coale *et al.*, 2004). Recent experimental (Brzezinski *et al.*, 2003a) and modeling (Tagliabue and Arrigo, 2005) evidence highlights the importance of accounting for both species composition and stoichiometry in estimates of elemental flux.

3.2. Silica, nitrogen, iron ratios interactions

Of particular interest in relation to Si:N interactions and diatoms is the relatively recent finding that iron provides a strong regulating influence on the species composition of phytoplankton assemblages, as well as on the elemental ratios of diatoms. Fe and Si supply appear to be particularly important in several large areas where high concentrations of other macronutrients (N, P) are present in surface waters. These HNLC areas (Minas *et al.*, 1986) are characterized by low phytoplankton biomass

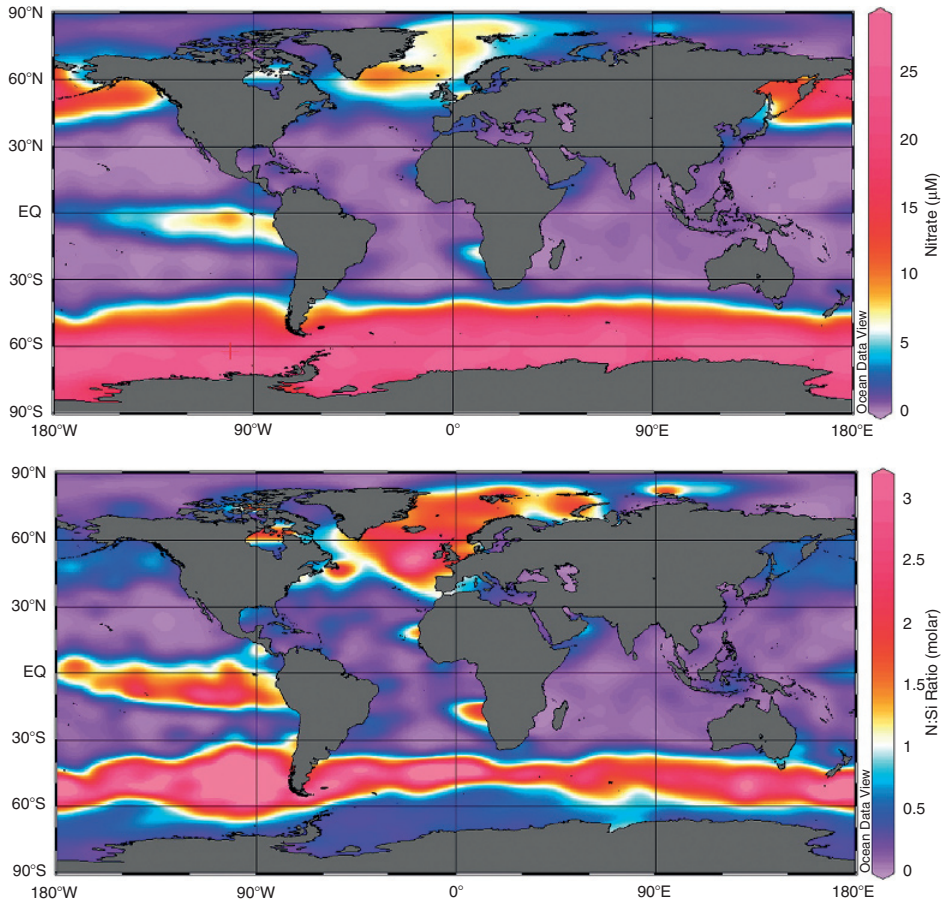
and elevated (i.e., nonlimiting) concentrations of macronutrients (specifically nitrate), a condition shared by *ca.* 40% of the world's ocean (Fig. 37.5). Fe-enriched shipboard incubation experiments (also called grow-out experiments) have been conducted in the subarctic North Pacific (e.g., Boyd *et al.*, 1996; Coale, 1991; Martin *et al.*, 1989), equatorial Pacific (e.g., Martin *et al.*, 1991; Price *et al.*, 1991, 1994); the Southern Ocean (e.g., Cochlan *et al.*, 2002; de Baar *et al.*, 1990; Helbling *et al.*, 1991; Martin, 1990; Martin *et al.*, 1991), and the coastal waters of the north and south Pacific (e.g., Firme *et al.*, 2003; Franck *et al.*, 2005; Hare *et al.*, 2005; Hutchins *et al.*, 1998, 2002). Biomass levels increased and macronutrients (nitrate and phosphate) were greatly reduced after enrichment, providing strong support


Figure 37.5 A global map of nitrate (top) and the Si:N ratio (bottom) for surface waters of the world's oceans. The elevated surface N values (top) roughly correspond to the world's Fe-limited HNLC regions (Minas *et al.*, 1986); in contrast, the elevated N:Si ratio in the Antarctic Polar Front and equatorial Pacific suggest that these areas might be better classified as HNLSiLC waters (Dugdale *et al.*, 1995). The North Atlantic and African upwelling systems, while exhibiting elevated nitrate and a low N:Si ratio, are regions of elevated chlorophyll. Data source: World Ocean Atlas, 2001 (Schlitzer, R., Ocean DataView, http://www.awi-bremerhaven.de/GEO/ODV, 2005).

for the idea that Fe limits phytoplankton growth in HNLC areas. These findings have been confirmed and greatly extended with the subsequent development of mesoscale Fe-enrichment experiments in all of the major HNLC regions (with the de Baar and Boyd, 2007).

Despite the extensive confirmation of Fe-limitation in HNLC waters, and subsequent dominance by diatoms when Fe-limitation is removed, not all HNLC waters are identical, as one would expect (see review by de Baar and Boyd, 2000), and there are some HNLC regions that are also strongly regulated by silicic acid (Fig. 37.5). Partially to address this issue, (Dugdale et al., 1995) invoked the concept of a "High Nitrate, Low Silicate, Low Chlorophyll" (HNLSiLC) system. According to this classification scheme, the Si:N ratio in some HNLC regions (notably the eastern equatorial Pacific upwelling regime and parts of the Southern Ocean; (Brzezinski et al., 2005; Dugdale and Wilkerson, 1998; Dugdale et al., 1995) is regulated in a chemostat-like fashion, where silicic acid concentrations provide a "set point" for diatom production, which in turn limits the drawdown of nitrogen. This occurs because biogenic silica is rapidly and preferentially exported from the euphotic zone relative to nitrogen; this is referred to as the "silicate pump" (Dugdale et al., 1995), or more correctly, the "silica pump", since it is biogenic Si and not silicate, that is being exported (Brzezinski et al., 2003b).

The silica pump model is based in large part on the observation that while silicic acid accumulates at depth along the path of the deep-water conveyer belt (Broecker and Peng, 1982) and is typically found in ratios significantly greater than 1:1 (Si:N) at mid-water depths and deeper (Rageuneau et al., 2000), the Si:N ratio is often <1:1 in near-surface waters. According to the original silica pump hypothesis, little or no silicic acid is recycled in the euphotic zone, making Si dynamics strikingly different from N (or P) dynamics (Dugdale et al., 1995), and leading to the preferential loss of Si relative to N from the euphotic zone. As a result, the Si:N ratio of waters in the near-surface, including the euphotic zone, are often less than the optimal stoichiometric ratio of diatoms. This is hypothesized to ultimately lead to Si-limitation of diatoms, and a shift from large cells to smaller, grazer-controlled phytoplankton, resulting in the development of HNLSiLC conditions, despite the abundance of Si at depth. One necessary prerequisite for the silica pump model to be valid is that biogenic Si is preferentially exported relative to particulate organic C and N, or conversely that very little Si regeneration (dissolution) occurs in the surface ocean. Since seawater is always undersaturated for Si, biogenic Si will always dissolve when exposed to seawater, largely dependent on the thermodynamics of the rate reaction (i.e., to first order, dependent on temperature). Very few studies have directly quantified what fraction of Si production is maintained by the regeneration of biogenic silica in the near-surface; however, work by Nelson et al. (1995) and Brzezinski et al. (2003b) suggest that the global average may be as high as 50%. If so, then Si production would (as an annual average) behave much more like C and N; recent estimates of global f-ratios provide an annual average of ~20% export of net photosynthesis (Laws, 2000), comparable to the ca. 50% regeneration rate for silicic acid.

Despite the potentially high global average for the ratio of Si production to dissolution, Brzezinski et al. (2003) argue that this average is driven by mean non–bloom ratios that are elevated, while the ratio during diatom blooms, expected

to account for the majority of flux out of the euphotic zone, exhibit much lower ratios. Thus, although it is not strictly true that there is little or no silicic acid recycling in surface waters (e.g., Beucher *et al.*, 2004; Bidle and Azam, 1999; Brzezinski *et al.*, 2003b; Fujii and Chai, 2005; Nelson *et al.*, 1995), this makes a reasonable approximation, and models based on this assumption have been used to evaluate the role of diatom production in the modern and paleo-ocean (e.g., Chai *et al.*, 2002; Dugdale *et al.*, 1995, 2004; Moore *et al.*, 2002; Mongin *et al.*, 2003; Pondaven *et al.*, 1998).

In the silica pump scenario, Fe is thought to control the set point for Si:N drawdown, by modulating the growth of diatoms (with a high Fe requirement) relative to other, non-siliceous phytoplankton (e.g., Franck *et al.*, 2003). This has been attributed to the higher Fe-requirement for large diatoms relative to pico-plankton (e.g., Boyd *et al.*, 1996; Coale *et al.*, 1996; Franck *et al.*, 2005; Hudson and Morel, 1990; Price *et al.*, 1994), although there is also a differential Fe requirement among diatoms, related to the occurrence of coastal versus oceanic species (Bruland *et al.*, 2001, 2005). As discussed above, Si-uptake will occur so long as there is ambient silicic acid in the environment, even when N or Fe-limitation inhibits cell division. As a result, Fe-stressed cells exhibit markedly higher Si:C and Si:N ratios compared to Fe-replete cells (Boyle, 1998; Hutchins and Bruland, 1998; Takeda, 1998). In almost all Fe-enrichment studies to date, whether in enclosures or as mesoscale enrichments, diatoms are the dominant group of phytoplankton respond-ing to the enrichment (Boyd *et al.*, 2000; Coale *et al.*, 1996, 2004; Smetacek, 2001; Tsuda *et al.*, 2003). When combined with the concept of a silica pump, the interrelationships between Si and Fe-limitation and stoichiometry have the potential to profoundly influence the bigeochemical cycling of carbon and nitrogen, particu-larly over glacial/interglacial time scales. Although Si:C:N:Fe interactions can potentially occur throughout the world's oceans, the Southern Ocean is of particular importance, because of its role in regulating global climate.

3.3. The southern ocean

The Southern Ocean is thought to be one of the most important areas of the world in regulating global climate (Anderson, 1993). Model simulations (Knox and McElroy, 1984; Sarmiento and Le Quéré, 1996; Sarmiento and Toggweiler, 1984; Sarmiento *et al.*, 2004; Siegenthaler and Wenk, 1984) suggest that, over time scales of 10^2–10^5 years, atmospheric carbon dioxide is controlled largely by conditions in the polar oceans and that the largest CO_2 fluxes to the ocean occur south of 40° (Sarmiento *et al.*, 1992). These Southern Ocean fluxes demonstrate high sensitivity to changes in primary productivity and global warming (Sarmiento and Le Quéré, 1996; Sarmiento *et al.*, 2004), which arises in part because large amounts of the major plant macronutrients remain unused, providing the potential for much greater primary production than occurs in the modern ocean. These regions are also the source of abyssal water in all the ocean basins, and under present conditions, these regions are the main routes by which the huge reservoir of dissolved carbon in the deep sea exchanges with the atmosphere. As a consequence, Southern Ocean open waters have a disproportionately large influence on atmospheric carbon

dioxide even though they represent only 10–20% of the oceanic surface area. Sarmiento and Toggweiler's model further suggests that complete utilization of the macronutrients in the Southern Ocean HNLC regions would result in a decrease in the (pre-anthropogenic) steady state atmospheric CO_2 on the order of 80 ppm (Sarmiento and Toggweiler, 1984), equal to the drawdown during glacial periods.

Previous studies in HNLC regimes including the Southern Ocean have revealed that despite high ambient NO_3 concentrations, autotrophic N utilization is usually met by regenerated NH_4 and urea from within the euphotic zone (review by Dugdale and Wilkerson, 1992; Chapter 12 by Cochlan, this volume). Brzezinski et al. (2003a) have demonstrated that under Fe-limited conditions in the Southern Ocean, diatoms will increase utilization of regenerated N compounds to maintain a quasi-Redfield cellular composition while growing, but that Si:N export of particles is increasingly enriched in Si, consistent with the silica pump hypothesis. As a result, diatoms in Fe-limited HNLC regions precipitate silicate at ratios of ca. 4:1 (molar) for Si:N (e.g., Brzezinski et al., 2005; Firme et al., 2003; Franck et al., 2005; Hutchins and Bruland 1998; Pondaven et al., 2000; Takeda, 1998) rather than the expected ratio of ca. 1:1 for Fe-replete diatoms (Brzezinski, 1985). With the release of Fe-limitation, the stoichiometric composition of the particulate material again approaches 1:1 (Bruland et al., 2005) while the f-ratio increases, resulting in a drawdown of excess nitrate (Brzezinski et al., 2002; Coale et al., 2004).

