the NO-temperature relationship, and used an advection-reaction model (Rayleigh fractionation) and a diffusion-reaction model to compute the fractionation factor (ϵ) of 22‰ and 25‰, respectively. Altabet *et al.* (1999) obtained a somewhat higher value ($\sim$30‰) taking $-N^\star$ as the NO_3^- deficit and assuming Ralyleigh fractionation. These estimates of ϵ for the Arabian Sea are similar to those for the eastern tropical North Pacific (Brandes *et al.*, 1998; Cline and Kaplan, 1975), implying relative constancy of isotopic fractionation associated with open-ocean denitrification.

Isotopic discrimination during uptake by phytoplankton results in an increase in $\delta^{15}N$ of NO_3^- in near-surface waters in most areas including the eastern Indian sector of the Southern Ocean (Sigman *et al.*, 1999). Going against this trend, observations in the Arabian Sea show a strong decrease from the suboxic-layer maximum to values that are not much above the oceanic average at the top of the nitracline (Figs. 14.15 and Fig. 14.16). This requires inputs of isotopically lighter NO_3^- either through advection from the south or, more plausibly, from a local source as the water at this depth (the Arabian Sea high-salinity surface water) is of local origin. This decrease in $\delta^{15}N$ of NO_3^- is accompanied by an increase in $N^\star$, strongly pointing to additions of new nitrogen through N_2-fixation by diazotrophs, a process that involves little or no isotopic fractionation (Wada and Hattori, 1990). Brandes *et al.* (1998) estimated the amount of N_2-fixation required to produce the observed NO_3^- isotope distribution. Taking the $\delta^{15}N$ of NO_3^- of water originating from the suboxic zone to be 11‰, simple mass balance requires that 40% of NO_3^- at the top of the nitracline should come from N_2-fixation. Using data on primary productivity, the rate of N_2-fixation was worked out to be $\sim$6 Tg N year^{-1}.

Isotopic data on N_2O, again coming only from the Arabian Sea (Figs. 14.15 and Fig. 14.16), reveal large variability in the composition of both the elements with depth as well as geographical location (Naqvi *et al.*, 1998a,b; Yoshinari *et al.*, 1997). The most prominent feature is the enrichment of heavier isotopes within the SNM at levels ($\delta^{15}N$ and $\delta^{18}O$, versus air, at times exceeding 20‰ and 60‰, respectively), which are the highest reported from any natural environment. These are associated with low N_2O concentrations (Figs. 14.15 and 14.16), and are obviously caused by the preferential reduction of isotopically lighter N_2O. However, a puzzling aspect of these data is that the $\delta^{15}N$ of N_2O always exceeds that of NO_3^-, opposite to the trend exhibited by cultures of *Paracoccus denitrificans* grown under steady-state conditions (Barford *et al.*, 1999): the culture experiments suggested greater fractionation during the reduction of NO_3^- to N_2O ($\sim$16‰) than of N_2O to N_2 ($\sim$13‰), with the overall fractionation (NO_3^- to N_2, $\sim$29‰) well within the range of the above-mentioned values derived from the field data. The higher $\delta^{15}N$ of N_2O implies that the natural bacterial populations should bring about a larger fractionation for the final reduction sequence. Moreover, as this trend persists also in N_2O-rich waters below the SNM (Figs. 14.15 and Fig. 14.16), it indicates possible involvement of denitrification in N_2O production well outside the SNM. Based on the analysis of N_2O isotopomer ratios (site preference of ^{15}N in the linear N_2O molecule), Yamagishi *et al.* (2005) also identified denitrification to be the dominant process responsible for N_2O production in the O_2 minimum zone of the North Pacific.

The isotopic data suggest a more important role for nitrification in N_2O production in the upper water column. The shallow, sharp peak of N_2O is characterized by

the lowest values of $\delta^{15}N$ and $\delta^{18}O$. The isotopic minima, more pronounced in case of nitrogen as compared to oxygen, are similar to those reported from the Pacific Ocean (Dore *et al.*, 1998; Popp *et al.*, 2002) except that in the Arabian Sea they are located at shallower depths. Going by its known isotopic signatures (Yoshida, 1988), nitrification has been proposed to be mainly responsible for the production of N_2O at shallow aphotic depths in the North Pacific (Dore *et al.*, 1998). The nitrification-related production may occur through two possible pathways: $NH_4^+ \rightarrow NH_2OH \rightarrow NOH \rightarrow NO \rightarrow N_2O$ and $NH_4^+ \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O$, and the relative importance of these pathways can be gauged from the oxygen isotopic composition of N_2O (Ostrom *et al.*, 2000; Popp *et al.*, 2002). The oxygen atom of NH_2OH is derived from O_2 (Dua *et al.*, 1979), whereas of the two atoms of oxygen in NO_2^- one each comes from O_2 and H_2O (Anderson and Hooper, 1983). Thus, if the oxygen isotopic compositions of O_2 and H_2O differ significantly, one can distinguish between the two formative pathways. The low $\Delta^{18}O$ (= $\delta^{18}O_{N_2O} - \delta^{18}O_{H_2O}$) values at Station ALOHA have been taken to support N_2O production from NO_2^-. Recently published enzymatic data from the Arabian Sea have been interpreted to invoke an important role of such nitrifier denitrification in N_2O production at low O_2 levels (Shailaja *et al.*, 2006). While concomitant data on the isotopic composition of O_2 and water are not available from this region, it would appear that significant production may also occur from the pathway involving NH_2OH. This is because the $\delta^{15}N$ and $\delta^{18}O$ often show contrasting behaviors, i.e. there is greater depletion of ^{15}N as compared to ^{18}O (Naqvi *et al.*, 1998a,b). In general, the $\delta^{18}O$ of N_2O is higher in the Arabian Sea (Naqvi *et al.*, 1998a,b; Yoshinari *et al.*, 1997) than in the Pacific Ocean (e.g., Kim and Craig, 1990; Popp *et al.*, 2002). Naqvi *et al.* (1998a) suggested that N_2O produced from NH_2OH-derived-NO should be slightly depleted with ^{15}N but enriched with ^{18}O. This pathway is also expected to lead to the concentration of ^{15}N at the central (α) position (Popp *et al.*, 2002; Stein and Yung, 2003), and so isotopomer analysis may help test this hypothesis.

4.2. Particulate and sedimentary organic nitrogen

Sediment trap studies in the deep sea (depth > ~1 km) carried out for several years at a number of sites in the North Indian Ocean showed that the PON undergoing sedimentation is more enriched in ^{15}N in the Arabian Sea than in the Bay of Bengal and, for that matter, most other parts of the ocean (Table 14.1; Gaye-Haake *et al.*, 2005; Schäfer and Ittekkot, 1993, 1995; Unger *et al.*, 2003, 2006). Denitrification in the former region and large influx of terrigenous material to the latter area are obviously responsible for this difference. The data also exhibit site-specific variations. For example, in the western Arabian Sea and southern Bay of Bengal, fractionation occurring during plankton growth under NO_3^--replete conditions affects the nitrogen isotopic composition of sinking particles in opposite directions, presumably due to different distances from the upwelling sites. At the western Arabian Sea trap site, which receives water upwelled off Oman, relatively low $\delta^{15}N$ values are characteristic of the peak SWM when the particle flux is at its maximum (Schäfer and Ittekkot, 1995). In contrast, at the southern Bay of Bengal trap site that is influenced by advection of water upwelled off the southwest coast of

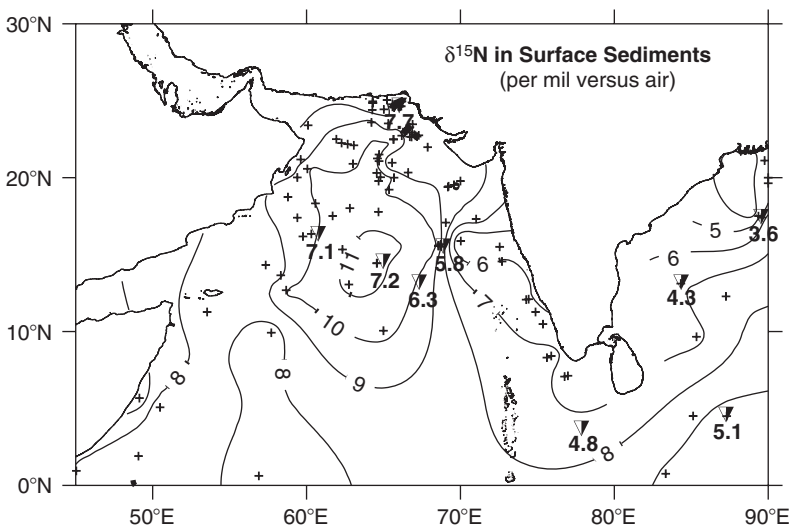
India/west coast of Sri Lanka, a prominent $\delta^{15}N$ maximum is observed instead at this time (Unger *et al.*, 2006). N_2-fixation during the spring intermonsoon season can substantially lower the $\delta^{15}N$ of sinking PON as indicated by the time–series data from the southern Bay of Bengal (Unger *et al.*, 2006), as well as the shallower (100 and 500 m) drifting traps data collected from the Arabian Sea during the occurrence of the basin-scale *Trichodesmium* bloom mentioned in Section 3.3 (Montoya and Voss, 2006). In the latter instance, the material trapped at 500 m had an average $\delta^{15}N$ value of 1.9‰; in contrast, the $\delta^{15}N$ of the PON from the 100-m trap was inexplicably much higher (mean 7.1‰). As observed elsewhere (e.g. Altabet *et al.*, 1991; Thunnel *et al.*, 2004), the $\delta^{15}N$ values decrease slightly from the traps deployed in the mesopelagic to those in the bathypelagic realm (Gaye-Haake *et al.*, 2005). The sediment trap and surface sediment data follow similar trend of variability, but with the $\delta^{15}N$ for the near-bottom traps being consistently lower than the $\delta^{15}N$ for the underlying surface sediments by 2–3‰ except for the two shallowest, northernmost trap locations in the Arabian Sea and the Bay of Bengal (Fig. 14.17; Gaye-Haake *et al.*, 2005). This has been attributed to early diagenesis in sediments that removes isotopically lighter nitrogen; this interpretation is supported by a significant correlation between $\delta^{15}N$ and Degradation Index based on amino acid contents (Gaye-Haake *et al.*, 2005). Thus, sedimentary $\delta^{15}N$ is maximal (>11‰) in the central Arabian Sea and minimal (<4‰) in the northern Bay of Bengal with the values respectively decreasing and increasing southward to ~8‰ in the equatorial region. A local minimum (<6‰) is also observed over the western Indian continental margin, associated with a maximum in total nitrogen content (~0.5%). The sedimentary nitrogen content is generally higher closer to the coast


Figure 14.17 Distribution of $\delta^{15}N$ (‰ vs. air) in surface sediments of the North Indian Ocean (contours) and in sinking matter (bold numbers below the triangles that show locations of sediment trap moorings); the latter are long term weighted averages for the deepest traps (modified from Gaye-Haake *et al.*, 2005).

and in the Arabian Sea than in the Bay of Bengal, the latter in part due to the dilution caused by the river-derived sediments (Gaye-Haake *et al.*, 2005).