Because the subantarctic mode water, formed in the Southern Ocean, is the main source of nutrients for the world's oceanic thermocline (Sarmiento et al., 2004), any changes in the drawdown ratio of Si:N in the Antarctic will have a direct impact on phytoplankton at lower latitudes. The subantarctic intermediate and mode water ratio of Si:N is <1:1 in the modern ocean (Dugdale and Wilkerson, 2001); if there were major changes in the availability of Fe, and therefore a shift in the Si:N drawdown ratio in the Southern Ocean, it has been proposed that there would be a subsequent "silicic acid leakage" northward (Matsumoto et al., 2002). This leakage to northern latitudes would potentially favor diatoms relative to coccolithophores (see review by Archer et al., 2000), and is consistent with the higher opal content in the glacial subantarctic (Chase et al., 2003; François et al., 1997). More recently, Dugdale et al. (2004) have argued that the opal mass accumulation rate in the Antarctic and equatorial Pacific covary, casting doubt on the regulation of low latitudes by changes in the Si:N source ratio. Higginson and Altabet (2004) confirmed the increase in coccolithophore:diatom production in Peru margin sediments using class-specific phytoplankton biomarkers from sediment cores during glacial/interglacial periods (18.0–15.5 Ka), but also demonstrated that there are inconsistencies in this record if the sole source of variability was silicic acid leakage from the Southern Ocean. Another alternative hypothesis has been proposed by Harrison (2000), who suggested that direct changes in silicic acid concentration could be caused by dissolution of silica deposited on the surface ocean by dust events, based on increased Aeolian transport during glacial periods. This "silica hypothesis" would result in a 40% decrease in coccolithophores with a 2–8× increase in dust concentrations.

Although the precise mechanisms for the changes in pCO_2 during glacial periods is unclear, it is evident that changes in Si:N export (the biological and silica pumps),

possibly driven by variability in Fe availability, and the subsequent changes in nutrient ratios for the worlds oceans can have profound effects on the phytoplankton composition over millennial time scales, resulting in oscillating patterns of diatom versus coccolithophore dominance. Climate-driven shifts in terrestrial ecosystem diversity are now well documented (Korner, 2003; Walther *et al.*, 2002), but similar experimental evidence for marine environments is scarce or nonexistent (see review by Riebesell, 2004). This information is essential to parameterize more realistic models that can predict future changes in climate regimes and biogeochemical fluxes (e.g., Boyd and Doney, 2002), and the interplay of Si:N ratios in the ocean are a critical component.

4. ANTHROPOGENIC CHANGES IN SILICA TO NITROGEN RATIOS

4.1. Causes and consequences of silica to nitrogen ratios changes

For much of the world's oceans, silicic acid reaches the euphotic zone via upwelling, and the upper limit for biological production by diatoms is set by the ratio of Si to N (Dugdale and Wilkerson, 1998; Dugdale *et al.*, 1995) modulated by Fe-availability (e.g., Leynaert *et al.*, 2004). The source of this dissolved Si is ultimately from the chemical weathering of the continental crust, with subsequent input to the coastal ocean by rivers (*ca.* 84% of dissolved Si input to the oceans; Tréguer *et al.*, 1995). The second largest source, Aeolian transport, is substantially lower (*ca.* 7.5%; Tréguer *et al.*, 1995), although there is evidence that Aeolian deposition of Si can have a great impact on biological productivity on time scales greater than about 10,000 years (Harrison, 2000). Coastal waters play a disproportionately important role in marine productivity; although these regions represent only 10% of the oceanic area and less than 0.5% by volume, coastal marine ecosystems produce nearly 95% of the annual global production of marine biomass (Sherman, 1991), while shelf and delta-influenced sediments account for ca., 80% of the organic carbon sequestration in the modern ocean (Berner, 1982; Jahnke *et al.*, 1990; Walsh, 1991), and riverine inputs to the coastal ocean have been shown to impact the annual global carbon budget (Smith and Hollibaugh, 1983).

Despite the high silicic acid load associated with rivers (discharge-weighted average silicic acid concentrations have been estimated at 150 μM; Tréguer *et al.*, 1995), there is ample evidence for biological removal in estuaries and coastal waters. Nelson and Dortch (1996) demonstrated biological removal of 80–99% of the silicic acid in the Mississippi River plume. Milliman and Boyle (1975) reported a 25% drawdown of silicic acid within the Amazon River estuary, with further depletion in the nearshore ocean. Kimmerer (2005) demonstrated *ca.* 85% drawdown of silicic acid within San Francisco Bay, directly related to diatom production. In contrast, silicic acid concentrations are rarely less than 0.5 μM in much of the world's oceans (*cf.* Nelson and Dortch, 1996), despite the prevalence of diatoms and the dominance of diatom productivity in export flux.

Given the importance of riverine input to Si cycling in the oceans, any changes in the source or nutrient ratios could have an impact on diatom production and

ecological structure in the oceans. Inputs of reactive N have increased globally by a factor of 20 since 1860, due to a combination of fossil fuel combustion, rice and legume production, and fertilizers; today, anthropogenic N fixation exceeds natural terrestrial fixation (Galloway and Cowling, 2002). Accompanying this increase in reactive N, phosphorous, also from fertilizers, has increased as well; the net result is that N and P loading to the coastal zone from rivers has increased by a factor of 2.5 and 2.0, respectively (Humborg *et al.*, 2000). In contrast, the global flux of riverine Si has been steady or decreasing (Humborg *et al.*, 1997, 2000; Turner *et al.*, 2003b), since human activities for the most part have not increased the use of Si in the terrestrial environment. The net result is that the elemental ratio of Si:N:P in these rivers has also decreased globally, with *ca.* 7.3% and 21% of the world's population now living in watersheds with a Si:N ratio of 1:1 and 2:1, respectively (Turner *et al.*, 2003b).

There is no a priori reason to expect a reduction in dissolved Si to have a direct impact on marine primary production, since a change in the Si:N:P ratio should simply select against diatoms and for non–siliceous organisms (e.g., Egge and Aksnes, 1992). However, as discussed above, diatoms are associated with enhanced productivity in the marine environment, and one might expect at minimum, a change in the ecological structure of coastal food webs as the Si:N ratio approaches the optimal 1:1 requirement of diatoms (Brzezinski, 1985). As the Si:N ratio is reduced, there will be a corresponding decrease in efficiency of Si–transport relative to that of N transport (i.e., the ratio of the ambient Si concentration to the K_s for Si is constant or decreasing, while the ratio of the ambient N concentration to the K_s for N is constant or increasing, favoring N–utilization and inhibiting Si–utilization). This is not a new concept, and the potential role of Si:N dynamics in modulating cultural eutrophication has been of interest for several decades (Conley *et al.*, 1993; Officer and Ryther, 1980). The first well publicized evidence for widespread changes in ecological function related to shifts in Si:N ratios was provided by Schelske and colleagues, in a series of papers documenting shifts in phytoplankton community composition for the Laurentian Great Lakes in response to anthropogenic changes in land use and water quality (Schelske and Stoermer, 1971, 1972; Schelske *et al.*, 1983).

Since those first studies, there have been dramatic effects reported in the marine environment directly related to changes in the Si:N:P ratios of riverine inputs to coastal waters, due to both increased loading of N and P, and decreases in Si (Conley *et al.*, 1993; Ittekkot *et al.*, 2000; Turner *et al.*, 2003b). Some of these changes have been directly attributed to cultural eutrophication (e.g., Turner and Rabalais, 1991, 1994) while other regions have been heavily influenced by hydrological changes related to the building of large dams (e.g., Humborg *et al.*, 1997, 2000; Ittekkot *et al.*, 2000; Liu *et al.*, 2003; Milliman, 1997). Although dams potentially reduce all nutrients (N, P, Si, Fe) by trapping them in reservoirs and/or promoting freshwater blooms (Humborg *et al.*, 1997), N and P are largely replaced downstream of the dam due to increased anthropogenic loads, while Si is not. The net ecological result can be difficult to predict, since the marine community may respond to increased nutrient loads (more diatoms) as well as to decreased Si:N ratios (fewer diatoms), as well as selection for and against specific species of phytoplankton (see reviews by

Conley *et al.*, 1993; Humborg *et al.*, 2000; Officer and Ryther, 1980). The Black Sea provides a particularly clear example of these potential consequences. The River Danube, which provides 70% of the freshwater input to the Black Sea, was dammed ("The Iron Gates") in 1970–1972, resulting in a decrease in the Si:N ratio from *ca.* 42 to 2.8 (Humborg *et al.*, 1997; Ittekkot *et al.*, 2000). In the decade following this hydrological alteration, diatoms increased by a factor of 2.5, but non-siliceous organisms, including dinoflagellates, the Prymnesiophyte *E. huxleyi*, the facultative toxic genera *Chromulina*, and the Euglenophyte *Eutreptia lanowii*, increased by a factor 6. While Si-limitation did not eliminate diatoms from the community, there was a dramatic shift in the overall phytoplankton composition, as expected (Humborg *et al.*, 1997).

4.2. Harmful algal blooms

Harmful algal blooms (HABs) appear to be increasing in frequency and intensity worldwide (Glibert *et al.*, 2005a). While the causes for this are potentially complex, one oft-cited rationale for this trend is the concomitant change in nutrient loading, and the stoichiometric shift in Si:N:P ratios (Anderson *et al.*, 2002; Glibert *et al.*, 2005b; Smayda, 1990). Officer and Ryther (1980) suggested that as Si:N ratios in marine waters approached unity, an alternative phytoplankton community (most likely flagellates) would replace diatoms as the dominant organism, as was seen in the Black Sea. Smayda (1990) argued that the apparent increase in HABs worldwide could be directly related to a shift in the Si:N ratio. Anderson *et al.* (Anderson *et al.*, 2002) concurred, although they pointed out that shifts in community structure related to HABs were often associated with changes in the N:P ratio as well as changes in the N:Si ratio.

There are many regional examples of HAB proliferation attributed to changes in the N:Si ratio to corroborate the apparent global patterns. In addition to the increase in *Chromulina* spp. associated with the damming of the Danube (Humborg *et al.*, 1997), Maestrini and Granéli (1991) attributed the exceptional bloom ($>10^7$ cells L^{-1}) of *Chrysocromulina polylepis* in the Skagerrak in 1988 to a series of environmental conditions favoring this flagellate. Specifically, Maestrini and Granéli proposed that high, N-rich runoff in the spring was followed by strong vertical stratification; this was followed by two large *S. costatum* (diatom) blooms, reducing the Si and P concentrations, but further enriching the waters in N. The subsequent weak turbulence, strong stratification, and elevated N:P and N:Si ratios favored the formation of the *C. polylepis* bloom, which subsequently inhibited grazers and other organisms via toxin production. Noxious blooms of the Prymnesiophyte *Phaeocystis pouchetii* in the North Sea have similarly been associated with selection against diatoms resulting from changes in the Si:N ratio (Anderson *et al.*, 2002; Radach *et al.*, 1990).

The greatest impacts from cultural eutrophication and hydrological modifications may have yet to be realized. Bouwman *et al.* (2005) predict a global increase in river N from 1970 to 2030 of 46% for the Indian, 38% for the Pacific, and only 6% for the Atlantic oceans, because of the predominance of developing countries in watersheds draining into the Indian and Pacific basins. These authors predicted a

corresponding increase in P loads, but no change or decreases in Si loads. Zhao *et al.* (2005) report that Jiaozhou Bay, on the eastern side of the Yellow Sea (China), has exhibited a shift from N–limitation towards P– and Si–limitation from 1960 to 1990, related to increasing anthropogenic loading. This shift in nutrient ratios is correlated with a decrease in phytoplankton biodiversity, and an increasing dominance of the phycotoxin–producing diatom *Pseudo-nitzschia*.

China also began development of the Three Gorges Project (TGP) in the upper region of the Changjiang (Yangtze River) in 1994, which when completed in 2010, will be the world's largest dam system (Zhang *et al.*, 1999). The Changjiang is the largest river in Asia, and is third in length, fourth in sediment discharge, and fifth in water discharge worldwide (Liu *et al.*, 2003). Changes in nutrient loading and stoichiometric ratios related to the TGP are already evident (Liu *et al.*, 2003), with N:Si and N:P ratios increasing relative to pre–dam periods. Chen *et al.* (2003) report that prior to the TGP project, the East China Sea was dominated by diatoms (*S. costatum*). With the shift in nutrient ratios, the predominant phytoplankton species have shifted to a suite of HAB organisms, including the dinoflagellates *Prorocentrum dentatum, Noctiluca scintillans*, and *Alexandrium* spp. (the latter produces paralytic shellfish poisoning). These changes in both nutrients and algal species are expected to continue to shift towards non–diatom production once the TGP is completed.

4.3. *Pseudo-nitzschia*: A case study

In 1987, the first confirmed case of a naturally occurring neurotoxic diatom bloom was reported in Prince Edward Island, Canada, later confirmed to be caused by the production of domoic acid from the pennate diatom *Nitzschia pungens*, now renamed *Pseudo-nitzschia multiseries* (Bates *et al.*, 1989; Subba Rao *et al.*, 1988). Since this first outbreak, many (but not all) species of *Pseudo-nitzschia* have been confirmed to produce domoic acid (as well as some species of *Amphora* and now *Nitzschia* (Kotaki *et al.*, 2000); see Bates, 1998, 2000, for a summary). These potentially toxic species include *P. multiseries, P. pseudodelicatissima, P. delicatissima, P. seratia, P. australis, P. pungens*, and *P. fraudulenta*, although it is apparent that not all species are toxic in all locations, nor are individual strains toxic under all conditions.

Some ecosystems are either intermittently or borderline Si limited, which allows diatoms with low Si requirements to dominate, rather than resulting in a shift to non–diatoms (e.g., Nelson and Dortch, 1996). One of the few direct examples of direct stimulation of a HAB organism by eutrophication can be found on the Louisiana shelf, related to the changing Si:N ratios of the Mississippi outflow. Blooms develop in the spring when river flow and nutrient loading is highest (Dortch *et al.*, 1997; Pan *et al.*, 2001). *Pseudo-nitzschia* is characterized as a lightly-silicified genus (Parsons and Dortch, 2002) and appears to be well adapted to low light and moderately low Si:N ratios (Sommer, 2004), and is tolerant to a wide range of salinities, although optimal growth is achieved at higher rather than lower salinity ranges (Thessen *et al.*, 2005). Abundances of *Pseudo-nitzschia* determined from sediment cores demonstrate a marked increase beginning in the 1950s, coincident with changes in nutrient loading of the Mississippi (Parsons and Dortch, 2002),

strongly suggesting that anthropogenic changes in Si:N ratios have directly selected for this cosmopolitan diatom. The recent evidence from China (Zhao *et al.*, 2005) suggests that these patterns are not isolated to the Louisiana shelf.

Multiple factors have been shown to trigger the production of domoic acid by the genus *Pseudo-nitzschia* (*cf.*, reviews by Bates, 1998, 2000; Bates *et al.*, 1998), but the most thoroughly characterized are macro-nutrient limitation by either phosphate or silicate (Pan *et al.*, 1996a,b,c). Despite the general trend for decreasing Si:N ratios to favor non-siliceous organisms, *Pseudo-nitzschia* has previously been associated with eutrophication and a reduction in these ratios. Freshwater runoff (which typically exhibits decreased N:Si ratios) has been implicated in triggering DA events (*cf.* review by Bates *et al.*, 1998) and there is circumstantial evidence that the massive domoic acid poisoning event which occurred in Monterey Bay, California in 1998 was similarly triggered by post-El Niño runoff (Scholin *et al.*, 2000). Thus, cultural eutrophication might have the unanticipated consequence of both selecting for *Pseudo-nitzschia* and promoting toxin production in this organism.

In addition to the apparent stimulation of *Pseudo-nitzschia* by riverine runoff, this organism also consistently blooms in response to Fe-additions to HNLC waters. Iron limitation directly modulates Si:N ratios in diatoms (see above), and has been linked to domoic acid production in *Pseudo-nitzschia*, which may serve as an Fe-acquisition mechanism (Maldonado *et al.*, 2002; Rue and Bruland, 2001); either directly, or through the stimulation of a Cu-mediated transport system (Wells *et al.*, 2005). Although domoic acid has not been measured in most of the Fe-enrichment experiments performed to date, potentially toxic *Pseudo-nitzschia* were stimulated in bottle experiments from the Pacific northwest (Boyd *et al.*, 1996), coastal California (Hutchins and Bruland, 1998; Hutchins *et al.*, 1998); and coastal Peru (Hutchins *et al.*, 2002). The toxigenic diatom was also identified in many of the mesoscale Fe-enrichment experiments, including Iron Ex II in the equatorial Pacific (Landry *et al.*, 2000), EisenEx (Gervais *et al.*, 2002) and SOFeX (Coale *et al.*, 2004) in the Southern Ocean, and in the subarctic Pacific as part of SERIES (Marchetti and Harrison, 2004). Based on these findings, it appears that anthropogenic changes in nutrient ratios, both due to Si:N changes in riverine runoff, and more recently due to direct manipulation of Fe-concentrations in the coastal and open ocean, may have the unintended consequence of selecting for the toxigenic diatom *Pseudo-nitzschia*.

4.4. Impacts on higher trophic levels

In addition to direct impacts of Si:N interactions in the marine environment, such as a shift towards flagellates or a promotion of potentially harmful algae, there are also indirect impacts on higher trophic levels. The world's fisheries are largely dependent on the formation of large diatom blooms in upwelling and temperate waters (Ryther, 1969). Copepods are generally considered to be the dominant grazers of diatom blooms (Irigoien *et al.*, 2002), although food quality and grazer deterrence by diatoms is also important (Harris, 1996; Jones and Flynn, 2005; Miralto *et al.*, 1999). Both Officer and Ryther (1980) and Conley *et al.* (1993) speculated that changes in the biogeochemical cycling of Si and N due to anthropogenic influences could lead to drastic changes in the food web structure of freshwater and marine systems due to the shift from diatoms to non-siliceous organisms, with subsequent increases in the

microbial food web (Sommer *et al.*, 2002) and a reduction in carbon transport to higher trophic levels (Cebrian, 2002, 2004; Sommer *et al.*, 2002).

In the Gulf of Mexico, changes in the Si:N ratio have led to increasing diatom species diversity (e.g., Nelson and Dortch, 1996) but also to a restructuring of the mesozooplankton populations (Turner *et al.*, 1998). Turner *et al.* reported a decrease in copepod abundance from >75% of the mesozooplankton population to <30% as the Si:N ratio decreases from 1:1 to 0.5:1. These food web shifts can in turn impact the occurrence and impact of bottom–water hypoxic events (Rabalais, 2002; Rabalais *et al.*, 2002; Turner and Rabalais, 1994; Turner *et al.*, 1998). In San Francisco Bay, Kimmerer (2005) attributes changes in the number and species composition of pelagic consumers to the decline of diatoms, again due to a shift in the Si:N ratio. Turner *et al.* (Turner *et al.*, 2003a) suggest that this shift from Si-enriched to N and P enriched river discharge is a global phenomenon, and that we may expect to see alternative, if not harmful, phytoplankton communities in an increasing number of coastal waters.

5. Conclusions

Despite the dominant role of nitrogen in the marine environment, the interplay of silica and nitrogen clearly has a strong modulating effect on ecological processes, from cellular metabolism to global climate. In the modern ocean, diatoms are the key organisms that regulate this process, because of their absolute requirement for silicon (Lewin, 1962) and their dominance in the biogeochemical cycling of this element (Treguer *et al.*, 1995). Despite the importance of Si:N coupling, we still know relatively little about the interactions of these elements at the cellular and genetic level (Armbrust *et al.*, 2004; Martin–Jézéquel *et al.*, 2000), although the rapid advances in genomic information and techniques will undoubtedly shed light on these processes (Armbrust *et al.*, 2004; Grossman, 2005).

The importance of diatom production for both the modern ocean (e.g., Ryther, 1969) and as a regulator of climate (Ragueneau *et al.*, 2000; Tréguer and Pondaven, 2000) and global productivity (Sarmiento *et al.*, 2004) has also been recognized recently. As a result, significant advances have been made in modeling Si:N interactions at both the cellular level (Flynn and Martin–Jézéquel, 2000) and in coupled biogeochemical ecosystem models (Chai *et al.*, 2002; Dugdale and Wilkerson, 2001; Dugdale *et al.*, 1995; Mongin *et al.*, 2003; Moore *et al.*, 2002; Yool and Tyrrel, 2003), while the importance of Fe as a modulating factor on Si:N dynamics is increasingly well documented (e.g., Brzezinski *et al.*, 2002; de Baar and Boyd, 2000; Dugdale *et al.*, 2004; Harrison, 2000).

There is also increasing evidence for fundamental changes in ecosystem structure in response to shifts from diatoms to other organisms as previously predicted (Conley *et al.*, 1993; Officer and Ryther, 1980). While these shifts in ecosystem structure are not necessarily negative (e.g., Nelson and Dortch, 1996), the long-term consequences of anthropogenic influences on Si:N dynamics are likely to be an overall decrease in fisheries production (Sommer *et al.*, 2002) and an increase in noxious and harmful algal species (Anderson *et al.*, 2002; Glibert *et al.*, 2005b; Smayda, 1990).

Linking the Oceanic Biogeochemistry of Iron and Phosphorus with the Marine Nitrogen Cycle

David A. Hutchins *and* Fei-Xue Fu

Contents

1. Introduction

Modern biological oceanography has evolved from an emphasis on single limiting nutrients to a perspective that includes multiple, interacting limiting factors. It is no longer necessary to consider solely an "either/or" scenario when discussing algal nutrient limitation. In fact, the single Liebig–limiting nutrient paradigm does not adequately describe many of the limitation processes that are important for primary producers in the ocean. Both physical factors (e.g., light, temperature, and carbonate chemistry) and biological factors (e.g., competition, grazing and viruses)

can strongly modulate the effects of nutrient limitation, and vice versa. The growth, biomass and productivity of particular algal taxa can be influenced to different degrees by several of these factors simultaneously. Likewise, multiple limiting nutrients can also interact in numerous ways to help determine phytoplankton production and community structure. Experimental and observational biological oceanographers have been aware of the implications of multiple resource limitation for quite some time; unfortunately, much of the theoretical ecological literature is still based on simple single nutrient Liebig limitation models.

Arguably, phosphorus (P) and iron (Fe) are the two nutrients that most impact the global marine nitrogen (N) cycle. Over the past 15 years a proliferation of new work on Fe limitation has left no doubt that this micronutrient profoundly influences nitrogen biogeochemistry over perhaps the majority of the ocean's surface. Recent work has also brought a renaissance of renewed attention to P limitation, and to its reciprocal interactions with nitrogen.

In this chapter, we synthesize the state of the discipline with regards to Fe and P interactions with the N cycle. First we briefly review what is currently known about the cycles of Fe and P, with concurrent comparisons and contrasts with the N cycle. Then, we consider how these two elements individually and together may impact dinitrogen (N_2) fixation in the ocean. Along with presenting new evidence and discussing long-standing or emerging paradigms, we attempt to point out areas that still remain uncertain and questions that still need to be answered.

2. The Marine Iron Cycle

In recent years the Fe biogeochemical cycle has probably received more intensive scrutiny than that of any other element in the ocean. Despite this huge international investment of research effort, crucial parts of the Fe cycle remain speculative and unquantifiable. For some major Fe pools, fluxes, and rate processes, even the general chemical species involved are still relatively unknown. In large part these persistent uncertainties are directly related to the analytical difficulties associated with low-level measurements of Fe speciation and biogeochemical transformations. Another reason is that a great deal of the community research emphasis has been on diagnostic evaluations of biological Fe limitation, rather than on obtaining a realistic understanding of the unperturbed, *in situ* Fe cycle (Boyd *et al.*, 2005).

Despite this, we have made major forward progress in conceptual and even quantitative modeling of Fe cycling (Bowie *et al.*, 2001; Fung *et al.*, 2000; Moore *et al.*, 2002, 2004; Parekh *et al.*, 2004, 2005; Moore and Doney 2007; Krishnamurthy *et al.* 2008; Tagliabue *et al.* 2008). Trace-metal clean measurement and manipulation methods that were once the exclusive preserve of a few elite laboratories are now in relatively common use by many research groups all over the world. The advent of new technologies has also greatly advanced the field, notably *in situ* manipulative experiments, molecular methodology, and advances in analytical chemistry and computer modeling capabilities. This array of novel tools has allowed a much more in depth picture of Fe biogeochemistry than has ever been available in the past. A conceptual diagram of our current picture of the marine Fe biogeochemical cycle is presented in Fig. 38.1; many of these processes are discussed in more depth in the following sections.
Figure 38.1 A conceptual diagram of important pools and fluxes in the marine Fe cycle. *Non-living pools* (rectangles) include particulate inorganic Fe (suspended lithogenic material or colloids), dissolved inorganic Fe (III) and Fe (II), and dissolved organically complexed Fe. *Living pools* (ovals) include prokaryotic and eukaryotic phytoplankton, protozoan and metazoan grazers, and bacteria and viruses. *New inputs* (brown text and arrows) include upwelled dissolved Fe (inorganic or organically bound), aeolian deposition (dust particles) and advected sources (largely from shelf sediments). *Transformations between non-living pools* (white arrows) include dissolution of dust to dissolved Fe(III) or Fe(II) (in the ocean or in the atmosphere prior to deposition), organic complexation and dissociation of dissolved Fe(III), redox cycling between dissolved inorganic Fe(III) and Fe(II), and photochemically-mediated reduction of ligand-bound Fe(III) (yellow arrow). *Biological uptake pathways* (green arrows) include assimilation of organically bound Fe by phytoplankton and bacteria, including photochemical (yellow arrow) and biological reduction fluxes. Direct uptake of dissolved inorganic Fe(III) and Fe(II) is assumed to be negligible as they comprise <1% of the total dissolved Fe pool. Also shown is trophic transfer of cellular Fe via grazing and possible direct uptake of particulate Fe by ingestion of dust particles or colloids by grazers. *Regeneration pathways* (orange arrows) include recycling of biological Fe by grazers, viruses and bacteria as dissolved inorganic Fe and/or organically bound iron. *Production of organic ligands* (black arrows) includes siderophore production by bacteria and cyanobacteria, and possible release of intracellular chelators by eukaryotic phytoplankton. *Export pathways* (red arrows) include direct sinking of lithogenic and biological particulate iron (PFe); although arrows are shown from all living pools, larger phytoplankton and grazers are likely to be dominant sources. Another important export pathway is scavenging of dissolved inorganic Fe(III); export of organically bound Fe is also depicted, although the importance of scavenging or downwelled export of this Fe species has not been established.

2.1. Iron limited regimes

The three classic oceanic high nutrient, low chlorophyll (HNLC) regimes are now universally recognized by oceanographers as being Fe-limited. A plethora of deck-board and open ocean Fe addition experiments have conclusively demonstrated

that Fe is a limiting nutrient for phytoplankton growth in the Equatorial Pacific, the subArctic Pacific, and throughout most of the vast Southern Ocean (Boyd, 2002; Boyd *et al.* 2007; Coale *et al.*, 2004; Martin *et al.*, 1990, 1991). Recent work has extended the scope of potentially Fe-limited waters to include the coastal upwelling areas off California (Firme *et al.*, 2003; Hutchins *et al.*, 1998; King and Barbeau 2007) and Peru (Hare *et al.*, 2005; Hutchins *et al.*, 2002), the Bering Sea (Leblanc *et al.*, 2005; Aguilar-Islas *et al.* 2006), parts of the Northeast Atlantic (Blain *et al.*, 2004), and even some estuaries (Lewitus *et al.*, 2004; Zhang, 2000). In addition, broad areas of the oligotrophic oceans traditionally considered to be major nutrient–limited are probably actually co-limited by both Fe and major nutrients (Behrenfeld and Kolber, 1999; DiTullio *et al.*, 1993). Iron limitation is now recognized as a global scale phenomenon, and modeling work suggests that as much as 50% of the world ocean exhibits evidence for Fe limitation of algal growth and production (Moore *et al.*, 2002).