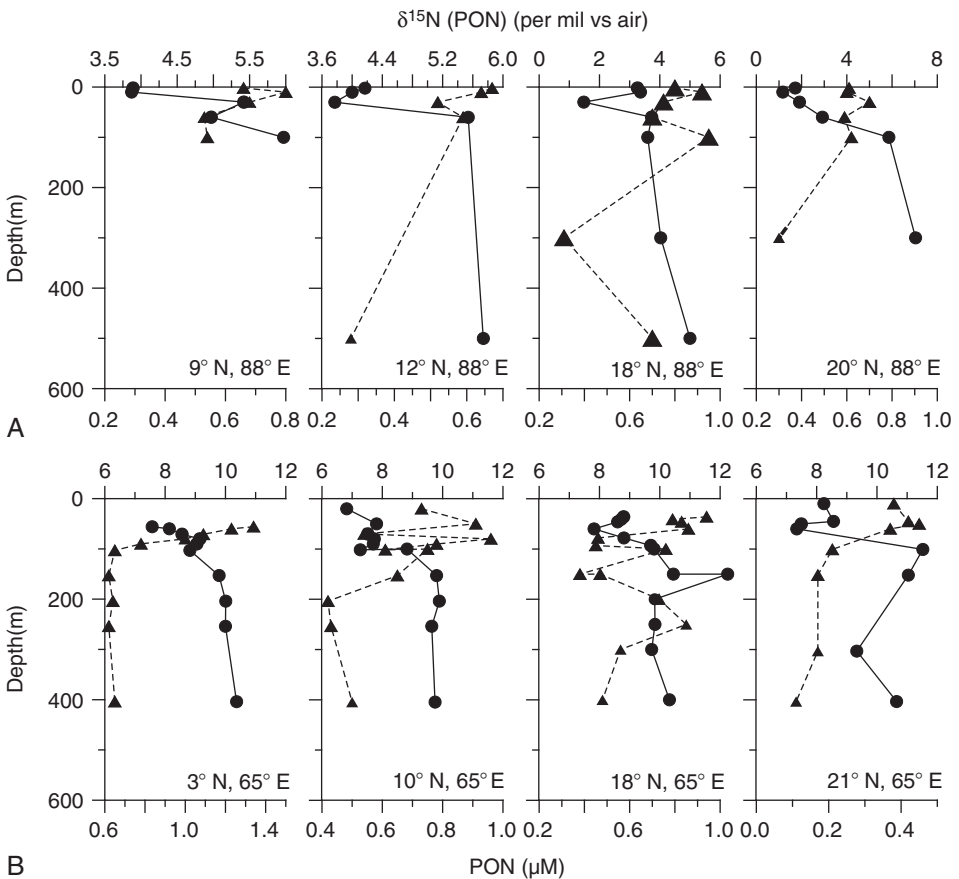
While the concentrations of suspended PON are somewhat higher in the Arabian Sea but still comparable and showing similar depthwise variability as in the Bay of Bengal, the nitrogen isotopic compositions of the PON are vastly different (Fig. 14.18) as observed for the settling and sedimentary PON, i.e. greater enrichment of ^{15}N in the Arabian Sea (Montoya and Voss, 2006) than in the Bay of Bengal (Kumar *et al.*, 2004). One intriguing aspect of the Arabian Sea data set is relative lack of variability in δ^{15}N below the surface layer with either depth or geographical location, with all values falling between 9 and 11‰ north of the equator. Surface-layer values are lower, but still substantially above (>6‰) the normal oceanic range (e.g., Altabet, 1989; Mino *et al.*, 2002; Montoya *et al.*, 2002). Exceptions from this general trend were noticed, though, in the region of abundant


Figure 14.18 Vertical profiles of PON (▲) and its δ^{15}N (●) in (A) Bay of Bengal (upper panels; sampling period April–May 2003; Kumar *et al.*, 2004) and (B) Arabian Sea (lower panels; sampling period May, 1995; Montoya and Voss, 2006).

Trichodesmium blooms (Montoya and Voss, 2006). These results highlight the dominance of denitrification in determining the composition of particulate material over an area and a depth range much larger than those of the SNM. In the Bay of Bengal too the subsurface δ^{15}N data show little north-south variability with most values hovering around 6‰ (Fig. 14.18). Moreover, as in case of the Arabian Sea, the δ^{15}N of PON in Bay of Bengal also falls by >2‰ towards the surface, with the vertical profiles often showing a minimum at the base of the euphotic zone that has been ascribed to isotopic discrimination during NO_3^- uptake by phytoplankton (Kumar *et al.*, 2004). The general association of the lowest values (2–3‰) in coastal waters with salinities <32 has been interpreted to reflect riverine inputs in the Bay of Bengal. However, at higher salinities, the range is still quite large (2–7.6%), and while NO_3^- supplied through vertical mixing is believed to be the primary source of nitrogen (Kumar *et al.*, 2004), atmospheric deposition of fixed nitrogen, which has been reported to support a significant fraction of new production in the region (Schäfer *et al.*, 1993), could also significantly influence isotopic compositions of both suspended and sinking materials. Unfortunately, isotopic data on DIN are not yet available from the Bay of Bengal to assess the relative importance of these sources.

4.3. Glacial–interglacial changes in denitrification

The isotopic discrimination effect associated with denitrification (enrichment of ^{15}N in sediments) has been applied to reconstruct changes in mid-depth redox conditions on the geological time scale. This approach involves the assumption that NO_3^- brought up to the euphotic zone through upwelling and vertical mixing is locally consumed on an annual basis such that the signature of elevated δ^{15}N is transferred to sinking PON and ultimately preserved in sediments. This premise, however, needs to be qualified with some caveats: (1) As discussed above, several independent approaches point to substantial N_2-fixation in the Arabian Sea. However, the overall balance between denitrification and N_2-fixation, that determines the isotopic composition of sinking PON, is apparently strongly in favor of the former process such that organic matter synthesized in the surface layer and preserved in underlying sediments is on average more enriched in ^{15}N than is typical of areas that do not contain intense ODZs. Thus, the sedimentary δ^{15}N is more correctly a proxy of the balance between denitrification and N_2-fixation rather than of denitrification alone, and although it is not known if and how this balance changed with time, the implicit assumption is that during periods of intense denitrification in the past it was similar to what exists today. (2) As shown previously, early diagenesis causes an enrichment of ^{15}N in surface sediments relative to sinking PON by 2–3‰. This effect is, however, not seen at locations receiving high PON flux (Altabet *et al.*, 1999; Ganeshram *et al.*, 2000; Gaye-Haake *et al.*, 2005). Most of the data from the Arabian Sea come from such sites; but even for those locations where the near-bottom waters are exposed to relatively higher O_2 concentration and/or the sediments receive low PON flux, one may assume that the offset is time invariable so that changes observed within a record would still provide insights into denitrification variability. The qualitative similarity of the deep-sea records (e.g., from the core V34-101 raised from ∼3 km depth and

having a core top total nitrogen content of only 0.07%) to other records from the region justifies this assumption (Altabet *et al.*, 1999). (3) Sites of the most intense upwelling in the Arabian Sea are found along its western boundary (off Oman and Somalia), which are located outside the denitrification zone. The water that upwells here is derived from the south and its NO_3^- is not expected to be isotopically heavy. However, as this water advects $\sim$1000 km from the coast before its NO_3^- is fully consumed (Naqvi *et al.*, 2006a,c), substantial enrichment of ^{15}N must occur due to fractionation during phytoplankton uptake. Altabet *et al.* (1999) did, in fact, record surface δ^{15}N–NO_3^- values as high as $\sim$10‰ at an offshore station arising from this effect, whereas Schäfer and Ittekkot (1995) observed a related seasonal minimum in δ^{15}N of sinking PON at their western Arabian Sea trap site. Thus, even though on the basin-scale the upwelled NO_3^- is fully consumed annually, one may expect gradients in sedimentary δ^{15}N along the trajectory of flow of the upwelled water similar to those observed in the equatorial Pacific (Altabet and François, 1994). Since the bulk of the vertical flux occurs during the SWM season (Haake *et al.*, 1993), this potentially important effect deserves a detailed investigation. Altabet *et al.* (1999) argued that despite the large gradients in δ^{15}N of NO_3^- within the ODZ, the homogenous distribution of heavy δ^{15}N values just below the euphotic zone, facilitates uniform preservation of the denitrification signal all over the Arabian Sea. This in a way is analogous to the above-mentioned uniform distribution of δ^{15}N in the SPM, even though the processes that bring about such a homogenization are not understood.

Over the past ten years, a number of sedimentary time series of δ^{15}N have been published from several sites in the Arabian Sea representing a range of oceanographic settings and sedimentation rates (Agnihotri *et al.*, 2003; Altabet *et al.*, 1995, 1999, 2002; Ganeshram *et al.*, 2000; Suthhof *et al.*, 2001). These records show that large enrichment of δ^{15}N in sediments has been prevalent not only throughout the Holocene, but also all interglacial periods over the past 1 Ma. In contrast, lighter isotopic values ($\sim$5–6‰), comparable to those found in non-reducing environments today, characterize sediments that accumulated during the glacial stages indicating that denitrification weakened or was absent during such periods (Altabet *et al.*, 1995, 1999, 2002; Ganeshram *et al.*, 1995, 2000; Suthhof *et al.*, 2001). Sedimentary δ^{15}N exhibits a nearly normal distribution about a median of $\sim$6.5‰, with the present day values being close to the upper end of the range, and without a long term trend (Altabet *et al.*, 1999). Spectral analysis of the records indicates clear cyclicity associated with the three Milankowitch frequencies of 100, 41 and 23 kyr, significantly coherent with records of proxies of ice volume (foraminiferal δ^{18}O) for all three frequencies, and of the SWM strength (lithogenic grain size) for all but the eccentricity one, thus testifying the roles of both hydrography and productivity in controlling Arabian Sea denitrification (Altabet *et al.*, 1995, 1999). Higher resolution records indicate variations on an even shorter (millennial) time scale, closely linked with the climatic changes recorded by the Greenland ice cores (Altabet *et al.*, 2002; Suthhof *et al.*, 2001). For example, the δ^{15}N records in two sediment cores from the Oman Margin generated by Altabet *et al.* (2002) show oscillations that are remarkably similar in structure and timing to the Dansgaard/Oeschger events recorded in the Greenland (GISP2) ice cores (Fig. 14.19). When smoothened with a 3000 yr
Figure 14.19 Records of $\delta^{15}N$, a denitrification proxy, from cores RC27-14 and RC27-23 (two middle panels), and of sedimentary nitrogen and total chlorin contents, proxies of productivity (upper panel), from RC27-23, compared with the GISP2 $\delta^{18}O$ record (lower panel) for the past 65,000 years. Radiocarbon dates converted to calender years for the two cores are marked on the $\delta^{15}N$ records. Numbers (1−18) on the bottom panel refer to Dansgaard−Oeschger events (from Altabet *et al.*, 2002).

running average − to account for the dampening effect of the residence time of nitrogen in the sea − the Arabian Sea denitrification records are remarkably similar to the Antarctic temperature and CO_2 records, leading Altabet *et al.* (2002) to conclude that changes in denitrification in the ODZ of the Arabian Sea, and probably in other

similar areas of the eastern tropical Pacific, may have a major impact on global climate. Furthermore, it has been suggested that such changes probably also contributed to the variability in atmospheric N_2O content as recorded in polar ice (Altabet et al., 1995, 2002; Flückiger et al., 2002; Suthhof et al, 2001).

The potential role of nitrogen cycle process in modulating glacial–interglacial changes through controls on inventory of fixed nitrogen, first proposed by McElroy (1983), has also been invoked by Falkowski (1997) and Broecker and Henderson (1998), who emphasized an enhanced N_2-fixation in the glacial ocean facilitated by greater aeolian supply of iron, as opposed to, or in addition to, reduced denitrification, favoured by Altabet et al. (1995, 1999, 2002) and Ganeshram et al. (1995, 2000). However, in order to account for the full amplitude of the glacial–interglacial atmospheric CO_2 change, the oceanic combined nitrogen inventory should have increased by at least 30%, provided that the ratio between inorganic carbon to organic carbon export decreased concurrently to keep $CaCO_3$ flux to deep sea at or below the present day level (Gruber, 2004; Sigman and Boyle, 2000). Moreover, for the increased nitrogen inventory to be effective for CO_2 sequestration there is an additional requirement of increased N:P ratio over the Redfield value – otherwise the production would become phosphorus limited. Gruber (2004) argued that the feedbacks within the nitrogen system do not allow very large departures from this ratio in today's ocean. He concluded that while changes in N_2-fixation and denitrification probably contributed to increased oceanic sequestration of CO_2 during the glacial periods, this was in all likelihood not the dominant mechanism.

More recently, Altabet (2007) has examined high resolution $\delta^{15}N$ records from several sites considered to be sensitive to oceanic average $\delta^{15}N$ and found no detectible change over the last 3 kyr or so (roughly the residence time of nitrogen in the ocean) implying a balanced marine nitrogen budget over the latest Holocene. This observation does not conform to the widely held view that nitrogen budget in today's ocean in severely out of balance with losses through sedimentary and water column denitrification far exceeding inputs (by >200 Tg N year^{-1}) from the atmosphere (mainly N_2-fixation) and land (Codispoti et al., 2001); a sustained imbalance of this magnitude is expected to produce detectable change in oceanic mean $\delta^{15}N$ over the investigated time period (Altabet, 2007). In contrast, most of the longer $\delta^{15}N$ records that extend to the last glacial maximum show a 2–3‰ increase over deglaciation followed by ~1‰ decrease in the early Holocene (see also Deutsch et al., 2004; Gruber, 2004). This seemingly global signal is also seen in the Arabian Sea data (e.g., Fig. 14.19), but the timing of the peak also corresponds to the intensified SWM in response to maximal summer insolation (Prell, 1984) that probably led to an intensified denitrification in the region. Altabet (2007) postulated that a transient deglacial imbalance in the global oceanic nitrogen ocean could have led to 10–30% decrease in the oceanic combined nitrogen inventory during this period before the feedback processes restored the balance. The mid-Holocene minimum in $\delta^{15}N$ seen in the Arabian Sea records (Fig. 14.19) is, however, not found in records from the other suboxic zones. The slow, secular increase in $\delta^{15}N$ since ~6 kyr B.P. implies a gradual intensification in the Arabian Sea denitrification that does not seem to have significantly affected oceanic combined nitrogen inventory.

5. Nitrogen Budgets

There have been several attempts to quantify key nitrogen fluxes in the Arabian Sea (Somasundar et al., 1990; Naqvi et al., 1992; Bange et al., 2000; Naqvi et al., in press). The budget given in Table 14.2 is reproduced from Naqvi et al. (in press), which in turn is not much different from that of Bange et al. (2000). Note that estimates for both water column denitrification and N_2-fixation are probably conservative, but the difference between the two terms will perhaps not change much, should the two estimates be revised upward in view of the following constraint. The estimated net loss of combined nitrogen (32.5 Tg N year^{-1}) must be balanced by NO_3^- inputs through circulation. The net NO_3^- flux by waters flowing in from the south (38 Tg N year^{-1}) computed from the hydrographic data matches very well with this deficit (Bange et al., 2000); notwithstanding the uncertainties involved in various calculations, this provides some confidence in the overall budget.

The budget for the Bay of Bengal (Table 14.3), also from Naqvi et al. (in press), is comparatively more uncertain. Due to the massive river runoff one would expect this region to receive copious amounts of nutrients from land, but the estimated riverine flux of DIN, based on measurements in the Hooghly estuary, is only ~0.5 Tg N year^{-1}, an order of magnitude lower than the estimate (4.2 Tg N year^{-1}) of Seitzinger et al. (2002) for inputs by the South Asian rivers. The riverine flux of PON (3.5 Tg N year^{-1}) is larger, but also more uncertain. Inputs of DON by rivers and DIN by groundwaters still remain to be measured, but they are unlikely to be quantitatively very important. In contrast, the atmospheric deposition of DIN has been reported to range from 0.3 to 2.5 (average 1.4) Tg N year^{-1} (Schäfer et al.,

Table 14.2 Combined nitrogen budget for the Arabian Sea

	Tg N year^{-1}	Tmol N year^{-1}
Inputs

N$_2$O loss to atmosphere	0.07	0.005
Sedimentary burial	1	0.071
Total	4.1	0.291

1993). Rates of N$_2$-fixation in the Bay of Bengal have not been measured so far. However, as already stated, it is probably much lower than in the Arabian Sea and is tentatively taken as 0.5 Tg N year^{-1}.

The major modes of nitrogen losses from the Bay of Bengal are sedimentary denitrification and burial. Note that the estimate for sedimentary denitrification (3 Tg N year^{-1}) is based on only one measurement at the outer shelf off Chennai (Naik, 2003), while the burial in sediments was computed from the carbon burial using a C:N value of 10.

While accurate uncertainty estimates associated with the above flux estimates cannot be provided, the numbers are probably valid within a factor of two. Taking this into account, the fluvial and aeolian inputs of nitrogen into the Bay of Bengal may approximately match losses through burial and sedimentary denitrification. However, the input terms have been, in all likelihood, anthropogenically enhanced and will most certainly rise further in future due to the ongoing rapid increases in fertilizer and fuel consumption associated with growths of population and economy (see Seitzinger and Harrison, this volume; Paerl and Piehler, this volume).

6. CONCLUDING REMARKS

The work carried out during the past few decades has greatly improved our understanding of nitrogen cycling in the Indian Ocean, but several shortcoming still remain and new questions have emerged that should be answered by future research. These relate to (a) distributions and fluxes, (b) processes, and (c) anthropogenic impact. We now have a fairly good knowledge of the spatial and temporal variability of major inorganic nitrogen forms, but additional information is needed from some areas (e.g., the upwelling zone off Indonesian islands and the shelves of Pakistan and Myanmar) and during certain periods (e.g., Indian Ocean Dipole event). In contrast,

data on DON are severely lacking from most areas. Moreover, we know very little about the composition of DON, its reactivity/bioavailability and turnover rates. As for the fluxes, there exists large uncertainty on the supply side. As discussed above, the few directly determined rates of N_2-fixation focusing on *Trichodesmium* are much lower than suggested by the geochemical and isotopic data. The contribution of small diazotrophs is yet to be evaluated. Riverine inputs of both dissolved and particulate nitrogen to the ocean are poorly quantified, and no information is available on groundwater inputs so far. The situation concerning the loss terms is only slightly better. Despite several modeling and field studies including direct measurements, the water column denitrification rate for the Arabian Sea perhaps carries an uncertainty of up to $\pm 50\%$, and sedimentary denitrification rates are largely unknown for most areas.

With regard to the nitrogen cycle processes, the recently observed mismatch between nitrate deficits and N_2 excess within the Arabian Sea ODZ and the occurrence of significant deficits within the deeper oxycline in the North Indian Ocean provide a reflection of our inadequate quantitative understanding of the various potential pathways of N_2 production. The role of anammox vis-à-vis denitrification, in particular, remains to be evaluated for this region. Another hitherto neglected aspect of nitrogen cycling is the link between nitrogen and trace metal cycles (see Hutchins and Fu, this volume). Biologically-mediated nitrogen transformations involve a variety of enzymes that require metal cofactors. For example, reduction of NO_3^- by both denitrifying bacteria and phytoplankton, as well as N_2-fixation by diazotrophs, requires Fe. The low Fe levels in the Southern Ocean are well known to limit PP (Martin *et al.*, 1990). In the Arabian Sea, Fe supply via atmospheric dust deposition has been believed to maintain sufficiently high dissolved Fe levels for it not to be limiting (Measures and Vink, 1999; Smith, 2001). However, results of both modeling (Wiggert *et al.*, 2006) and field measurements (Naqvi *et al.*, manuscript in preparation) indicate possible limitation of PP by Fe in the nutrient-replete upwelled water in parts of the western Arabian Sea during the late SWM. The biogeochemical and ecological implications of such Fe deficiency in the Arabian Sea and in other parts of the Indian Ocean suggested by Wiggert *et al.* need to be investigated in detail. Within the ODZ, pronounced maxima in total dissolved Fe and Fe(II) concentrations have been found to coincide with the SNM. As Fe(II) is thermodynamically unstable even at submicromolar O_2 levels, active biological reduction of Fe(III) has been hypothesized as a possible explanation of the anomalous observation (Moffett *et al.*, 2007), which should be verified by future workers.

One other remarkable aspect of the biogeochemistry of the Indian Ocean is the large contrast in redox conditions prevalent within the OMZs of the Arabian Sea and Bay of Bengal despite very subtle difference in the ambient O_2 levels. In addition to understanding, through modeling, physical processes supplying O_2 to the OMZ that help the Bay of Bengal remain delicately poised just above the denitrification threshold, future research should target the fundamental question as to what environmental factors trigger the transition from oxic to suboxic (denitrifying) metabolisms. Inevitably this will involve a comprehensive study of ecology of microbes involved, which will also provide insights into the formative mechanisms of the bacteria-rich INL and the clear, relatively sterile zone just above this feature that are ubiquitous to all suboxic zones.

The global nitrogen cycle is being greatly impacted by human activities, and in the open ocean domain this impact is not expected to be more severe anywhere than in the North Indian Ocean. A more sluggish deep circulation and stronger stratification resulting from global warming are expected to lead to a decrease in O_2 content of deep water in conformity with the observed trend in recent years (Joos et al., 2003). The global warming is also projected to cause an intensification of the SWM, the effects of which are reported to be have already become discernible in terms of intensified summer winds, upwelling and phytoplankton blooms in the western Arabian Sea (Goes et al., 2005). Together with the increased nutrient loading from land, through both river runoff and atmospheric deposition, it is expected to result in an increase in O_2 demand at depth. Ultimately, however, how the global warming modifies the biological productivity, and the intensity and spatial extent of the OMZ in the North Indian Ocean will depend upon alterations of the cross equatorial meridional cells, which supply subsurface nutrient-rich waters from the south to the upwelling zones (McCreary, 2006). Due to the potential feedback to global climate through increased production of greenhouse gases, and the impact on regional marine living resources that may have serious socio-economic impacts, there is an urgent need to build coupled physical–biogeochemical models capable of predicting future evolution of the Indian Ocean biogeochemistry including redox nitrogen transformations under various scenarios of global change.