2.2. Iron limitation and marine food webs

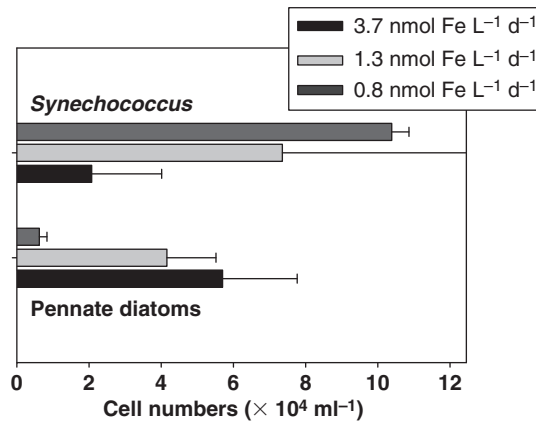
It is now an accepted paradigm that relieving Fe limitation in HNLC areas fosters the growth and productivity of diatoms (reviewed in Wells, 2003, Fig. 38.2). In most cases, these have been pennate species (Boyd *et al.*, 2000; Cavender-Bares *et al.*, 1999; Coale *et al.*, 2004; Gervais *et al.*, 2002; Hutchins *et al.*, 2002; Martin *et al.*, 1991; Price *et al.*, 1991), although centric diatoms have also bloomed after Fe enrichments in coastal California (Firme *et al.*, 2003; Hutchins and Bruland, 1998) and in the SEEDS open ocean experiment in the western subarctic Pacific (Tsuda *et al.*, 2003). These diatom blooms are not necessarily followed by commensurate


Figure 38.2 A progressive shift from a *Synechococcus*-dominated community to a diatom-dominated assemblage with increasing Fe supply in an experiment in the Peru Upwelling region. A shipboard continuous culture system was used to supply a continuous flow of Fe-amended sea-water at a dilution rate of $1\,day^{-1}$, simulating upwelling of water with three different Fe concentrations. Iron supply rates used were 0.8, 1.3, or 3.7 nmol Fe $L^{-1}\,day^{-1}$. Values are the means and error bars are the standard deviations of triplicate incubation bottles. Redrawn from Hare *et al.* (2005), *Aquatic Microbial Ecology* 38: 269–282.

drawdown of silicate, however, as the relationship between Fe availability and silicate utilization is complex (Hutchins and Bruland, 1998, see Chapter 7 by Kudela, this volume). It is widely believed that Fe-mediated increases in the contribution of large diatoms to community biomass also increase the potential for carbon (C) and N export (Boyd *et al.*, 2004; Buesseler *et al.*, 2005).

However, diatoms are not the only phytoplankton group that responds to Fe additions. Cavender-Bares *et al.* (1999) showed that cellular size and fluorescence of all phytoplankton groups, including *Prochlorococus*, *Synechococcus*, and ultra- and nano-eukaryotes increased during the Equatorial Pacific IronEx II experiment. Similarly, eukaryotic nanoplankton have shown rapid initial increases in other addition experiments such as the Southern Ocean SOIREE experiment (Boyd *et al.*, 2000), usually followed by decreases as the diatom bloom progresses. Like diatoms, these smaller algal groups are also clearly Fe-limited in HNLC areas, but tight coupling with their micrograzers usually keeps large biomass increases in check after fertilization.

Heterotrophic bacterial production and sometimes abundance have also been shown to increase following Fe enrichments, although there is no consensus about whether this represents a response to increased phytoplankton-derived dissolved organic carbon (DOC) supplies, or a direct release from Fe limitation (Arrieta *et al.*, 2004; Church *et al.*, 2000; Cochlan 2001; Hutchins *et al.*, 1998; Kirchman *et al.*, 2000; Oliver *et al.*, 2004; Pakulski *et al.*, 1996). There has been little work to examine Fe effects on bacterial community structure, but one study (Hutchins *et al.*, 2001) concluded that shifts in bacteria assemblages are probably less dramatic and pronounced than those seen in the algal community. A recent study, however, documented significant changes in bacterial diversity across a natural Fe gradient in the Southern Ocean (West *et al.* 2008). Culture studies also show that protozoan grazer growth rates can be limited by the Fe content of their bacterial prey (Maranger *et al.*, 1998; Nodwell and Price, 2001). No work to date, however, has examined whether metazoan grazers and other higher trophic levels are also subject to Fe constraints on their growth.

2.3. Sources of iron

The broad outline of the marine Fe cycle is analogous to the N cycle, in that regenerated forms are thought to support the bulk of biological production while new inputs determine the potential for export (Fung et al., 2000; Hutchins *et al.*, 1993; Landry *et al.*, 1997). As with N, vertical advection is an important source of new Fe, and new fluxes to the large oceanic HNLC areas of the polar Southern Ocean and the Equatorial Pacific are heavily dominated by upwelling sources (Coale *et al.*, 1996; de Baar *et al.*, 1995). In the subArctic Pacific HNLC region and throughout most of the oligotrophic ocean, however, aeolian input is the most important new iron source (Boyd *et al.*, 1998; Jickells and Spokes 2001; Johnson *et al.*, 2003). Calculations suggest that even "extraterrestrial Fe" from meteorite deposition could be quantitatively significant in the open ocean (Johnson, 2001).

In coastal regimes or downcurrent from island platforms, sedimentary sources play a predominant role in supplying new iron (Blain *et al.* 2007; Bruland *et al.*, 2001, 2005; Bucciarelli *et al.*, 2001; Croot and Hunter, 1998; Croot *et al.*, 2004a; Hutchins

and Bruland 1998; Johnson *et al.*, 1999, 2001; Planquette *et al.* 2007). The influence of sedimentary Fe was previously thought to be limited to surface waters in close proximity to the coast, but recent evidence suggests that Fe from this source can penetrate far into the interior of the ocean along isopycnal lines. Evidence to support this process is presented in Elrod *et al.* (2004), who coupled measurements of benthic Fe fluxes with water column measurements showing strong onshore/offshore gradients in Fe (Fig. 38.3). Thus, Fe from continental shelf sediments may contribute a much larger share of total new Fe inputs to the open ocean than has been generally realized (Lam *et al.* 2006).

Iron has been shown to be transferred rapidly between algal size classes (Hutchins *et al.*, 1993) and plankton trophic levels (Twining and Fisher, 2004), and regenerated Fe is believed to support up to 90% of total production in oceanic regimes (Landry *et al.*, 1997). Gordon *et al.* (1997) calculated that new Fe inputs could only support between 4% and 20% of biological demand in the equatorial Pacific. Direct experimental comparisons suggest that recycling efficiencies for Fe are slightly lower (∼25%) than those of N (Hutchins and Bruland, 1995). Direct field comparisons of Fe and N recycling in the ocean are lacking, but one study found that mixed layer residence times (presumably a proxy for recycling efficiency) are about twice as long for N as for Fe (Frew *et al.*, 2006, see below).

The processes responsible for Fe turnover and recycling are also likely the same as those that drive Fe cycling. Grazing by both protozoan and metazoan zooplankton has been shown to rapidly make biological and colloidal Fe available for algal uptake (Barbeau *et al.*, 1996; Chen and Wang 2001; Hutchins and Bruland 1994; Hutchins *et al.*, 1995; Maranger *et al.*, 1998; Wang and Dei, 2001). Viral lysis of phytoplankton and bacteria has also been shown to be potentially important in Fe recycling (Gobler *et al.*, 1997; Poorvin *et al.*, 2004), and calculations suggest that this process could even be a dominant regeneration source in prokaryote-dominated HNLC areas (Poorvin *et al.*, 2004).
Figure 38.3 Iron concentrations in surface waters versus distance offshore on a transect from central California to Hawaii. Elrod *et al.* (2004) used benthic flux measurements and these water column data to make a case for transport of Fe from shelf sediments out into the open ocean gyre. Elrod *et al.* (2004), *Geophysical Research Letters* 31: L12307.

Despite similarities between the general outlines of the N and Fe cycles, the details of their biogeochemistry are strikingly different. Our ability to quantify particular new and regenerated fluxes of Fe lags far behind the well developed methodology available for N. The chemical species involved in new and regenerated Fe inputs remain speculative, and consequently realistic uptake measurements cannot be performed. Current methodology also does not allow the detection of Fe uptake using isotopic methods at true tracer levels, and all attempts at measuring rate parameters or f-ratios for the Fe cycle are thus compromised by potential artifacts. As our knowledge of Fe chemical speciation and our ability to precisely measure various Fe species advances, a crucial objective of future research will be to definitively quantify the relative importance of new and regenerated Fe in marine regimes.

2.4. Iron export and residence time

In contrast to N, surprisingly little information is available on export rates of Fe from the surface ocean, despite the obvious importance of this parameter to biogeochemical models. Partly, this is due to the difficulties associated with making trace-metal clean measurements of sinking fluxes out of the mixed layer. Two published estimates from relatively nearshore waters present quite high export estimates of 2 μmol m^{-2} day^{-1} (in the Drake Passage, Martin *et al.*, 1990) and <10–140 μmol m^{-2} day^{-1} (in the Baltic Sea, Pohl *et al.*, 2004).

Frew *et al.* (2006) used trace-metal clean sediment trap methods developed by Kremling *et al.* (1996) in subAntarctic HNLC waters to obtain much lower export estimates of 218–548 nmol m^{-2} day^{-1} (Fig. 38.4A). This flux roughly corresponds to published estimates of aeolian deposition rates in this region (Jickells and Spokes, 2001) and represents a daily loss of about 1% of the mixed layer Fe inventory. In the same trap arrays, daily fluxes of particulate organic C (POC), N (PON) and P (POP) were <0.5% and BSi (biogenic silica) fluxes were ~1.9% of the total mixed layer inventories of these elements. Patterns of Fe export between duplicate arrays and with depth were qualitatively similar to those of PON (Fig. 38.4B) and POP (Fig. 38.4C), despite orders of magnitude differences in absolute amounts. In this study sinking particulates exhibited dramatically increasing Fe:C and Fe:N ratios below the mixed layer, suggesting preferential remineralization of C and N relative to Fe and/or additional scavenging of Fe by particles during sinking (Frew *et al.*, 2006).

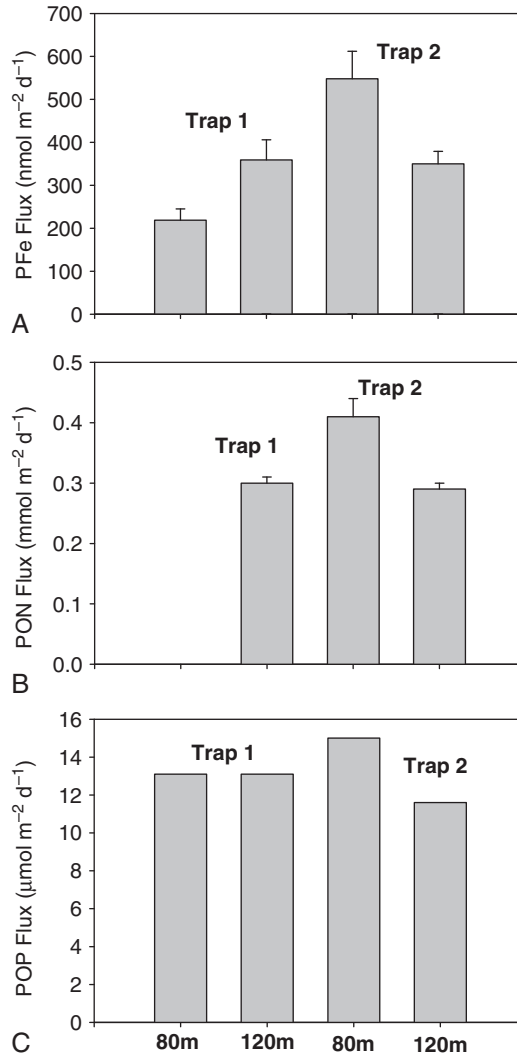
Compared to N and other nutrient elements the residence time of Fe in both the surface and deep ocean is quite short, much shorter than the overall mixing time-scales of the ocean. This is largely due to the high biological demand for Fe relative to its supply, and to rapid removal by its scavenged chemical behaviour. Recent data compilations suggest that there are inter-ocean differences in deep-water Fe concentrations (Parekh *et al.*, 2004, 2005), contrary to earlier suggestions (Johnson *et al.*, 1997). These differences between the Atlantic and Pacific are not, however as large as for other nutrient-type elements and are likely related to distance gradients from major source terms such as Saharan dust inputs (Boyle, 1997; Watson *et al.*, 2000), rather than to differences in accumulated remineralization


Figure 38.4 Export fluxes out of the mixed layer measured in unperturbed subAntarctic HNLC waters near New Zealand during the FeCycle experiment for (A) PFe, (B) PON, and (C) POP. Samples were collected at 80 and 120 m using two trace metal-clean drifting sediment trap arrays deployed for 7 days. Values are the means of four (PFe), two (PON), or one (POP) collection cylinders at each depth, after subtraction of procedural blank values (deployed but unopened cylinders). Error bars represent standard errors. PON samples were lost from the 80 m depth of Trap 1. Adapted from Frew *et al.* (2006), Global Biogeochemical Cycles 20: GB1S93.

fluxes as for N and P. Estimates of Fe residence times in the mixed layer range from 6–62 days (Croot *et al.*, 2004b) to 100 days or so (Frew *et al.*, 2006). On larger spatial scales, Moore *et al.* (2004) suggest an upper ocean residence time of 1–10 years, and Boyle *et al.* (2005) estimated a surface ocean residence time in the Pacific of about half a year.