CHAPTER 15

Nitrogen in Inland Seas

Edna Granéli *and* Wilhelm Granéli

Contents

1. Introduction

Inland or enclosed seas are characterized by limited water exchange with the open ocean. External nitrogen loading can be measured more accurately than for an open system, which makes inland seas ideal for budget calculations and modelling, similar to lakes. A few inland seas are well studied, and could serve as models for larger, open systems. Examples in this review will be taken mainly from the Baltic Sea. The Baltic Sea has a long history of research, is well studied from a systems point of view, has undergone dramatic changes during the last 100 years, and the focus on research and management has been on nitrogen during the last decades. For other inland seas information is much less complete.

We will treat external N loading (riverborne N, atmospheric deposition, N_2 fixation), N uptake by phytoplankton, denitrification and N losses to sediments and adjacent seas. It would be impossible to treat nitrogen in isolation. Thus, the question of nitrogen versus phosphorus as the limiting nutrient will be discussed. Comparisons between the Baltic Sea and the Mediterranean Sea, an inland sea with characteristics very different from the Baltic Sea, will be made at the end of the

chapter. Discussions will be limited to more principal differences: positive versus negative freshwater balance, estuarine versus inverse estuarine (Mediterranean type) circulation, nutrient trap versus nutrient escape (Wulff *et al.*, 1990), N/P ratios and limiting nutrients.

2. THE MODEL INLAND SEA—THE BALTIC SEA

Inland seas make up only a small percentage of the surface and volume of the oceans (2.9% and 0.8%, respectively). Ketchum (1983) includes in his review of enclosed seas the Mediterranean Sea, the Black Sea, the Red Sea, the Baltic Sea, the Bering Sea, the Okhotsk Sea, the Japan Sea, the East China Sea, the Gulf of St. Lawrence and the Gulf of California. The Baltic Sea is the second largest brackish–water system in the world (after the Black Sea), but it is among the smallest of the inland seas (Table 15.1).

There are several excellent review articles on the Baltic Sea (Elmgren, 1989, 2001; Jansson, 1997; Jansson and Dahlberg, 1999; Leppäkoski and Mihnea, 1996; Wulff *et al.*, 2001) some of which treat nutrients or nitrogen in particular (Elmgren and Larsson, 2001; Granéli, 2004; Granéli and Granéli, 1999; Larsson *et al.*, 1985; Wulff *et al.*, 1990). The Baltic Sea is comprised of a number of distinct basins (Fig. 15.1), the main three being the Bothnian Bay, the Bothnian Sea and the Baltic Proper. The Bothnian Bay has the lowest salinity (Fig. 15.2) and is oligotrophic, while the Bothnian Sea is a transition area to the more nutrient-rich Baltic Proper.

Eutrophication of the Baltic Sea is well described in several review papers (Elmgren, 1989, 2001; HELCOM, 2003; Jansson, 1997; Jansson and Dahlberg, 1999; Leppäkoski and Mihnea, 1996; Nausch *et al.*, 1999; Rosenberg *et al.*, 1990; Wulff *et al.*, 1990). Besides increased nutrient loading and concentrations, these changes include: decreased Secchi depth (from 10 m in summer 1914–1939 to 7 m in 1969–1991) (Sanden and Håkanson, 1996), decreased depth penetration of macro-alagae, e.g., *Fucus vesiculosus* (Kautsky *et al.*, 1986), increased primary production (Elmgren, 1989; Rahm and Danielsson, 2001; Stigebrandt, 1991) and deep-water oxygen consumption (Pers and Rahm, 2000), increased macrofauna biomass above

the halocline and reduced or eliminated below (Rosenberg *et al.*, 1990), increased fish catches (Hansson and Rudstam, 1990; Jansson and Dahlberg, 1999) and virtual elimination of the most important top carnivores, seals (Elmgren, 1989).

   Due to its shallowness and strong permanent vertical density stratification the Baltic Sea has as some of its characteristics: (1) strong influence from benthic processes and (2) irregular (a few years to decades) cycling between deep-water anoxia and periods with below-halocline ventilation and good oxygen conditions. This makes the Baltic Sea different from e.g., the Black Sea and other permanently anoxic basins, as well as inland seas with a higher and more uniform salinity, and without widespread deep-water anoxia (e.g., the Mediterranean Sea). Even though

the Baltic Sea has the advantage of being probably the most intensively studied marine area in the world, nitrogen analyses of good quality only exist since the end of the 1960s. Much of the more recent nitrogen research in the Baltic Sea has been motivated by applied aspects, principally eutrophication, and includes international efforts to calculate external loading (Ehlin, 1999; HELCOM, 2004), as well as research on nitrogen management, its costs and its possible effects on the Baltic Sea eutrophication problem (Elmgren and Larsson, 2001; Granéli and Granéli, 1999; Gren et al., 1997; Hart and Brady, 2002; Löfgren et al., 1999; Ollikainen and Honkatukia, 2001; Savchuk and Wulff, 1999; Sundell, 1997).

2.1. Nitrogen in surface and deep water—Concentrations and pools

Concentrations of nitrogen and phosphorus have increased markedly in the Baltic Proper since measurements started 30–40 years ago (Fig. 15.3, see also Nausch et al., 1999; Perttilä et al., 1995; Rahm et al., 1996). Compared to conditions before 1950, concentrations of N and P have probably increased even more, but there are no data to verify this. In deep water, below the halocline (>60–80 m in the Baltic Proper), dramatic and rather rapid changes in nutrient concentrations may take place. This is caused by intermittent inflow of oxygenated, saltier deep-water, which will replace oxygen-deficient or anoxic (H_2S-containing), stagnant deep water. Complete renewal of deep-water only occurs with intervals of several years and stagnation periods may be more than decade-long. As a consequence there may be an initial build-up of nitrate in oxygenated deep-water, which is subsequently denitrified and instead ammonia will accumulate under anoxia.

Most of the water masses in the Baltic Sea are found above the halocline, e.g., in the Baltic Proper only 20% of the volume is below the halocline. Deep-water entrainment and especially internal nutrient turnover processes (phytoplankton uptake, N_2 fixation, sedimentation, denitrification) have a profound influence on concentrations in surface water. Decreases in nutrient concentrations in surface waters of the Baltic Sea have been interpreted as consequences of reduced external loading. However, the total amount of N and P in the water mass and active
Figure 15.3 Inorganic nitrogen ($NO_2 + NO_3 + NH_4$) and phosphorus (PO_4) in surface water (0–10 m) of the Baltic Proper during winter (at the Landsort deep, redrawn from Larsson and Andersson (2004)).

sediments, as well as the amounts turned over annually, are several times larger than the annual external addition. This means that changes in the balance between internal nutrient sources and sinks will influence concentrations. Nutrients accumulated in deep water will at least partly be transported to surface water. This means that the length of "stagnation" periods, as well as the magnitude of irregular intrusions of deep water, are important for nutrient conditions also in surface waters (Larsson and Andersson, 2004; Pitkänen *et al.*, 2001).

The mean N pool size in 1971–1981 in the Baltic Sea as a whole was 5400 kt Tot-N, with 3900 kt in the Baltic Proper (change 1971–1981 + 121 kt N year^{-1} according to Wulff *et al.*, 1990. Larsson and Andersson (2004) gave a similar estimate for the Baltic Proper in 1995–2003, the N pool fluctuating between 3200 and 4300 kt, with a decreasing trend of roughly 100 kt N year^{-1}. Thus, over a period of less than 10 years, the pool size of N in the water masses of the Baltic Sea can change by more than 1000 kt. However, in our N budget we will assume that the net change is 0.

Net ecosystem production is approximately 50 g C m^{-2} year^{-1} in the Baltic Proper (Sandberg *et al.*, 2000; Stigebrandt, 1991), which, applying the Redfield ratio, would require 2200 kt N year^{-1} (Eilola and Stiegebrandt, 1999; Rahm *et al.*, 2000), while phytoplankton primary production (approximately 100–150 g C m^{-2} year^{-1} in the Baltic Proper and the Bothnian Sea) would require around 5000 kt N year^{-1}. Since a large fraction, on the order of 75% (Carlsson and Granéli, 1993; Carlsson *et al.*, 1993; Eilola and Stiegebrandt, 1999; Granéli *et al.*, 1999; Larsson and Andersson, 2004), of the total N in the water is in dissolved organic form, the N demand of phytoplankton exceeds the available DIN pool even during the spring bloom, when the store of DIN and DIP above the halocline is maximal (Eilola and Stiegebrandt, 1999).

2.2. Exchange with the north sea

Inflow of river water into the Baltic Sea exceeds evaporation by approximately 500 km^3 year^{-1}, while 1000 km^3 year^{-1} leaves the Baltic Sea as surface water to the Kattegat. This means that 500 km^3 year^{-1} of saltier water enters the Baltic Sea at deeper levels (Stigebrandt, 2001). The net N outflow is 100–140 kt N year^{-1} (Larsson *et al.*, 1985; Wulff *et al.*, 1990, 2001). We will use 150 kt N year^{-1} for our N budget. The N loss through the Danish Straits and the Öresund is on the order of 10% of the total N load to the Baltic Sea (see below). Thus 90% of the N load is retained in the system.

2.3. Nitrogen loading from river water including sewage—DON availability

Figures for N loading in rivers have constantly been modified, usually upwards (Grimvall and Stålnacke, 2001), not because there has been an upward trend in river-transported nutrients, but because more reliable measurements have become available. The mean riverine load of total N for 1980–1993 to the whole Baltic Sea (excluding the Kattegat but adding direct sewage emissions) can be estimated to 800 kt N year^{-1} using data from Stålnacke *et al.* (1999). The load was directly

proportional to water flow and showed a variation from roughly 600–1000 kt N year^{-1}. The corresponding Helsinki Comission (HELCOM, 2004) mean figure for 1994–2000 would be 640 kt N year^{-1}, with 77% from monitored rivers, 17% from unmonitored rivers and coastal areas and only 6% from municipalities, industries and fish farms along the coastline, discharging directly into the Baltic Sea. Although the HELCOM (2004); Stålnacke *et al.* (1999) figures do not cover an overlapping time period, there is no reason to believe that river transport of N has changed dramatically during the last 2–3 decades (Grimvall and Stålnacke, 2001). We will use 700 kt N year^{-1} as a reasonable figure for river plus sewage loading to the Baltic Sea.

Probably a substantial—but unknown—fraction of the riverine N load, as well as N in direct sewage emissions, is lost through denitrification and burial in the coastal zone, and will thus not reach the offshore water masses. In the Gulf of Gdansk, into which the River Vistula discharges (the second largest river draining into the Baltic Sea) it is estimated that 23% of the N load is retained, even though the water residence time is only 15 days (Witek *et al.*, 2003). Most of the retention is due to denitrification. Similarly, Neumann (2000), using a modelling approach, calculated that the Pomerian Bight, into which the Oder river discharges, retained through denitrification 65% of the riverine N load and that less than 15% of the load was exported to the offshore regions.

The discharge-normalized N load from rivers has been rather constant during the last two or three decades, irrespective of changes in fertilizer use, sewage treatment etc (Grimvall and Stålnacke, 2001; HELCOM, 2004; Löfgren *et al.*, 1999; Stålnacke *et al.*, 1999). However, compared to the beginning of the 20th century, the riverine N load has probably increased several folds. Larsson *et al.* (1985) estimated that the increase was 4× for N and 8× for P, when comparing the1980s with conditions before 1900, while Jansson and Dahlberg (1999) put the increase between 1940 and the 1990s to 3× and 5× for N and P, respectively. This last figure for N fits more or less with an estimated 30% natural background loss of N from the drainage area (HELCOM, 2004) compared to present losses. The increase in riverine N load most likely occurred before more systematic nitrogen monitoring was implemented, probably mainly during 1950–1970, a period when fertilizer use increased dramatically (Löfgren *et al.*, 1999; Nausch *et al.*, 1999). In the Daugava River (Latvia) nitrate increased from 0.2 mg N l^{-1} 1950–1965 to more than 1.0 mg N l^{-1} 1985–1995 (Grimvall and Stålnacke, 2001).

A large part of the total dissolved nitrogen in river water is in organic form. Riverine DON (roughly 1/2 to 1/3 of the total N load (HELCOM, 2004) may not be directly (hours–days) available to bacteria and phytoplankton after entering the Baltic Sea. However, since little N leaves the system in dissolved or particulate form through the outlets, and since there is certainly much less DON-export than the DON that enters and is produced internally in the Baltic Sea, there must be processes that mineralizes DON to DIN and/or transforms DON to particulate form, which will then partly be permanently buried in sediments. Since the residence time of N in the Baltic Sea is several years, a large fraction of DON could be mineralized through photochemical and microbiological processes (see Chapter 7 by Mulholland and Lomas, this volume).

Stepanauskas *et al.* (2002) made a survey of the availability to bacteria of DON from rivers around the whole Baltic Sea. They found that in summer the mean proportions of DIN, DON and PON in river water was 50%, 40%, and 10%. Although the share of DON may be somewhat lower in winter, DON is still a large fraction of N in river water and even higher in Baltic Sea surface water. Through regrowth bioassays with bacteria, Stepanauskas *et al.* (2002) showed that as a mean 30% of the DON in river water was potentially available to bacteria within 2 weeks. Also different phytoplankton species have been shown to utilize DON and PON from river water indirectly but also by direct incorporation of humic compounds (Carlsson and Granéli, 1993; Carlsson *et al.*, 1995; Granéli and Moreira, 1990; Granéli *et al.*, 1985, 1999).

2.4. Atmospheric deposition

For the Baltic Sea recent figures indicate that nitrogen deposition from the atmosphere may contribute up to 300 kt N year^{-1} (220–300 kt N year^{-1}), thus roughly half the amount transported to the Baltic Sea in river water (HELCOM; Hertel *et al.*, 2003; Jansson, 1997; Larsson *et al.*, 1985; Marmefelt *et al.*, 1999). Correcting for the Kattegat, a reasonable figure for present atmospheric deposition of N to the Baltic Sea is 250 kt N year^{-1}.

As atmospheric deposition of N occurs directly on the whole surface of the Baltic Sea, a proportionally smaller fraction than is the case for riverborne nitrogen will be intercepted in the coastal zone. This may increase the relative importance of atmospheric nitrogen compared to land-derived sources of nitrogen. Also, different from N in river water, the proportion of DON is probably low in atmospheric deposition, although most studies have neglected organic N totally. There is a marked south to north decreasing gradient in atmospheric N deposition, from 1000 kg km^{-2} year^{-1} in the SW Baltic Proper to less than 300 kg N km^{-2} year^{-1} in the Northern Bothnian Bay, with approximately equal total amounts of NH_4 and NO_3 and most (70–80%) of the nitrogen in wet deposition (Granat, 2001; Hertel *et al.*, 2003).

There are no long-term trends available for atmospheric deposition, but HELCOM reports a mean deposition of 300 kt N year^{-1} (including the Kattegat) for 1996–2001, with a variation between 230 and 330 kt N year^{-1}. Although emissions have decreased during this period, there is no indication of a decreased deposition of N over the Baltic Sea (Bartnicki *et al.*, 2003). The average nitrogen deposition on the Baltic Sea has most likely doubled to tripled during the last 50 years (Granat, 2001).

2.5. Cyanobacteria and nitrogen fixation

The Baltic Sea has as one of its most characteristic features large summer blooms of several species of heterocyst-bearing, colonial, N_2 fixing cyanobacteria. There are species of the genera *Aphanizomenon* and *Anabaena* (Janson and Granéli, 2002), well known from eutrophic lakes. Although *Aphanizomenon* normally has the largest share of the total biomass of N_2 fixing cyanobacteria, the most characteristic and

conspicuous species is *Nodularia spumigena*. To what extent there are also other N_2 fixers, e.g., smaller noncolonial cyanobacteria without heterocysts, is uncertain. Results from size-fractionated N_2 fixation studies indicate that this could be the case, but little direct evidence exists (Wasmund *et al.*, 2001 but see Montoya *et al.*, 2004 (see also Carpenter and Capone, Chapter 4, this volume).

Cyanobacteria blooms and N_2 fixation have been intimately linked to eutrophication of the Baltic Sea, a scenario well known from lakes receiving sewage with high concentrations of phosphorus. It has thus been thought that cyanobacteria blooms in the Baltic Sea are essentially a man-made problem, and that N_2 fixation has been provoked by anthropogenic discharges of P to the Baltic Sea, driving the N/P ratio to low values, a condition usually thought to favour cyanobacteria. Recent studies have shown that cyanobacteria are very good competitors for inorganic nitrogen as well in these waters (Stolte *et al.*, 2002). However, historic records, dating more than a century back, and paleoecological investigations, clearly show that cyanobacteria blooms have been a phenomenon intrinsic to the Baltic Sea for several thousand years (Bianchi *et al.*, 2000; Finni *et al.*, 2001; Poutanen and Nikkilä, 2001). Unfortunately, older observations (Finni *et al.*, 2001), and especially paleoecological indicators, are only qualitative or semiquantitative. Thus, even if there were cyanobacteria blooms in the Baltic Sea long before man could have influenced nutrient conditions to any great extent, it is generally (but not unanimously) believed that blooms have become more widespread, of prolonged duration and with higher biomasses after the middle of the last century (Poutanen and Nikkilä, 2001). This question is of great concern when discussing limiting nutrients for the Baltic Sea and possibilities to reduce cyanobacteria blooms through nutrient management (Bianchi *et al.*, 2000; Elmgren and Larsson, 2001).

N_2 fixation occurs mainly in the Baltic Proper, where the N/P ratio is low compared to the Redfield value during summer (Granéli *et al.*, 1990; Wulff *et al.*, 2001; Fig. 15.4). Because of the patchy nature of cyanobacteria blooms, strong
Figure 15.4 The DIN/DIP ratio of surface water (0–10 m) in the Baltic proper (at the Landsort deep) during winter (redrawn from Larsson and Andersson (2004)).

vertical gradients in biomass, rapid changes in distribution and great interannual variations due to weather conditions (Savchuk and Wulff, 2001), it has been difficult to get reliable figures of N_2 fixation through rate measurements *in situ*. Early figures, based on the acetylene-reduction method, were approximately 100 kt atmospheric N fixed annually for the Baltic Proper (Niemistö *et al.*, 1989), but newer figures based on the ^{15}N tracer technique indicate over 3 times this value (e.g., Wasmund *et al.*, 2001), nearly 400 kt N year^{-1}.

N_2 fixation can be quantified by measuring the increase in total N in the euphotic layer during periods when other sources of phytoplankton N (deep-water entrainment, additions from sediments, rivers and coastal point-sources) are insignificant or can be quantified. Using this approach Larsson *et al.* (2001) estimated that N_2 fixation in the Baltic Proper was 180–430 kt N year^{-1}, sufficient to sustain 30–90% of the pelagic net community production during summer.

Stable N isotope ratios may indicate the presence of N_2 fixation, since atmospheric N has a distinct (close to zero) $\delta^{15}N$ signal. Thus, low $\delta^{15}N$ values in seston and sediments have been interpreted as a consequence of incorporation of nitrogen from cyanobacteria N_2 fixation into the plankton, and subsequent sedimentation of plankton remains with a large fraction of N from N_2 fixation. Several studies using the stable N isotope technique indicate that N_2 fixed from the atmosphere (by cyanobacteria) is an important and even underestimated N source for the Baltic Proper. Rolff (2000) showed that during summer a depleted nitrogen isotopic signal, indicative of utilization of fixed nitrogen from cyanobacteria, was propagated through all size-classes of plankton. Based on the strength of the "N_2 fixation signal", the author drew the conclusion that N_2 fixing cyanobacteria are more important as a nitrogen source than previously assumed. Struck *et al.* (1998) calculated that in the top 5 cm of central Baltic Proper sediments 20% or 60% of the N content could be of cyanobacterial origin, depending on assumptions. However, some caution is necessary when using N isotopic signals in sediments and seston for discussions about the importance of N_2 fixation by cyanobacteria, as a low $\partial^{15}N$ signal may have other explanations than N_2-fixation (compare similar discussion for the Mediterranean Sea in Krom *et al.* (2004).

In summary, it can be concluded that there is no reliable figure for N_2 fixation in the Baltic Sea. It may in addition vary substantially between years. A lower limit is 100 kt N year^{-1}, while the upper limit is more uncertain, it could be as high as 500 kt N year^{-1}. We will use 300 kt N year^{-1} as a compromise.

2.6. Nitrogen sinks—Denitrification and burial

As shown above only small amounts of N leave the Baltic Sea in dissolved and particulate forms through the "outlet". Some 650,000 tons of fish are removed annually from the Baltic Sea through commercial fisheries, which is equivalent to only 15 kt N year^{-1} (Hjerne and Hansson, 2001). The N pool in the water masses of the Baltic Sea, some 5000 kt N, has shown decadal changes of on the order of 1000 kt N, both an increase and a decrease. However, mean changes are at present <100 kt N year^{-1} (Larsson and Andersson, 2004; Larsson *et al.*, 1985; Savchuk and Wulff, 2001; Wulff *et al.*, 1990). Neither exchange with the Kattegat/North Sea,

nor changes in the N pool in the water mass can account for any large fraction of the total annual N load on the Baltic Sea, which amounts to well over 1000 kt N year^{-1} (river + atmospheric + N$_2$ fixation, conservatively estimated to 700 (range 600–800) + 250 (range 200–300) + 300 (range 100–500) kt N year^{-1} = 1250 kt N year^{-1}). This means that internal processes, denitrification and permanent sediment burial, are of overriding importance for the fate of nitrogen introduced into the Baltic Sea and must remove some 1100 kt N year^{-1} (with outflow to the Kattegat removing 150 kt N year^{-1} and a mean net accumulation in the water mass of 0 kt N year^{-1}).