Johnson et al. (1997) calculated an overall oceanic residence time for Fe of about 100 years. The order-of-magnitude difference between this estimate and recent oceanic residence time calculations for fixed N (roughly 1500–3500 years, Codispoti et al., 2001) is due almost entirely to iron's scavenged chemical behaviour. In most oxygenated waters below the euphotic zone, nitrate (NO_3^-) is probably minimally impacted by biological demand, and relatively unreactive chemically. Although little is known about biological demand for Fe below the euphotic zone, it is also likely small. Relatively rapid particle scavenging throughout the water column (compared to species like NO_3^-), however, reduces the turnover time of Fe in the ocean to mere decades.

2.5. Dissolved and particulate iron pools

Iron is the only nutrient element for which particulate concentrations are typically higher than dissolved levels (de Baar and de Jong, 2001). Despite this, considerably more research attention has focused on measuring dissolved pools than on the particulate fraction. The literature on total dissolved Fe concentrations is now far too extensive to comprehensively review here, but most analysts report oceanic surface concentrations of <0.1–0.5 nM (de Baar and de Jong, 2001; Johnson et al., 1997), and deep-water levels ranging from 0.3 to 0.7 nM (Parekh et al., 2005). Some differences in reported dissolved Fe levels could be due to analytical artifacts, since various methods used by different groups may measure different fractions of dissolved and/or colloidal and particulate pools. Methods intercomparisons are currently underway that could help to clarify these issues.

Reported surface PFe values are more variable (Croot et al., 2004a,b; Gordon et al., 1998; Martin et al., 1990; Tovar-Sanchez et al., 2003; Weinstein et al., 2004), but are generally also less than 1 nmol L^{-1} in HNLC areas. Much of the interest in PFe has been directed towards understanding the solubility of lithogenic Fe from dust (Spokes and Jickells, 1996), although biogenic Fe particulate concentrations are often equivalent or higher in many areas (Frew et al., 2006; Tovar-Sanchez et al., 2003). Various estimates of dust Fe solubility range from 1–10% (Jickells and Spokes, 2001), but Boyle et al. (2005) arrived at an estimate of 30–40% in the Pacific near Hawaii. Johnson et al. (2003) also calculated a possible dissolution value of about 20% for this region, and suggested that the process is likely far more complex than is recognized by current simple dissolution models.

Frew et al. (2006) also suggest that an exclusive emphasis on understanding abiotic dust dissolution processes may be misplaced. Their results show that as much as 53% of suspended lithogenic Fe in the euphotic zone is transformed to biogenic Fe on a timescale of weeks, prior to export with sinking particle fluxes. Efficient biological transformation pathways (such as bacterially-mediated dissolution or grazer ingestion of dust particles) probably result in much higher bioavailability of aeolian Fe inputs than simple chemical solubilization calculations would suggest. It seems that dust dissolution is not a simple, short term process governed by thermodynamics, but is instead a kinetic process where biological influences can substantially shift the equilibrium.

Biogenic PFe actually consists of two distinct pools, intracellular or biological Fe and surface-adsorbed or scavenged Fe (Hutchins, 1995). The latter has usually not been considered to be a true component of the cellular Fe quota, and a titanium (Ti) wash method (Hudson and Morel, 1989) has therefore been commonly employed to remove surface-bound Fe in radiotracer studies (Eldridge *et al.*, 2004; Hutchins *et al.*, 1999; Poorvin *et al.*, 2004; Sunda and Huntsman, 1997; Sunda *et al.*, 1991). However, the titanium reagent is itself heavily contaminated with Fe and so its use is questionable for non-radioactive measurements.

Tovar-Sanchez *et al.* (2003) developed a trace-metal clean oxalate-based reagent which can be used to evaluate surface-bound and internal pools of Fe in natural samples. Using this method, they showed that scavenged Fe in suspended particulates in several parts of the Southern Ocean comprised 16–86% of the total particulate concentrations. Results obtained using the oxalate wash have been shown to be quite comparable to those obtained from the Ti wash (Tang and Morel, 2006). Methods like this one hold great promise to actually quantify and compare relative biological uptake and particle scavenging rates *in situ*, crucial parameters for estimating dissolved Fe removal processes in Fe biogeochemical models (Fung *et al.*, 2000; Moore *et al.*, 2002).

2.6. Organic complexation and redox chemistry

Chemists have been aware for at least a decade that the dissolved speciation of Fe is heavily dominated by organic chelates, with typically 99% of total dissolved Fe bound in these complexes. The development of several cathodic stripping voltammetry electrochemical methods has allowed measurements of conditional stability constants for iron-binding by these natural ligands (Croot and Johansson, 2000; Gledhill and van den Berg, 1994; Rue and Bruland, 1995; Wu and Luther, 1995), and these analyses have now been carried out in surface waters of virtually every ocean basin and on a growing number of depth profiles (reviewed in de Baar and de Jong, 2001; Johnson *et al.*, 1997).

The picture these data present is remarkably consistent. Iron ligands are frequently placed into two classes that are operationally defined by their electrochemical analytical detection "windows," a weaker "L2" class with a typical concentration of 0.2–1.5 nmol kg^{-1} and a stronger "L1" class with a lower concentration of 0.3–0.4 nmol kg^{-1} (Bruland and Lohan, 2004). Because the L1 class has conditional stability constants at least an order of magnitude higher than those of L2, however, most of the dissolved Fe is bound in L1-type complexes. Electrochemical techniques however have limitations, partly because the specific analytical window of each particular method precludes measurement of potential ligand classes outside these limits, and partly because ligands already bound to Fe *in situ* must be indirectly estimated by difference since only "free" or unbound ligands can be detected directly. Nevertheless, electrochemistry does yield unambiguous information about the uncomplexed ligand concentrations available to bind new Fe inputs.

The chemical structures and biological sources and functions of these Fe-binding ligands remain mysterious. Witter *et al.* (2000) point out that electrochemically-derived conditional stability constants can give little useful

information about ligand structure, since a wide variety of completely unrelated Fe-binding functional groups yield very similar values in seawater. It seems clear that L1 and L2 ligands do not represent single compounds, but instead are mixtures of broad classes of organic molecules with similar binding constants but probably quite heterogeneous structures.

Among the candidates for organic ligands in seawater are siderophores, high-affinity Fe-binding compounds with various functional moieties that are produced by Fe-stressed prokaryotes as an uptake strategy (Butler, 1998). Many marine bacteria and cyanobacteria can produce diverse siderophores in culture (Granger and Price, 1999; Wilhelm and Trick, 1994). Using column concentration methods, Macrellis *et al.* (2001) identified siderophore-type functional groups in bulk DOM isolated from seawater, and known siderophores have been detected in Baltic seawtare using capillary electrophoresis (Kosakowska *et al.*, 1999; Mucha *et al.*, 1999). Electrospray mass spectrometry also offers a promising avenue for determining the actual structures of unknown siderophores in seawater (McCormack *et al.*, 2003), and a method combining high performance liquid chromatography with electrospray mass spectrometry has detected a number of siderophores in coastal seawater incubations enriched to promote bacterial growth (Gledhill *et al.*, 2004). Some intracellular biomolecules such as porphyrins are also very strong Fe chelators (Rue and Bruland, 1997; Witter, 2000), and are likely released to the water by grazing or cell lysis (Hutchins *et al.*, 1999).

A number of studies have looked at bioavailability of Fe chelated to various "model" Fe ligand complexes (Fig. 38.5, Achilles *et al.*, 2003; Guan *et al.*, 2001; Hutchins *et al.*, 1999; Kuma *et al.*, 2000; Maldonado and Price, 1999; Weaver *et al.*, 2003). It has been suggested that different taxonomic groups of marine plankton may have preferences for Fe bound to particular types of ligands (Guan *et al.*, 2001; Hutchins *et al.*, 1999). Biological Fe uptake from various colloidal species has also been investigated (Kuma and Matsunaga, 1995; Nishioka and Takeda, 2000; Nodwell and Price, 2001; Wang and Dei, 2003). Colloids may include a substantial fraction of organically complexed Fe, and also could represent an intermediate form in conversions between the lithogenic and biogenic pools. Despite these advances, the chemical nature and biological implications of Fe organic complexation remain largely obscure, and this uncertainty persists as a surprisingly intractable barrier to a full understanding of the biogeochemistry of this element.

Like N, Fe has multiple redox states and can cycle between oxidized Fe(III) and reduced Fe(II) chemical species. Under oxic conditions, the ferric ion is by far the dominant form, but Fe(II) in aerobic waters can be produced transiently through photochemical interactions with DOM (Rose and Waite, 2003; Waite and Morel, 1984) or by biological uptake system reductive processes (Shaked *et al.*, 2004). Barbeau *et al.* (2003) suggest that some organic complexing ligands such as particular types of siderophores can act as electron donors in the photochemically-mediated reduction of chelated Fe(III), and thereby perhaps increase its bioavailability. Appreciable Fe(II) concentrations were observed in the fertilized patches for an extended period of time during the SOIREE and EisenEx open ocean Fe addition experiments in the Southern Ocean (Croot *et al.*, 2001, 2005). Although Fe(II) oxidation kinetics are slower at cold temperatures, this situation is highly
Figure 38.5 Short term Fe uptake rates from model iron/ligand complexes by *Trichodesmium* colonies collected in the subtropical Atlantic Ocean. Shown are uptake rates from Fe complexed to a trihydroxamate siderophore (desferrioxamine), a dihydroxamate siderophore (rhodoturulic acid), and a porphyrin (protoporphyrin IX). For comparative purposes, uptake rates were also measured using added inorganic Fe (III). Achilles *et al.* (2003), Limnology and Oceanography 48: 2250–2255.

thermodynamically unfavorable. The persistence of high Fe(II) levels thus suggests either continual replenishment through ongoing biological or photochemical reduction processes, or that the ferrous ion was stabilized with respect to oxidation by an (unknown) Fe(II) chelator.

2.7. Iron and nitrogen acquisition

From the earliest shipboard addition experiments in the late 1980s (Martin *et al.*, 1991), an empirical relationship between Fe availability and NO_3^- drawdown has been recognized. Deckboard Fe addition experiments in HNLC areas invariably demonstrate increased utilization of NO_3^-, relative to control treatments, and NO_3^- is always consumed much faster in unenclosed Fe-enriched mesoscale patches than in surrounding unfertilized waters (Fig. 38.6, Boyd 2002; Coale *et al.*, 2004). It is well known that algal enzymatic systems for oxidized N assimilation contain Fe, and that Fe-intensive photosynthetic electron transport systems must supply reductant for NO_3^- reduction and uptake (Raven, 1988). Consequently, nitrate-grown cells have higher Fe uptake rates (Maldonado and Price, 1996) and intracellular Fe quotas (Wang and Dei, 2001) than those growing on ammonium (NH_4^+). Adequate Fe supplies are thus an absolute prerequisite to growth on nitrate.

Laboratory work suggests, however, that Fe limitation probably does not directly inhibit NO_3^- uptake by compromising nitrate reductase activity (Milligan and Harrison, 2000). Instead, Fe limitation may block the NO_3^- reduction pathway further downstream, by preventing nitrite (NO_2^-) reduction to NH_4^+ due to insufficient supplies of photosynthetically-produced reductant. This study showed that Fe-deficient diatom cells continue to take up and reduce NO_3^- to nitrite.
Figure 38.6 Effects of Fe enrichment on NO_3^- drawdown in the South Patch (66.45°S, 171.8°W) during the SOFeX Southern Ocean mesoscale iron addition experiment. Shown are NO_3^- concentrations versus time in the iron-fertilized patch (closed circles) compared to nearby unfertilized control waters (open circles). Coale et al. (2004), Science 304: 408–414.

Since nitrite reductase activity is impaired, however, the cells then excrete much of the "excess" accumulated NO_3^- back to the water. Iron/light co-limitation of phytoplankton near the base of the euphotic zone (Boyd *et al.*, 2001; Maldonado *et al.*, 1999; Sunda and Huntsman, 1997) could contribute to the persistent subsurface NO_3^- maximum zones that commonly occur in many parts of the ocean, along with other sources such as bacterial denitrification or ammonium oxidation (Keifer *et al.*, 1976).

Iron interactions with N sources are not limited to phytoplankton. Kirchman *et al.* (2003) found that the growth rate, respiratory electron transport system activity, and growth efficiency of a marine gamma proteobacterium (*Vibrio harveyi*) were much lower in Fe-limited cultures grown with NO_3^- than when NH_4^+ or amino acids were supplied as N sources. They suggested that these results may help to explain why natural bacterial communities in nitrate-rich, iron-poor HNLC areas also typically exhibit reduced growth rates and efficiencies.