There are heavy accumulations of *Aphanizomenon* and *Nodularia* in the Baltic Sea, and these cyanobacteria need microzones with low oxygen tension to be able to fix nitrogen. However, there are no indications that such blooms are associated with denitrification (Hietanen *et al.*, 2002), even though the genetic potential for denitrification in cyanobacterial aggregates seems to be present (Tuomainen *et al.*, 2003). Denitrification is instead most likely mainly a process that occurs in above-halocline sediments, and is based on a sequence of sedimentation, ammonification, nitrification and denitrification, which is promoted by macrofaunal reworking of surface sediments.

There are surprisingly few direct measurements of denitrification in water or sediment of the Baltic Sea (Brettar and Rheinheimer, 1992; Stockenberg and Johnstone, 1997). The first attempts to quantify denitrification in the Baltic Sea were made by Rönner (1985) and by Schaffer and Rönner (1984), and were based on models/indirect calculations. These authors mainly considered denitrification below the permanent halocline in the Baltic Proper, where anoxic conditions are common. Their estimate was 410 kt N year^{-1}, with most of the denitrification taking place in the sediments. This is most probably an overestimation of denitrification below the halocline.

Most calculations of denitrification are indirect, and are based on N budgets, denitrification being the difference between input and output, when accumulation of N in the water and permanent sediment incorporation of N have been taken into account. There are also modelling approaches to denitrification (Savchuk and Wulff, 2001; Schaffer and Rönner, 1984), but assumptions made in these models have often been shown to be unrealistic Jansson (2001). In one of the earliest attempts to make a N budget for the Baltic Sea, Larsson *et al.* (1985), ended up with an unexplained net sink of 423 kt N year^{-1}, while their denitrification estimate was 470 kt N year^{-1}. The outcome of a mechanistic N model for the Baltic Proper was a denitrification sink of more than 1200 kt N year^{-1}, almost exclusively (94%) taking place in the sediments (Savchuk and Wulff, 2001). Although this figure for denitrification may be closer to the truth than the first attempt by Schaffer and Rönner (1984), the model most likely seriously underestimated permanent burial of N.

In contrast to denitrification, permanent burial of N is probably mostly taking place in sediments below the halocline. Accumulation bottoms only account for approximately 40% of the Baltic Proper, and even less in the other major basins, while transportation and erosion bottoms make up some 40% and 20% of the Baltic Sea, respectively (Carman and Cederwall, 2001). Sediment nitrogen burial in Baltic Proper offshore sediments has been estimated to 91–245 kt N year^{-1} (Jansson,

2001). Since the Bothnian Bay and Sea are less productive than the Baltic Proper, are shallower, and have a less developed stratification, burial may be low. Assuming burial to be in proportion to accumulation bottoms and half the magnitude per area compared to the Baltic Proper, the Bothnian Bay and Sea would accumulate some 16–42 kt N year^{-1}. Thus, permanent burial in the Baltic Sea would be maximum some 300 kt N year^{-1}, leaving at least 800 kt N year^{-1} for denitrification (external loading including N$_2$ fixation less losses to the Kattegat and sediment burial). Burial in inshore areas, e.g., estuaries, is unknown, but could perhaps be significant (Neumann, 2000; Witek et al., 2003). Stockenberg and Johnstone (1997) estimated benthic denitrification in the Bothnian Sea and Bothnian Bay to be 50 kt N year^{-1}. Thus most denitrification must take place in the Baltic Proper. Accepting a total denitrification of 800 kt N year^{-1} for the Baltic Sea would mean that something like 65% of the external load of N (1250 kt N year^{-1}) would be denitrified. This is high compared to estuaries, but is not incompatible with figures for lakes (Seitzinger, 1988). Denitrification in the Baltic Proper could be proportionally higher than in estuaries and most lakes due to the longer residence time of nitrogen in the Baltic Sea compared to the more rapidly flushed lakes and estuaries. Another way to check if estimated total denitrification in the Baltic Sea is reasonable, is to calculate what rate is necessary per area to eliminate 800 kt N year^{-1}. Discounting denitrification in the Bothnian Bay and Sea, 750 kt N year^{-1} would remain. The Baltic Proper (excluding the Kattegat) covers 270,000 km^2. Denitrification would thus have to be at least 3 t N km^{-2} year^{-1} (3 g N m^{-2} year^{-1}, 0.2 mol N m^{-2} year^{-1}), which is compatible with values measured in other systems (Seitzinger, 1988; Seitzinger et al., 1984).

An important but unresolved question is if eutrophication, with increased below-halocline anoxia, will promote or reduce denitrification in the Baltic Sea (Rönner, 1985). In the latter case there would be more N available for phytoplankton and eutrophication would be a self-accelerating process. If the water below the halocline is totally anoxic, denitrification will stop and ammonia accumulate. With ample oxygen and an increased macrobenthic biomass (which has been one of the consequences of eutrophication of the Baltic Sea) above the halocline, denitrification should be promoted. Denitrification increases with increasing ecosystem production, and most likely faster than the increase in production. Thus denitrification would be very low in an ultraoligotrophic system (Krom et al., 2004), but would eliminate an increasing proportion of the external N load when the system undergoes eutrophication. N$_2$ fixation will never keep pace with denitrification, and the system will appear more and more N-limited. This gradient is clearly seen in the Bothnian Bay—Bothnian Sea—Baltic Proper (see also CONCLUSIONS).

2.7. A nitrogen budget for the baltic sea

From the above discussion of the different fluxes of N to and from the Baltic Sea (excluding the Kattegat), as well as N pools in the Baltic Sea, it can be concluded that (Fig. 15.5):

(1) Total loading (including N$_2$ fixation) has in this review been estimated to 1250 kt N year^{-1}, which is not very different from earlier estimates: Larsson
Figure 15.5 A nitrogen budget for the Baltic Sea (excluding the Kattegat) in kt N ton year^{-1}.

    et al. (1985) 1200 kt N year^{-1}, Enell and Fejes (1995) 1300 kt N year^{-1},
    Grimvall and Stålnacke (2001) 1250 kt N year^{-1} (corrections made for the
    Kattegat).
(2) While the external loading of nutrients shows a huge excess of N in relation to
    the Redfield ratio, by internal adjustments (large sinks for N but relatively
    smaller for P) the N/P ratio in the water masses (of the Baltic Proper) is well
    below the Redfield ratio, especially for DIN/DIP.
(3) The residence time of N in the Baltic Sea system (including water and
    sediments) is short (5 years) compared to the hydraulic/salt residence time
    (25 years) and is also much shorter than for phosphorus (>10 years). The
    Baltic Sea thus has a much longer "memory" for P than for N, and a change in
    N loading will affect N in the Baltic Sea much faster than a corresponding
    change in P loading. However, this would not be valid if changes in external
    N loading are compensated by changes in the balance between N$_2$ fixation
    and denitrification (at present not known).

2.8. Nitrogen versus phosphorus—Limiting nutrient controversy

Limnologists have for at least 50 years maintained the view that phosphorus is the
ultimate limiting nutrient for lake ecosystem production, while the nitrogen hypoth-
esis has dominated for marine systems since Ryther and Dunstan (1971). The P
regulation theory states that shortage of nitrogen will ultimately be compensated
through N$_2$ fixation, and N$_2$ fixers will be limited by phosphorus. This could create
the situation that phytoplankton growth/biomass accumulation is N limited (time
scales of days–weeks), while ecosystem net production is P limited (time scale of
months—years). What is the situation in the Baltic Sea, which is brackish, and thus
neither a lake, nor a marine system? The Baltic Sea is composed of several distinct
basins, with rather different nutrient conditions. The northernmost Bothnian Bay is
most lake-like, with very low salinities and high N/P ratios, receiving mostly

unpolluted river water, due to limited human population and agricultural activity in the drainage area. Sediments in the Bothnian Bay are more likely to retain P than in the more southerly basins, due to good oxygen conditions, low SO_4 and favourable Fe/P ratios. The Baltic Proper, which receives most of the anthropogenically derived external loading of nutrients, is characterized by very low inorganic N/P ratios, both above and below the halocline (Fig. 15.4). Here algal growth and maybe also ecosystem net production seems to be N limited. Is this a ''natural'' or a secondary phenomenon, and is really N the ultimate limiting nutrient? N limitation could, as is the case in hypertrophic lakes, be a secondary phenomenon, caused by low N/P ratios in sewage, internal loading of P from the sediments and loss of N through denitrification. On the other hand, sediment records show clear signs of deep-water anoxia and cyanobacterial blooms thousands of years ago (Bianchi et al., 2000), indicating that low N/P ratios may be a natural phenomenon in the Baltic proper. The question of N versus P limitation has haunted Baltic ecologists and environmental managers for at least 2 decades and it still remains unresolved.

Bioassay and mesocosm experiments, as well as physiological indicators (phosphatase activity) usually point strongly to N limitation of algal growth rate and biomass accumulation in the Baltic Proper (Granéli et al., 1990), except that cyanobacteria may be P limited (Moisander et al., 2003; Rydin et al., 2002). In the oligotrophic, low-saline Bothnian Bay, enrichment experiments point to P limitation (Hagström et al., 2001), in accordance with the high N/P ratio in the water (Wulff et al., 2001). These experimental studies also show that N_2 fixation can be greatly enhanced by P addition (Moisander et al., 2003; Rydin et al., 2002). However, N_2 fixing cyanobacteria are not present during the spring bloom, when the winter store of DIN is totally consumed, leaving some excess DIP. The spring bloom is thought to contribute proportionately more to net sedimentation (new production) and O_2 consumption than summer primary production based on regenerated N (Elmgren and Larsson, 2001).

P loading has most likely increased more than N loading, may be 8 versus 4 times the loading that existed a century ago (Larsson et al., 1985). This could have accentuated N limitation. On the other hand the N/P ratio in the Baltic Sea is not primarily a function of the N/P ratio in external loading, which is still high in comparison to the Redfield ratio (HELCOM, 2004; Wulff et al., 2001). The change in N/P ratio is thus caused by internal processes, that force P to remain in the water, while N is lost through denitrification and permanent burial (Wulff et al., 2001). Caraco et al. (1989) have shown that the ability of lake sediments to retain P is related to sulphate concentration and Blomqvist et al. (2004) have launched the theory that N limitation in brackish waters, in contrast to P limitation in lakes, can be explained by an unfavourable Fe/P ratio in brackish/marine shallow systems, due to formation of iron sulphides in anoxic sediments. There may be other explanations too, e.g., that the Baltic Sea has an unusually efficient denitrification, due to its shallowness (Larsson, 1988). A similar case has been made for the Adriatic Sea in contrast to the Eastern Mediterranen, where denitrification seems to be very low (Krom et al., 2004).

It is very difficult to make experimental tests of the hypothesis that net marine ecosystem production is N limited, in the same way as the lake ecosystem P limitation hypothesis has been tested through whole lake fertilization experiments

(Schindler, 1977). In this respect the Himmerfjärden experiments are unique. External N and P loadings, as well as ratios between these, have been manipulated in a controlled way for a semi-enclosed bay (Himmerfjärden) of the Baltic Proper, receiving substantial amounts of tertiary (both N and P removal) treated sewage (Elmgren and Larsson, 1997, 2001; Granéli *et al.*, 1990). These full–scale experiments showed that chlorophyll and algal biomass in the bay were reduced when N in sewage was reduced.

2.9. Management of nitrogen

Because P may regulate the growth of cyanobacteria, it has been argued that P reduction is important, even if N regulates overall ecosystem production (Elmgren and Larsson, 2001). However, during the last decades focus has changed somewhat from P to N management with respect to Baltic Sea eutrophication. Many sewage treatment plants have been equipped with N stripping facilities, even though most anthropogenic N entering the Baltic Sea is diffuse, emanating from agriculture (NH_4 and NO_3) and transportation/industry (NO_x). Politically set goals to half the anthropogenic load of N to the Baltic Sea in 10 years have been decided in different Baltic countries, as well as by multinational protocols. These N reduction goals were ambitious/optimistic and have not nearly been reached.

   Savchuk and Wulff (2001) modelled effects from a drastic reduction in P or N (50% each 5 years) alone or in combination. The model showed that P reduction alone in 20 years caused a reduction in primary production and N_2 fixation of approximately 30%. If both N and P were reduced, primary production was similar to the P alone case, whereas N_2 fixation increased initially. N reduction alone had no effect on primary production and caused a strong (40–50%) increase in N_2 fixation. Eilola and Stiegebrandt (1999), using a biogeochemical reactor model, came to the conclusion that DON would compensate for N deficiencies and that N thus is not limiting at the systems level. Hence they concluded that P reduction would be the only effective remedy for the Baltic Sea. Unfortunately such models are based on oversimplified biological assumptions and there is no way at present to judge the realism in the produced forecasts. Elmgren and Larsson (2001) advocated both N and P reductions, based on the assumption that P regulates N_2 fixation/cyanobacteria, while N regulates the spring bloom and thus oxygen consumption in deep water. Their arguments are based on empirical observations, e.g., the occurrence of cyano–bacteria blooms (based on paleoecological evidence) and N limitation for several thousand years in the Baltic Proper, as well as results from systems scale nutrient manipulations in the Himmerfjärden Bay (Elmgren and Larsson, 1997, 2001).

3. Comparisons with Other Enclosed Seas

   It is particularly instructive to compare the Baltic Sea with the Mediterranean Sea. The two inland seas of course differ with respect to size (area and depth) and climate, but of more principal interest are the differences in exchange with the open

ocean, freshwater balance, sill depth, river versus atmospheric N loading, nutrient status and nutrient limitation.

While the Baltic Sea is characterized by a net outflow of freshwater, and thus has a typical estuarine circulation, in the Mediterranean Sea evaporation exceeds rain plus river water input. This means that there is a net inflow of Atlantic water through the Strait of Gibraltar and that salinity in the Mediterranean Sea as a mean is higher than in the Atlantic Ocean. In the Baltic Sea there is an inflow of saltier water from the Kattegat/Skagerrak at depth, while freshened water flows out in a surface layer. In the Mediterranean Sea, on the contrary, saltier water leaves as a deeper current through the Strait of Gibraltar. This can be called inverse estuarine (Crispi *et al.*, 2001) or Mediterranean type circulation. There is also another difference: The Baltic Sea has shallow connections (the Sound and the Danish Belt Sea) to the Kattegat/Skagerrak (18 m), while the Gibraltar Sound is much deeper (300 m). This means that nutrients will get trapped in the Baltic Sea, while nutrients will be flushed out of the Mediterranean Sea (Wulff *et al.*, 1990). As a consequence the Baltic Sea has to some degree always been more eutrophic than the open ocean (cyanobacteria blooms thousands of years ago), and has become even more eutrophic due to nutrients of anthropogenic origin being trapped. The Mediterranean Sea (with the exception of smaller basins like the Adratic Sea) on the other hand is less nutrient rich than the Atlantic Ocean to which it is connected, and is in fact one of the more pronounced ocean deserts on the globe. There is a west–east gradient in the Mediterranean Sea, the Eastern Mediterranean being ultra oligotrophic with extreme Secchi depths (Berman *et al.*, 1985).

There are several mechanisms contributing to the nutrient poor status of large parts of the Mediterranean Sea and especially the Eastern Basin. There is e.g., an unbalanced fresh water inflow, which has become even more accentuated after damming of the Nile. Most river water enters in the west, leaving the eastern part without riverborne nutrients and far from the more nutrient rich Atlantic water entering through the Strait of Gibraltar. It has also been suggested that there is a ''biological pump'' transporting N to deep water through sedimentation and thus causing a successive impoverishment of the Mediterranean surface water moving eastwards (Crispi *et al.*, 2001).

In comparison to calculations of river input of nutrients to the Baltic Sea (which still after decades of efforts are not definite), similar figures for the Mediterranean Sea are very uncertain. The drainage basin of the Mediterranean Sea is to a large extent arid, and river discharge has diminished due to water use for irrigation etc. This is especially evident with respect to the Nile. However, this does not necessarily mean that total riverine and coastal point source loadings have decreased, since increases in N concentrations in river water have most likely more than compensated a decrease in runoff. UNEP (1997) has estimated the riverine N input to the Mediterranean Sea to 1000 kt N year^{-1}, and the atmospheric deposition is almost identical. Total N loading (river + atmosphere) is thus for the Mediterranean Sea $\approx$2000 kt N year^{-1}, while the figure for the Baltic Sea, excluding N$_2$ fixation, is $\approx$1000 kt N year^{-1}, thus half the Mediterranean value. However, the Baltic Sea is much smaller (0.37 $\times$ 10^6 km^2) than the Mediterranean Sea (2.52 $\times$ 10^6 km^2), which means that the external N loading per km^2 sea surface is several times higher for the Baltic Sea. Although

new figures for the Eastern Mediterranean (Krom *et al.*, 2004) indicate that the N loading on the Mediterranean may be substantially larger than the (UNEP, 1997) estimate, it is still low compared to the Baltic Sea. However, the difference in eutrophication between the Baltic Sea and the Mediterranean Sea is probably not only related to nutrient loading per unit area, but has also to do with differences in limiting nutrients and in nutrient exchange with the outside.

Since the Mediterranean Sea is surrounded by rather dry areas, atmospheric input of nutrients in dust is significant. In the SE Mediterranean (Herut *et al.*, 2002) calculated that dry fallout supplied 2.5 times more DIN than wet deposition and 2 times more than riverine N input (see also Krom *et al.*, 2004). Also for P, dry atmospheric input was a dominating source, and since atmospheric deposition has a high N/P ratio (Markaki *et al.*, 2003) this means that in the eastern Mediterranean water the N/P ratio is very high compared to the Redfield value (Krom *et al.*, 2004). In the ultraoligotrophic eastern Mediterranean atmospheric N deposition was several times higher than export production (as annual PON flux). Thus N does not seem to limit phytoplankton production, a conclusion supported by bioassay experiments (Diaz *et al.*, 2001). Atmospheric nutrient inputs to the Baltic Sea, as is the case for the Mediterranean Sea, have high N/P ratios and for the Baltic Sea also riverine N/P ratios are well above the Redfield ratio. Nevertheless N/P ratios in the water are very different in the two inland seas: markedly above 16:1 in the Mediterranean Sea and well below in the Baltic (Proper). This difference is due to internal sinks and sources. In the Baltic Sea the sink has a very high N/P ratio due to denitrification but not very efficient P binding to sediments. For the Mediterranean Sea the sink must have a low N/P ratio, indicating inefficient denitrification (Krom *et al.*, 2004) and/or efficient P sequestering to particulate material. The reason behind this may have to do with oxygen conditions and organic carbon availability. Since the Mediterranean Sea is so nutrient-depleted, denitrification may be carbon limited, while low production, great mean depth (1470 m) and absence of the strong density stratification characteristic for the shallow Baltic Sea, prevent reducing conditions that would liberate P from sediments.

In the Baltic Sea N_2 fixation is of great significance, both because the N_2 fixers (colonial cyanobacteria) are dominating components of the plankton community, and because N_2 fixation is an important (10% to >30%) source of N for phytoplankton. That N_2 fixation is a significant fraction of the N input to the Baltic Proper has been explained by low N/P ratios in the water and high P availability. This would suggest that N_2 fixation should be low in the Mediterranean Sea, because N/P ratios are high, which would select against N_2 fixing cyanobacteria, and because P is very low, which would also decrease the potential for N_2 fixation. However, $\partial^{15}N$ values of PON and NO_3 in the Mediterranean Sea on the contrary indicate that biological N_2 fixation is an important source of new N, especially in the eastern basin (Pantoja *et al.*, 2002). This contradicts Markaki *et al.* (2003), who suggested that atmospheric deposition would be more than adequate to cover the demand of new N for export production. On the other hand losses of N through the Strait of Gibraltar are higher than atmospheric plus riverine N inputs, suggesting the need for N_2 fixation to balance the deficit (Pantoja *et al.*, 2002). According to these authors up to 20% of N in the western Mediterranean Sea, and as much as 90% in the eastern basin, may be

derived from N_2 fixation. However, Krom *et al.* (2004) have argued that N_2 fixation is insignificant in the Eastern Mediterranean, and that low $\delta^{15}N$ values have other explanations than N_2 fixation, a conclusion consistent with the Mediterranean as a P limited inland sea.

4. Conclusions and Future Research Prospects and Needs

Nitrogen sources and sinks in the Baltic Sea are fairly well identified and quantified compared to other inland seas. However, there are serious uncertainities in the estimations of N_2 fixation, denitrification and N burial. Further, the influence of P on N and vice versa are not well understood, preventing us from making realistic forecasts of future conditions in the Baltic Sea under various N loading scenarios. There are still questions as to what has been most important for eutrophication, the increase in P or N or both, and when changes took place. However, most serious is our limited understanding of how the Baltic Sea system will react to reductions in N loading and how long it will take to reach a new equilibrium. In deeper, large lakes (e.g., Lake Vättern, Lake Washington, the Great Lakes) rather drastic reductions in external P loading have resulted in remarkably increased transparency and changes in nutrient concentrations, while in shallow lakes the sediment P memory may delay recovery for decades through internal P loading.

A comparison between contrasting marine ecosystems, e.g., the Mediterranean Sea and the Baltic Sea, with respect to primary production/Secchi depth, N_2 fixation, N/P ratios in the water (N vs P limitation of phytoplankton growth) and denitrification, can be instructive (Fig. 15.6). The N/P ratio in external loading is probably always much greater than the Redfield ratio (for most aquatic ecosystems), whether loading is mainly through atmospheric deposition or through riverborne N. However, the N/P ratio in the water is usually below the loading ratio. In an extremely oligotrophic system this difference is smaller than in a very productive/eutrophic system. In the Mediterranean Sea the N/P ratio is thus ≈ 30 in the water, compared to 16 in the open ocean and <10 in the Baltic Proper. In the Mediterranean Sea both N_2 fixation and denitrification are probably low, while in the Baltic Sea both processes contribute to a large fraction of N sources and sinks.