Another critical N cycle enzyme which requires large quantities of Fe is nitrogenase, which catalyzes the fixation of atmospheric N_2 to NH_4^+ by some prokaryotes. Consequently, diazotrophs may be especially vulnerable to iron limitation and there has been a tremendous amount of recent research effort to understand how this could impact global marine N_2 fixation (see Chapter 4 by Carpenter and Capone, this volume). Nitrogenase is a complex enzyme, with the most common form containing two proteins termed the molybdenum iron (MoFe) protein (dinitrogenase) and the Fe protein (dinitrogenase reductase) (Paerl and Zehr, 2000). The Fe use efficiency of nitrogenase, calculated as the rate of enzymatic substrate turnover per mole of Fe, is the lowest among all of the Fe-containing enzymes involved in N metabolism. In addition to this large enzymatic Fe requirement, N_2-fixing organisms also require a large amount of Fe to facilitate electron transfer reactions (Kustka *et al.*, 2003; Raven, 1988).

N_2 fixation can be affected by the availability of Fe through either direct effects on nitrogenase synthesis (Berman-Frank *et al.*, 2001; Küpper *et al.* 2008) or indirectly

through effects on photosynthesis and growth (Fu and Bell, 2003a). Berman-Frank *et al.* (2001) observed that only 11% of Fe-depleted cultured *Trichodesmium* cells contained nitrogenase, whereas 20% of Fe-replete cells tested positive for nitrogenase activity. Western blots of nitrogenase reductase also showed higher levels of this protein in their Fe-replete cultures. They concluded that the synthesis and expression of nitrogenase by *Trichodesmium* is directly controlled by Fe availability.

3. THE OCEAN PHOSPHORUS CYCLE

Phosphorus was traditionally considered not to be limiting on ecologically relevant timescales in the marine environment (Ryther and Dunstan, 1971) because N usually became limiting before P was depleted. However, evidence is accumulating for P limitation in several coastal systems and estuaries (Thingstad *et al.*, 1998; Yin *et al.*, 2000), the oligotrophic Atlantic Ocean (Cotner *et al.*, 1997; Sañudo-Wilhelmy *et al.*, 2001; Wu *et al.*, 2000), the North Pacific central gyre (Björkman *et al.*, 2000), and in the eastern basin of the Mediterranean Sea (Krom *et al.*, 1991, 1993).

Compared to N and Fe, the P cycle is relatively simple. Phosphorus lacks the gas phase that is so important for N, and unlike either N or Fe, is unaffected by redox cycling. The marine P cycle consists of a series of transformations between dissolved inorganic, particulate organic, and dissolved organic forms, presented diagrammatically in Fig. 38.7. The three main pathways of dissolved P delivery from the continents to the ocean are via riverine, atmospheric and volcanic sources. Supply is driven largely by continental weathering, but because P is only a minor component of most crustal rocks, its delivery is restricted relative to more abundant lithogenic elements like silicon (Cosgrove, 1977).

By far the dominant transport mode of P to the ocean is through river runoff. Pre-human riverine P loading to the oceans has been estimated at $2.6–3.3 \times 10^{11}$ mol P year^{-1}, and current anthropogenic inputs have elevated this input to $7.4–15.6 \times 10^{11}$ mol P year^{-1}(Froelich *et al.*, 1982; Howarth *et al.*, 1995). The atmospheric delivery of P from the continents to the ocean was first considered by Graham and Duce (1979), who estimated that a net flux of $\sim 3.2 \times 10^{10}$ mol P year^{-1} is transferred via atmospheric dust inputs. Chadwick *et al.* (1999) and Rea (1994) estimated an aeolian P flux rate ranging from $0.2–1.4 \times 10^{10}$ mol P year^{-1} using geochemical tracers of continental crust. Mills *et al.* (2004) also made a convincing case for the importance of aeolian P supply in the Atlantic. This supply of phosphate from the delivery of airborne dust is significant (Föllmi, 1996), because 21–51% of total aeolian phosphate (PO_4^{3-}) is bioavailable once deposited in the ocean (Duce *et al.*, 1991; Graham and Duce, 1982). However, this value could be underestimated by as much as 50% since it does not include acid soluble and high temperature soluble P fractions (Benitez-Nelson, 2000). The contribution of localized volcanic sources to ocean P delivery on a global scale is probably minor (Benitez-Nelson, 2000), although a few studies have suggested that volcanoes could be potential P sources to the ocean (Resing, 1997; Yamagata *et al.*, 1991).

Figure 38.7 A conceptual diagram of important pools and fluxes in the marine P cycle. *Non-living pools* (rectangles) include particulate inorganic P (suspended lithogenic material), dissolved inorganic P (phosphate), and dissolved organic P. *Living pools* (ovals) include prokaryotic and eukaryotic phytoplankton, protozoan and metazoan grazers, and bacteria and viruses. *New inputs* (brown text and arrows) include upwelled dissolved PO_4^{3-}, aeolian deposition (dust particles), and riverine sources. *Transformations between non-living pools* (white arrows) include dissolution of dust as PO_4^{3-}, and hydrolysis of dissolved organic P (DOP) to yield PO_4^{3-} by biological enzymatic activity. *Biological uptake pathways* (green arrows) include assimilation of phosphate (probably the dominant pathway in coastal and upwelling areas) and DOP (probably the dominant flux in oligotrophic regimes) by phytoplankton and bacteria. Also shown is trophic transfer of cellular P via grazing. *Regeneration pathways* (orange arrows) include recycling of cellular P as dissolved inorganic PO_4^{3-} (by viruses and bacteria) and DOP (by all organisms). *Export pathways* (red arrows) include direct sinking of lithogenic and biological particulate P; although arrows are shown from all living pools, larger phytoplankton and grazers are likely to be dominant sources. Another recently recognized pathway that could be important is scavenging of dissolved PO_4^{3-}; export of DOP is also depicted, although the importance of scavenging or downwelled export of this P species has not been established.

Sedimentary burial is the only important removal process for P from the ocean (Benitez-Nelson, 2000). In the marine system, almost all bioavailable PO_4^{3-} is taken up by primary productivity in the euphotic zone and incorporated into organic matter for export by the biological pump. Approximately 95% of the P is released as dissolved inorganic PO_4^{3-} during the oxidation of sinking organic particles, and will be reintroduced to the photic zone by upwelling processes and reused by the marine biota (Föllmi, 1996). The other 5% is removed from the ocean by sedimentary burial either with organic matter, as inorganic PO_4^{3-} absorbed on $CaCO_3$ shells and metal oxyhydroxides, or by incorporation of PO_4^{3-} into authigenic minerals such as apatites and phosphorites (Benitez-Nelson, 2000; Berner *et al.*, 1993). New evidence suggests that export and burial of intracellular P in

diatoms (as polyphosphates) may be a significant removal process in the biogeo-chemical cycle of this element (Diaz *et al.* 2008). The estimated residence time of P in the ocean ranges from 20,000–80,000 years based on P sources, but is reduced to 9300–29,100 years relative to P sinks (Benitez-Nelson, 2000; Ruttenberg, 1993).

3.1. Speciation of dissolved phosphorus

Dissolved P in the ocean is present as inorganic orthophosphates and as P-containing organic compounds. Bioavailable PO_4^{3-} comes from the continental weathering of phosphate-bearing igneous and sedimentary rocks (Föllmi, 1996), from remineraliz-ation of organic P by bacteria and algae through the extracellular enzymes alkaline phosphatase (Björkman and Karl, 1994; Li *et al.*, 1998) and $5'$ nucleotidase (Ammerman, 1991; Ammerman and Azam, 1985, 1991a,b; Tamminen, 1989), or from the viral lysis of bacteria (Scanlan and Wilson, 1999). Orthophosphates exist as three free ions, $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-}, and have a tendency to make ion pairs with bivalent metals such as Ca^{2+}, Mg^{2+}, and Fe^{3+} ions at neutral pH (Cosgrove, 1977; Lobban and Harrison, 1994). The major form of dissolved inor-ganic P at a seawater pH of 8 is HPO_4^{2-}, dominating ~87% in DIP (Benitez-Nelson, 2000). The ongoing acidification of the ocean through anthropogenic CO_2 emissions (Caldeira and Wickett, 2003) will tend to shift the phosphate buffer system incrementally towards $H_2PO_4^-$. The consequences of this process for future P biogeochemistry are unknown.

Like other dissolved organic nutrients, the chemical composition of organic P is relatively unknown. Marine dissolved organic phosphorus (DOP) composition has been mostly identified as particular compound classes such as monophosphate esters, phosphonucleotides, nucleic acids, phospholipids, phosphonates and polyphosphates (Benitez-Nelson, 2000). Kolowith *et al.* (2001) found that monophosphate esters and phosphonates are major components in the Pacific Ocean, the Atlantic Ocean and the North Sea. ATP (adenosine triphosphate), ubiquitous in all living cells, has been used as a model DOP compound in radiotracer experiments to obtain infor-mation on P sources and fluxes in natural environments (Björkman *et al.*, 2000; Karl and Bossard, 1985) and cyanobacterial cultures (Fu *et al.*, 2006).

DOP phosphorus is often present in concentrations up to an order of magnitude higher than DIP in oligotrophic regimes (Karl *et al.*, 2002). There is good evidence that phytoplankton in these areas rely heavily on DOP to support growth (Jackson and Williams, 1985; Li *et al.*, 1998); this literature is reviewed for *Trichodesmium* below. Alkaline phosphatase activity measurements are frequently used to detect DOP utilization in natural communities (Mulholland *et al.*, 2002; Stihl *et al.*, 2001; Yentsch *et al.*, 1972). For instance, there is a strong correlation between alkaline phosphatase activity and *Synechococcus* abundance in the Red Sea (Li *et al.*, 1998).

3.2. Surface-bound phosphorus

New evidence suggests that, like Fe, the cycling of P can be substantially affected by particle reactivity and scavenging. Although oxyanions such as PO_4^{3-} have not generally been considered by biologists to be scavenged chemical species,

geochemists have long recognized that PO_4^{3-} is removed from seawater by adsorption onto sediment and hydrothermal plume particles (Berner, 1973; Bjerrum and Canfield, 2002; Wheat *et al.*, 1996). Sañudo-Wilhelmy *et al* (2004) showed that ~30–50% of the total P associated with Atlantic *Trichodesmium* colonies was easily washed off the cells with an oxalate wash procedure that was originally developed to remove surface-bound trace metals (Tovar-Sanchez *et al.*, 2003). Correlations between adsorbed Mn oxides and surface-bound P suggested that P scavenging could be mediated by ligand/ligand complexation reactions between surface-bound metal cations and the PO_4^{3-} oxyanion (Sañudo-Wilhelmy *et al.*, 2004), but this proposed mechanism will require further investigation.

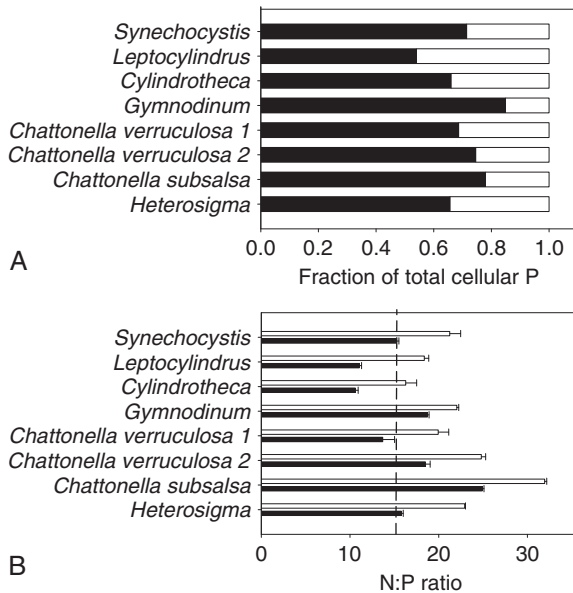
Both cultures and natural estuarine blooms of a wide variety of eukaryotic and prokaryotic phytoplankton other than *Trichodesmium* also have a large fraction of their total cell-associated P in surface-adsorbed pools (Fig. 38.8A, Fu *et al.*, 2005a). This study found that P scavenging was a unique property of inorganic phosphate, and DOP-grown phytoplankton did not exhibit any surface-adsorbed P. P-starved cultures were able to internalize some of their surface-bound P over the course of several days, suggesting that this pool could in effect serve as a cellular P reserve. The evident potential importance of scavenging in the biogeochemical cycle of P raises questions about the definition of cellular P quotas and kinetic


Figure 38.8 Effects of PO_4^{3-} scavenging on cellular partitioning of P and N:P ratios in eight natural estuarine bloom samples of prokaryotic and eukaryotic algae. (A) Fractions of total cell-associated P in the intracellular (filled bars) and surface-adsorbed (open bars) pools; (B) Nitrogen to phosphorus (N:P) ratios calculated using total cellular P (filled bars) and intracellular P pools after removal of surface-adsorbed P with the oxalate reagent (open bars). Error bars represent the standard deviations of triplicate samples, and the dashed lines indicate the Redfield ratio. Fu *et al.* (2005a), Limnology and Oceanography.

uptake constants, the interpretation of Redfield ratios (see below), and the possi-
bility that this process could be an important but currently unrecognized removal
mechanism for dissolved P in the ocean (Fu *et al.*, 2005a).

3.3. Phosphorus versus nitrogen as proximate and ultimate limiting nutrients

There are two viewpoints on which nutrient, P or N, controls primary production
in the ocean: the geochemical view and the biological view (Tyrell, 1999). The
geochemists think that P limits phytoplankton growth in most marine ecosystems.
The scenarios that have been proposed include: (1) N can be acquired via N_2
fixation from atmospheric N_2 and reduced to bioavailable NH_4^+. This of course
assumes that N_2 fixation can keep pace with demands of the photoautotophs (see
below); (2) There is no atmospheric or other alternative reservoir for P, and most is
supplied to the ocean from continental weathering and river inputs; and (3) the
residence time of P in the ocean is significantly longer than that of N and so the rate
of P supply is much lower than N. Finally, this assumption has been demonstrated
experimentally in freshwater environments (Hecky and Kilham, 1988; Howarth
et al., 1988; Smith, 1983) but not in marine ecosystems (Tyrell, 1999).

However, biologists have demonstrated that N is more likely to control phyto-
plankton productivity in the coastal and open oceans through nutrient enrichment
experiments and observations of nutrient distributions (Falkowski *et al.*, 1998).
Typically, NO_3^- runs out slightly before PO_4^{3-} when nutrients become depleted
in the surface waters (Fig. 38.9, GEOSECS 1996, Tyrell and Law, 1998). It has long
been known that additions of NO_3^- to natural samples collected from oligotrophic
surface ocean waters usually stimulate phytoplankton growth, whereas the addi-
tion of PO_4^{3-} usually does not (Codispoti 1989; Ryther and Dunstan, 1971).
Figure 38.9 Surface ocean NO_3^- versus PO_4^{3-} scatter plot from the GEOSECS global data set.
The intercept suggests that there is often PO_4^{3-} remaining when NO_3^- is fully depleted. Tyrell
1999, Nature 400: 525–531.

Although N_2 fixation certainly provides a significant source of new N to the ocean, diazotrophy may be limited by factors such as Fe limitation (see below). Hence the concentration of fixed N is variable (Falkowski, 2000).

The wide distribution across prokaryotic taxa and the close genetic homologies of N_2 fixation systems suggests that fixed inorganic N in the primeval ocean was likely scarce (Falkowski, 1997), whereas inorganic PO_4^{3-} was probably abundant (Van Cappellen and Ingall, 1996). Finally, due to denitrification, the ratio of sinking particulate organic N to particulate P is less than the ratio of dissolved inorganic N to P. For this reason, throughout most of the world's oceans dissolved inorganic N rather than P has been suggested to limit primary production on geological time-scales (Dugdale 1967; Falkowski, 1997; McElroy 1983; Ryther and Dunstan, 1971).

Tyrell (1999) produced a model showing that the proximate limiting nutrient in the ocean is NO_3^-, while the ultimate limiting nutrient is PO_4^{3-}. Mills and colleagues (2004) confirmed that N is the proximate limiting nutrient in the eastern tropical North Atlantic with nutrient addition experiments. N limitation or P limitation is not always constant temporally and spatially. Hence Karl *et al.* (2001) suggested that when considering nutrient limitation in the oceans, the exact time and spatial scale should be defined.

For example, an extensive 9-year data set from ALOHA indicates that the bulk dissolved matter N:P ratio is variable. In the subtropical North Pacific Ocean, N_2 fixation may supply up to half of the new N to sustain the rate of the annual particulate N export from the euphoric zone. A recent increase in this source of new N appears to have shifted the North Pacific subtropical gyre from N limitation to P limitation (Karl *et al.*, 1997). Hence in the oligotrophic ocean, N_2 fixation could lead to a decoupling of N and P pool dynamics and an alternation of N versus P control of primary production (Karl *et al.*, 2001). Similarly but on a shorter time-frame, in the central Baltic Sea the development of N_2-fixing cyanobacterial blooms can drive the system from N limitation to P limitation between May to September (Nausch *et al.*, 2004).

3.4. Variability in biological and dissolved nitrogen:phosphorus stoichiometry

Redfield (1958) first described the average composition of marine organic matter based on Fleming's data for the average elemental composition of marine organisms. The classical Redfield N:P stoichiometry of 16:1 is often regarded as an upper limit for differentiating N limitation from P limitation. Ratios less than 16 are assumed to indicate N limitation, and ratios above 16 are assumed to denote P limitation. The 16:1 ratio is accepted by biologists (Goldman *et al.*, 1979), whereas many geochemists prefer to use an N: P stoichiometry of 15 based on the covariation of nitrate and phosphate in deep seawater (Broecker and Peng, 1982).

The precise Redfield ratio values have, however, been widely challenged recently (Broecker and Henderson, 1998) with some best estimates being ~25 mol N: 1 mol P. Falkowski (2000) questioned whether the biologists could support or refute this value. Geider and LaRoche (2002) re-examined the observed range of N:P ratios. They found that algal N:P ratios range from 5 to 19 under

optimal nutrient–replete growth conditions, with most observations below the Redfield ratio (Fig. 38.10). Taxonomic trends are also evident, with cyanobacteria presenting high ratios and more recently evolved groups like diatoms characterized by lower values (Bertilsson *et al.*, 2003; Fu *et al.*, 2005a; Heldal *et al.*, 2003; Ho *et al.*, 2003; Quigg *et al.*, 2003). The critical N:P differentiating N limitation and P limitation for phytoplankton growth is significantly higher than Redfield, ranging from 20–50 mol N:mol P (Fig. 38.11). Contrary to the variability in the elemental composition of marine organisms, the inorganic N:P ratio is constant close to the Redfield ratio in most of the deep ocean. This constancy results from feedback mechanisms including nitrogen fixation and denitrification (Redfield, 1958).
Figure 38.10 N:P ratios of (A) nutrient-replete marine microalgal and cyanobacterial cultures; (B) marine particulate matter and (C) nutrient draw-down during phytoplankton blooms. Adapted from Geider and LaRoche (2002), European Journal of Phycology 37:1–17.
Figure 38.11 Contour plot of cell N quota versus P quota at three growth rates for the green alga *Scenedesmus* sp., showing the critical N:P threshold value for N versus P limitation. Adapted from Geider and LaRoche (2002), *European Journal of Phycology* 37:1–17.

The newly recognized reactivity of PO_4^{3-} with algal cell surfaces (Fu *et al.*, 2005a; Sañudo-Wilhelmy *et al.*, 2004) throws another variable into the Redfield mix. If the scavenged PO_4^{3-} on algal cells is not considered to be part of the cell quota, as it traditionally has not been for other particle-reactive species like Fe (Hudson and Morel, 1989; Tovar-Sanchez *et al.*, 2003), then true algal ''biological'' elemental ratios are probably often considerably higher than Redfield. Because P is used as a normalizer in the Redfield ratio, removing the surface-bound pool can easily result in calculated intracellular N:P ratios that are 50% or more above 16:1 (Fig. 38.8B, Fu *et al.*, 2005a). It appears that overall Redfield ratios integrate the scavenged and internal P pools of phytoplankton, as both together (the total cell-associated P) usually yield Redfield values (Fig. 38.8B). Oceanographers should agree on a common convention for particle-reactive nutrients such as Fe and PO_4^{3-}. When considering overall particulate ratios, such as in vertical flux estimates, it is probably most appropriate to include both interior and surface-bound pools. When discussing nutrient limitation and biological cell quotas, the use of intracellular values makes more sense. In general for any study involving Fe or P, it is necessary to carefully consider and specifically define what subset of the total cell-associated element is to be considered.

4. PHOSPHOSRUS AND IRON AS ALTERNATIVE OR CO-LIMITING CONTROLS ON N_2 FIXATION

There is a limited amount of evidence for direct control of N_2 fixation by P availability. In the subtropical and tropical Atlantic, *Trichodesmium* N_2 fixation rates were correlated to cellular P rather than to colony iron content, suggesting that P limits N_2 fixation in this area (Sañudo-Wilhelmy *et al.*, 2001). Their observations support the hypothesis that P could be limiting N_2 fixation in the North Atlantic

Ocean, due to extremely low dissolved inorganic phosphate levels (Wu *et al.*, 2000). Karl *et al.* (1997) found that diazotrophy increased in the subtropical North Pacific Ocean over seven years of time series observations in parallel with a decrease in soluble reactive P levels, suggesting a shift from N limitation towards P limitation. At some locations in the Baltic Sea, phosphorus additions show a significant impact on N_2 fixation by cyanobacterial communities dominated by *Nodularia*, *Aphanizomenon*, and *Anabaena* (Fig. 38.12A). The level of observed stimulation of N_2 fixation by P addition alone was equal to the simulation by P addition combined with Fe (Moisander *et al.*, 2003).

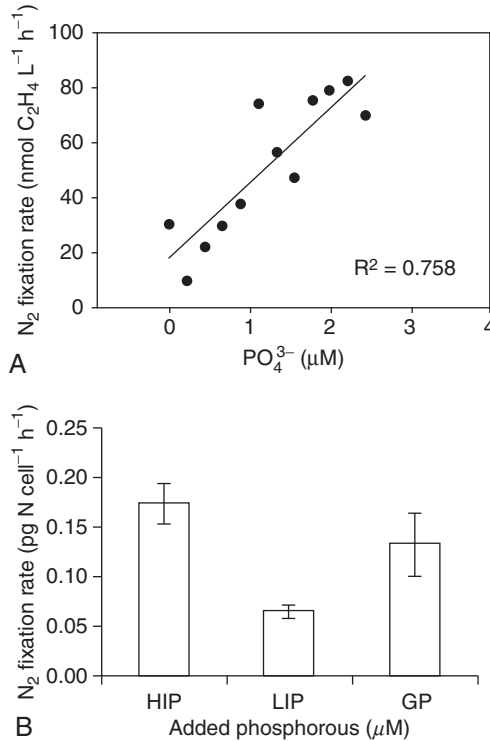
These observations support the overall limitation of N_2 fixation by P, although it has been suggested that *Trichodesmium* could acquire inorganic phosphorus via vertical migration to the nutricline (Karl *et al.*, 1992; Villareal and Carpenter, 1990; 2003). In most marine ecosystems in which *Trichodesmium* (and probably other N_2-fixing organisms) are found, mixed layer dissolved inorganic phosphate concentrations are very low. Support for the idea that DIP is not the primary source


Figure 38.12 (A) Effect of phosphate addition on N_2 fixation by cyanobacterial blooms at a station in the Baltic Sea. Moisander *et al.* (2003), Marine Ecology Progress Series 262: 81–95. (B) Changes in N_2 fixation of the Great Barrier Reef isolate *Trichodesmium* GBRTRLI101during growth on inorganic and organic phosphorus. HIP: 3.5 μM PO_4^{3-}; LIP: 0.5 μM PO_4^{3-}; GP: 3.0 μM Na-glycerophosphate. Values are the means and error bars are the standard deviations of triplicate bottles. Fu and Bell (2003b), FEMS Microbiology Ecology 45: 203–209.

of P to diazotrophs comes from the observation that rates of N_2 fixation measured in many different ocean regions do not correlate with levels of dissolved inorganic P (Hood *et al.*, 2000).

Culture data on PO_4^{3-} growth and uptake kinetics in two strains of *Trichodesmium* from the North Atlantic and the Great Barrier Reef suggest habitat-related trends in P requirements. The strain from the oligotrophic Atlantic had lower phosphate uptake and growth half-saturation constants than the isolate from the higher P environment of coastal Australia. However, neither strain could achieve appreciable growth rates at realistic nanomolar levels of PO_4^{3-} such as those commonly found in the central gyres, with calculated doubling times at these concentrations ranging from one month up to several years (Table 38.1). This suggests that *Trichodesmium* in these areas must necessarily acquire most of their P from DOP sources (Fu *et al.*, 2005b).

Falcon *et al.* (2005) examined the PO_4^{3-} requirements of Atlantic and Pacific unicellular diazotrophic cyanobacteria isolates, and found that half-saturation constants for growth ranged from 0.06 to 0.25 μM. These are similar to the growth half-saturation constants of 0.14–0.22 μM reported for *Trichodesmium* by Fu *et al.* (2005b), suggesting that these unicellular N_2-fixers would also be quite unlikely to meet their cellular P demands by relying on PO_4^{3-} at the reported concentrations in the oligotrophic oceans (∼5–40 nM, Table 38.1).

A single-cell fluorescent assay for expression of alkaline phosphatase (Dyhrman and Palenik, 1999), has been used to show that *Trichodesmium* populations in the Atlantic are likely phosphate-deficient and largely growing on DOP sources (Dyhrman *et al.*, 2002). These results are supported by several other studies showing that *Trichodesmium* is capable of efficiently using DOP (Stihl *et al.*, 2001; Yentsch *et al.*, 1972). Mulholland

Table 38.1 Calculated specific growth rates (μ, day^{-1}) and cellular doubling times (T_d, d) of *Trichodesmium* strains GBRTRLI101 and IMS101 for phosphate-supported growth at typical PO_4^{3-} concentrations reported for surface waters of the North Atlantic Central Gyre, Northern Red Sea, South China, North Pacific Central Gyre, and the Great Barrier Reef lagoon, Australia

Regime and typical $[PO_4^{3-}]$ (μM)	GBRTRLI101		IMS101

Calculations are based on growth kinetics data obtained from laboratory culture experiments. Fu *et al.* (2005b), *Journal of Phycology* 41: 62–73.

et al. (2002) observed that alkaline phosphatase activities per colony were as much as 350 times higher in the very low PO_4^{3-} environment of the subtropical Atlantic than in a higher PO_4^{3-} regime in coastal Australia. Laboratory cultures grown on organic P (e.g., Na–glycerophosphate) exhibit significant N_2 fixation rates compared to phosphate–grown cells (Fig. 38.12B), suggesting that organic P is a good substrate for growth and diazotrophy by *Trichodesmium* (Fu and Bell, 2003b). New work suggests that unlike many other cyanobacteria *Trichodesmium* has the capability to utilize P from phosphonates, a component of the DOP pool that was previously believed to be relatively refractory (Dyhrman *et al.*, 2006).

In addition to the possibility of P limitation, Fe control of N_2 fixation has become increasingly apparent. Most studies on Fe limitation and N_2 fixation have examined the cyanobacterium *Trichodesmium* spp., since they are known as major contributors of new N to oligotrophic marine ecosystems. Rueter, (1988) and Paerl *et al.* (1994) suggested that natural populations could be Fe-limited and hence Fe would affect the input of new fixed N to the ocean. Later, laboratory culture work also demonstrated that the addition of Fe stimulates N_2 fixation (Berman–Frank *et al.*, 2001; Fu and Bell, 2003a; Kustka *et al.*, 2003). Berman–Frank and her colleagues, (2001) used seasonal maps of aeolian iron fluxes and model–derived maps of surface water total dissolved Fe to suggest that in 75% of the oligotrophic ocean, Fe availability limits N_2 fixation by *Trichodesmium*.

There is both physiological and geochemical evidence showing that marine N_2 fixation may be Fe-limited. The nitrogenase in cyanobacteria contains 15 Fe atoms for each heterodimeric protein molecule (Berman–Frank *et al.*, 2001; Raven, 1988). Also, a high ratio of 24 photosystem I: 1 photosystem II partly explains the greater need for Fe by *Trichodesmium*, since each photosystem I complex contains 12 iron atoms (Falkowski *et al.*, 1998; Subramaniam *et al.*, 1999). Hence it is commonly thought that Fe requirements of marine N_2 fixers are higher than those of other phytoplankton (Raven, 1988). A recently revised estimate of Fe requirements suggests that N_2-fixing phytoplankton may have Fe requirements 2.5–5.2 times greater than NH_4^+ assimilating phytoplankton (Kustka *et al.*, 2003). Generally, 38–48 μmol Fe: mol C are required to sustain a diazotrophic growth rate of 0.1 day^{-1} in *Trichodesmium* (Berman–Frank *et al.*, 2001; Kustka *et al.*, 2002, 2003). N_2 fixation rates increase by 6.6 to 11-fold in Fe–replete *Trichodesmium* cultures compared to Fe-limited cultures (Berman–Frank *et al.*, 2001; Fu and Bell, 2003a; Kustka *et al.* 2002, Fig. 38.13A and B). New work on the Fe requirements of the unicellular N_2 fixer *Crocosphaera* suggests that it has lower Fe:C ratios than *Trichodesmium* ($\sim$27 μmol:mol at a growth rate of 0.1 d^{-1}, Fu *et al.* in press), and thus may be less likely to be Fe-limited *in situ* (Tuit *et al.* 2004).

Trichodesmium spp. probably rely on aeolian dust deposition and vertical mixing of Fe-rich subsurface water as Fe sources. Based on a regional correlation between *Trichodesmium* abundance and aeolian dust fluxes, Kustka *et al.* (2002) argued that *Trichodesmium* has a relatively high Fe demand. Although there is no direct evidence for stimulation of *Trichodesmium* by Fe contained in dust, Rueter *et al.* (1992) hypothesized that *Trichodesmium* may be able to intercept, adsorb and solubilize the Fe from dust and thus could possess a unique pathway for Fe acquisition. However, there has been little or no evidence for this uptake pathway presented in the years since.
Figure 38.13 (A) N_2 fixation rates of the North Atlantic isolate *Trichodesmium* IMS101 relative to cellular Fe:C content. Fe:C<50 is considered to be Fe–limited, and Fe:C>150 is considered to be Fe replete. Kustka *et al.* (2002), Research in Microbiology 153: 255–262. (B) N_2 fixation rates by the Great Barrier Reef isolate *Trichodesmium* GBRTRLI101 relative to the addition of Fe. Fu and Bell (2003a), Biotechnology Letters 25: 645–649.

In the subtropical North Atlantic Ocean, trade winds blowing westwards from the Sahara desert bring some of the highest particulate dust fluxes in the ocean, with Fe inputs of up to 1000 mg m^{-2} year^{-1} (Duce and Tindale, 1991). This region of high dust flux corresponds reasonably well to the areas of highest abundance of *Trichodesmium* (Tyrrell *et al.*, 2003). Voss *et al.* (2004) observed a strong correlation between whole community N_2 fixation and Saharan dust supply in this regime, although they suggested that diapycnal phosphate inputs are potentially important as well. Lenes *et al.* (2001) suggested that the summer delivery of Fe in Saharan dust to the western Florida continental shelf fertilized the ocean with Fe, and was followed by massive *Trichodesmium* blooms. Similar *Trichodesmium* blooms were observed at the Bermuda–Atlantic Time Series station after dust input events, and the Fe concentration per colony increased approximately 3-fold during maximal dust deposition (Orcutt *et al.*, 2001). Capone *et al.* (1998) observed dense surface accumulations of *Trichodesmium* associated with low wind speed and high Fe in

atmospheric aerosols in the Arabian Sea. A *Trichodesmium* bloom was also observed at the Hawaii Ocean Times Series station in the North Pacific following a storm (i.e., deposition) event (Wells *et al.*, 1995). Tovar-Sanchez *et al.* (2006), however, found that metal ratios in *Trichodesmium* colonies from the tropical and subtropical Atlantic suggested that their Fe content originated primarily from South American and African rivers, rather than from Saharan dust.

Not all field evidence supports the limitation of *Trichodesmium* diazotrophy by Fe. Both Karl *et al.* (1997) and Sañudo-Wilhelmy *et al.* (2001) observed that median Fe concentrations <1 nM Fe did not seem to limit N_2 fixation in field collected samples in the subtropical North Pacific Ocean and the Central Atlantic. It has been observed that there is no close correlation between total dissolved Fe and *Trichodesmium* abundance in the North Atlantic Ocean when only open ocean stations are considered, and little difference between total Fe concentrations where *Trichodesmium* is abundant and where it is scarce (Tyrrell *et al.*, 2003). Moisander *et al.* (2003) noticed that in the Baltic Sea, Fe addition did not show a significant impact on N_2 fixation or biomass production by three other genera of N_2-fixing cyanobacteria.

In the South China Sea, vast inputs of Fe from aeolian deposition do not result in dense populations of N_2-fixing *Trichodesmium* or the diatom symbiont *Richelia* (Chen *et al.*, 2004). They found that P enrichment here also failed to stimulate algal growth. These researchers suggested that a shortage of organic ligands could reduce the solubility of Fe and make it unavailable to diazotrophs, despite massive airborne dust inputs. There have, however, been no field studies that have measured Fe speciation and N_2 fixation simultaneously, so this explanation remains speculative. In contrast to Chen *et al.* (2004), Wu *et al.* (2003) supported the Fe-limited N_2 fixation hypothesis in the South China Sea by noting that low populations of *Trichodesmium* co-occur with low concentrations of dissolved Fe in this marginal sea.

It is now evident that marine N_2 fixation can be limited by either P or Fe, although the relative importance of these two nutrients is still highly debatable. There may be an interaction between iron supply and P limitation of primary production through N_2 fixation. Recently, Mills *et al.* (2004) used a factorial nutrient addition experiment to show that Fe and P can co-limit N_2 fixation in the eastern tropical North Atlantic. They used trace-metal clean techniques with the addition of N, P, Fe, or Saharan dust individually or in combination to investigate which nutrient limits N_2 fixation. Their experiments demonstrated that at two out of three stations, N_2 fixation was enhanced by 2–3 times by the addition of P and Fe together, but the addition of either P or Fe alone had less effect (Fig. 38.14). Added dust also enhanced N_2 fixation, which they suggested could be due to mineral dissolution of both Fe and P.

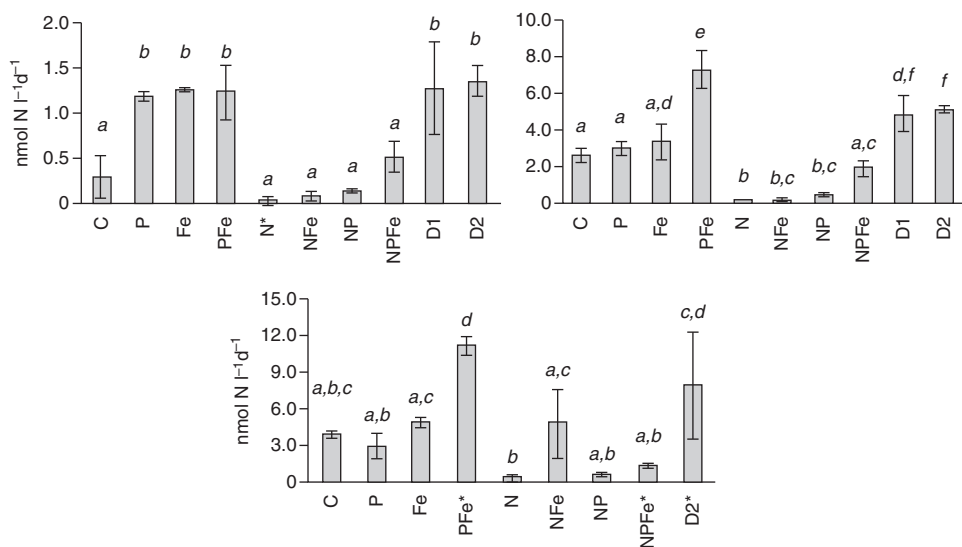
Mills *et al.* (2004) suggested that future work should investigate whether Fe/P co-limitation is a widespread phenomenon. Because supplies of both Fe and P are patchy in space and time, it seems likely that limitation of N_2 fixation by either nutrient or by both together is possible at a particular site, and that this may vary seasonally or over even shorter timescales. Distinguishing between Fe and P limitation of diazotrophs may not be a simple question of one nutrient or the other, and consideration of both will be needed to fully understand what controls inputs of new N by cyanobacteria in the ocean.


Figure 38.14 Effect of nutrient additions on N_2 fixation rates at three stations during bioassay experiments in the tropical Atlantic Ocean, illustrating Fe/P co-limitation effects. Treatments included controls (C), and nitrate/ammonium (N), phosphate (P), iron (Fe) and Saharan dust (D), added individually or in combination. Means that are not significantly different are labeled with the same letter. Mills *et al.* (2004), Nature 429: 292–294.

5. Conclusions and Future Directions

A tremendous amount of research effort in recent years has greatly expanded our knowledge of the ways that Fe and P affect marine N biogeochemistry. Significant gaps remain, however. For instance, our relative ignorance of the chemical composition of the organically bound Fe and DOP pools in the sea are major remaining obstacles that need to be overcome.

Biological oceanographers are also only now beginning to come to grips with the need to understand and predict anthropogenic global change influences on the ocean. Rapidly accelerating rising sea surface temperature and atmospheric CO_2, ocean acidification, and changes in stratification and circulation patterns will inevitably lead to profound changes in present day biogeochemical cycles over the next century (Bopp *et al.*, 2001; Riebesell *et al.*, 2000; Sarmiento *et al.*, 2004). How these factors will influence future dynamics between the Fe, P and N cycles and their control of ocean productivity is presently far from clear. However, new evidence suggests that N_2 fixation by *Trichodesmium* is C-limited at the present day atmospheric CO_2 concentration, and thus new N inputs by this genus could increase dramatically in the near future (Hutchins *et al.* 2007; Levitan *et al.* 2007; Ramos *et al.* 2007). These CO_2-mediated increases in diazotrophy occur regardless of P limitation in *Trichodesmium* (Hutchins *et al.* 2007), but are subject to control by Fe availability in *Crocosphaera* (Fu *et al.* in press). Thus rising CO_2 will undoubtedly interact strongly with both P and Fe limitation of oceanic N_2 fixation, but in different ways.

Little is known about Fe limitation of the recently discovered unicellular N_2 fixers, despite their abundance in oligotrophic regimes (Zehr et al., 2001) and their potentially large contribution to global new N inputs (Falcon et al., 2004; Montoya et al., 2004). The reason for this is that there is little published data on their Fe requirements, or on the potential for limitation of their N_2 fixation rates by this nutrient (Tuit et al. 2004; Fu et al. in press). Very little is known about their P requirements (Falcon et al., 2005) or their ability to use important P forms like DOP, either. Surprisingly, even the Fe requirements of many ubiquitous and well-studied phytoplankton groups such as Prochlorococcus are also not available in the literature. There is an obvious need to address these information gaps, as well as our ignorance of the Fe and P physiology of other plankton groups whose ecological significance has recently been recognized, such as the archaea (Karner et al., 2001).

Some of these questions will be answered using recently developed molecular and analytical approaches that are opening promising new avenues to explore the influences of Fe and P on the N cycle. Examples include the enzyme-labeled fluorescence (ELF) assay for cell-specific alkaline phosphatase activity (Dyhrman et al., 2002), the molecular marker PstS for P-limited Synechococcus (Scanlan and Wilson, 1999), and biomolecular indicators of Fe status like the IdiA (Webb et al., 2001) and IsiA (Michel and Pistorius, 2004) proteins, which are expressed by Fe-limited cyanobacteria. Powerful new analytical techniques are now becoming available such as synchrotron-based X-ray fluorescence, which can determine trace elemental stoichiometry in individual plankton cells (Twining et al., 2004). The increasing availability of entire microbial genome sequences will also facilitate studies of the regulation of critical biologically-mediated biogeochemical pathways (Armbrust et al., 2004; Dyhrman et al., 2006). Emerging technologies like metagenomic databases and genetic microarrays will also certainly find novel applications in studies of algal and bacterial Fe, P and N requirements in the ocean.

New biogeochemical processes like the recent discovery of surface-scavenged P pools in phytoplankton (Sañudo-Wilhelmy et al., 2004) or the co-limitation of diazotrophy by both Fe and P (Mills et al., 2004) also will continue to come to light as oceanographers delve deeper into the workings of marine nutrient cycles. One thing is already certain, however. The marine N cycle can never be considered realistically in isolation. Iron and P are two of the elements that are inextricably linked with the biogeochemistry of N in the sea, and future marine scientists will forever need to take their mutual interactions into account.