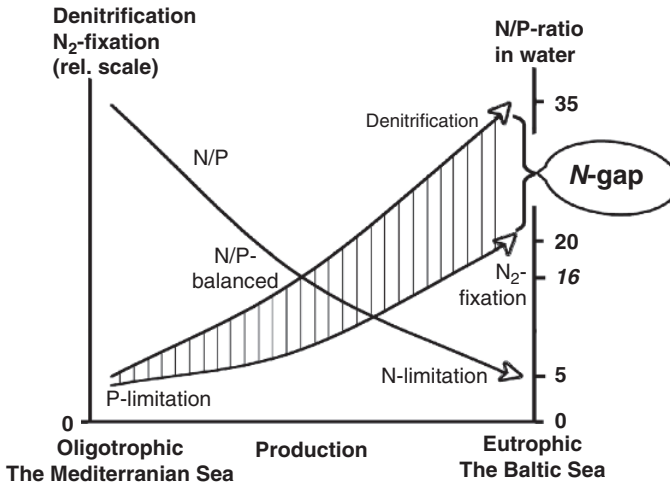
With increasing primary production denitrification increases out of proportion to nitrogen loading (atmosphere + riverborne). N_2 fixation will not increase proportionally to denitrification, driving the N/P ratio in the water to sub-Redfield values and creating a nitrogen "gap" and N limitation of phytoplankton growth. This process is reinforced through decreasing P immobilization by sediments with increasingly more eutrophic conditions. The same phenomenon can be observed in a gradient from ultraoligotrophic to hypertrophic lakes. The residence time of N in the system is obviously of importance. Here inland seas form a transition from estuaries to major oceans, making them very valuable model systems. There should


Figure 15.6 Schematic picture of a gradient of Inland seas or Lakes from ultraoligotrophic to hypertrophic. As production increases, denitrification increases, and N_2 fixation cannot close the N–gap, causing the N/P ratio to decrease and phytoplankton to appear N– instead of P-limited. External N/P-loading ratio (atmospheric deposition, riverborne load) is always much greater than Redfield ratio.

be much more to be learnt from studies of N in inland seas, especially if more systems were as in depth investigated as the Baltic Sea.

Contents

> # 1. PROLOGUE

The systematic transformation of nitrogen (N) from one form to another is referred to as N-cycle. This cycle is a key component of the much larger and interconnected hydrosphere-lithosphere-atmosphere-biosphere N-cycle of planet Earth (Boyer and Howarth, 2002; Galloway *et al.*, 2004; Karl and Michaels, 2001). Because N is a macronutrient required for the growth of all living organisms, the marine N-cycle is inextricably coupled to the production and decomposition of organic matter on both regional and global scales. Consequently, most N-cycle processes are coupled both to the flow of energy and to other bioelement cycles, most notably carbon (C), hydrogen (H), oxygen (O), phosphorus (P) and sulfur (S), as well as to the global cycles of many trace elements (e.g., iron, zinc, cobalt, copper,

cadmium, to name a few) (see Hutchins and Fu, Chapter 38, this volume). While this chapter and the volume that it is part of focus specifically on N, it is prudent to broaden the perspective and to acknowledge these critical nutrient element inter-connections and well established metabolic interdependencies.

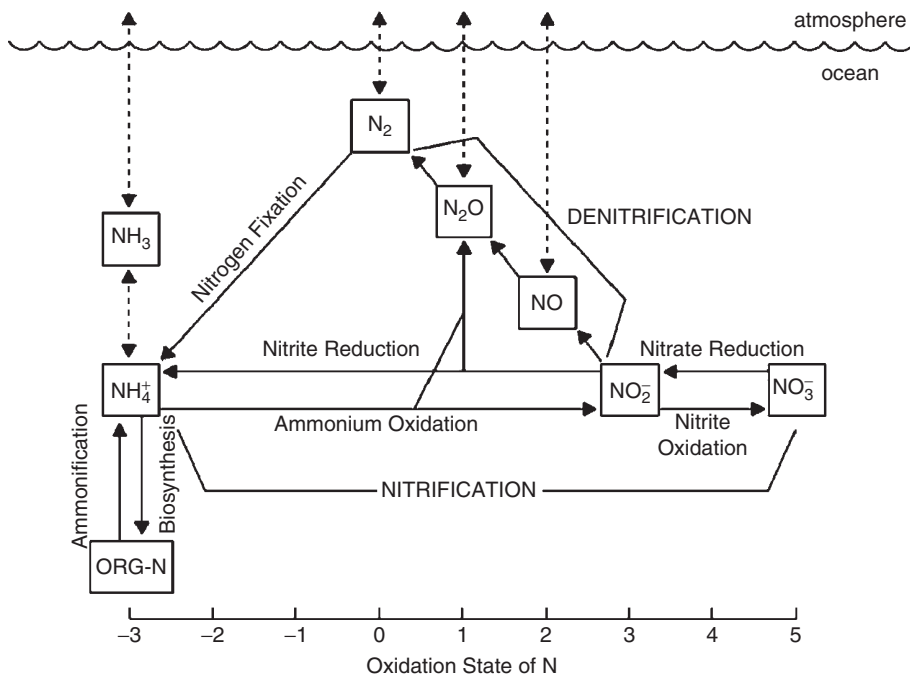
In open ocean marine ecosystems, N-cycle processes are driven almost exclusively by the metabolic activities of microorganisms, especially *Bacteria* and *Archaea*. Some abiotic N transformations can occur (e.g., photolytic alteration), but these are quantitatively negligible in open ocean ecosystems. Microorganisms require N as a nutrient source, but the redox potential of some N-containing substrates also provides an energy mediated pathway whereby microbes intersect the N–cycle (Fig. 16.1). The microbial transformations between these redox end-members and the intermediate oxidation states of the other stable N species are either energy-requiring (N reductions) or energy-yielding (N oxidations), and thus they have important metabolic and ecological consequences. In this regard, nitrite (NO_2^-) is a key redox intermediate (Fig. 16.2) even though NO_2^- concentrations and turnover rates are rarely measured in the field.


Figure 16.1 Schematic view of the marine N-cycle showing major pools and transformations. Shown on the bottom is the oxidation state of N in each of the major pools. Changes in the valence state of N require (reductions) or release (oxidations) energy and are often coupled to metabolism. Adapted from Capone (1991) and Karl and Michaels (2001). ORG-N = organic N; NH_2OH, not shown, is the precursor for NH_4^+ oxidation to N_2O.
Figure 16.2 The redox intermediate, nitrite (NO_2^-), occupies a central position in the marine N-cycle. Shown are the various processes that are either sources or sinks for NO_2^-. Abbreviations include (clockwise from top): ANR = assimilatory nitrate reduction, Nit = nitrification, photolysis = UV-driven photocatalysis, DNR/DN = dissimilatory nitrate reduction/denitrification, ANR and Nit = as above, Anammox = Anaerobic ammonium oxidation.

Some dissolved N species are transported great distances via ocean circulation, while others are locally generated and short-lived due to rapid metabolic turnover. Some N-containing molecules are gaseous thereby linking them to the atmosphere via thermodynamically driven air-sea exchange reactions. In fact, the most abundant form of N in the sea is dissolved gaseous dinitrogen (N_2), which accounts for more than 95% of the total N inventory in seawater (Table 16.1). The relative stability of the triple bond of N_2 ($N{\equiv}N$) renders this form of N nearly inert to most organisms. However, selected prokaryotes can reduce N_2 to NH_4^+ (a process called N_2 fixation), thereby enriching the ecosystem with a form of fixed N that is broadly available to most, if not all, microbes. In addition, fixed N can be converted back into N_2 via denitrification and anaerobic ammonium oxidation (anammox), leading to a loss of bioavailable N from those habitats unless local rates of N_2 fixation exceed denitrification plus anammox rates. This mobilization of N_2 gas does not directly depend upon ocean mixing. Therefore, both N_2 fixation and denitrification can decouple N from other bioelement cycles which depend on ocean mixing; this decoupling has potentially important biogeochemical implications (Gruber, 2004, Chapter 1, this volume).

Organic N is an important component of the marine N-cycle (Figs.16.1 and 16.3A and B; Table 16.1) (see Aliwahri and Meador, Chapter 3, this volume). In the marine environment, organic nitrogen exists in a more or less continuous spectrum of molecular and particle sizes from simple low molecular weight (LMW) compounds (e.g., urea and amino acids) through more complex high molecular weight (HMW) ''dissolved'' species (e.g., protein, colloids and gels) to true particles ranging

Table 16.1 Representative N Inventories for Open Ocean, Trades Biomes and Selected Production–Consumption Pathways

Substrate pool	Representative concentrations	Possible production pathways
Gaseous N		
N_2	0.4–0.5 mmol l^{-1}	Denitrification (including anammox), air–sea exchange
N_2O	5–10 nmol l^{-1}	Nitrification, denitrification, air–sea exchange
"Fixed" DIN		
NO_3^-	0.1–10 nmol l^{-1}	Nitrification, lightning, precipitation
NO_2^-	<1 nmol l^{-1}	Nitrification, assimilatory and dissimilatory nitrate reduction, photolysis
NH_4^+	1.5–30 nmol l^{-1}	Ammonification, biological N_2 fixation, precipitation
"Fixed" DON		
Total pool	5–6 μmol l^{-1}	Cell death/autolysis, excretion-exudation, grazing, viral lysis, biological N_2 fixation, hydrolysis of PON
– Combined amino acids	0.10–0.50 μmol l^{-1}	
– Free amino acids	1–10 nmol l^{-1}	
– ATP	50–150 pmol l^{-1}	
– DNA	0.2–4 μg l^{-1}	
– Urea	0.05–0.20 μmol l^{-1}	
Particulate N		
Total PON	0.3–0.5 μmol l^{-1}	Auto- and heterotrophic cell production and death, grazing, viral lysis, molting, condensation of DON
– DNA	2–5 μg l^{-1}	
– ATP	40–60 pmol l^{-1}	
– Biomass	0.1–0.3 μmol l^{-1}	
– Chlorophyll	0.05–0.15 μg l^{-1}	

Concentrations are all for near-surface waters (0–50 m).

from submicron (e.g., viruses, bacteria and some non-living particles) to meters or more (e.g., pelagic fishes, squids and whales). Typically, the operational boundary between LMW and HMW dissolved organic N (DON) is 1000 Daltons (~1 nm) and the operational distinction between DON and particulate organic N (PON) is operationally defined, for example if microfine glass fiber filters are used then the boundary is approximately 0.5–1.0 μm. For this reason, "dissolved" organics as reported in the scientific literature may also contain some small particles (Table 16.1). DON is just one subcomponent of the much larger dissolved organic matter (DOM) pool in seawater. DOM contains a broad spectrum of organic molecules, only some of which contain N. Isolation of LMW- and HMW-DOM combined with isotopic (^{15}N, ^{13}C, ^{14}C), structural and biochemical characterization can yield insights into the age, lability and compartmentalization of N within this large organic N pool (Benner *et al.*, 1997; Loh *et al.*, 2004; Meador *et al.*, 2007).

1.1. The North Pacific trades biome

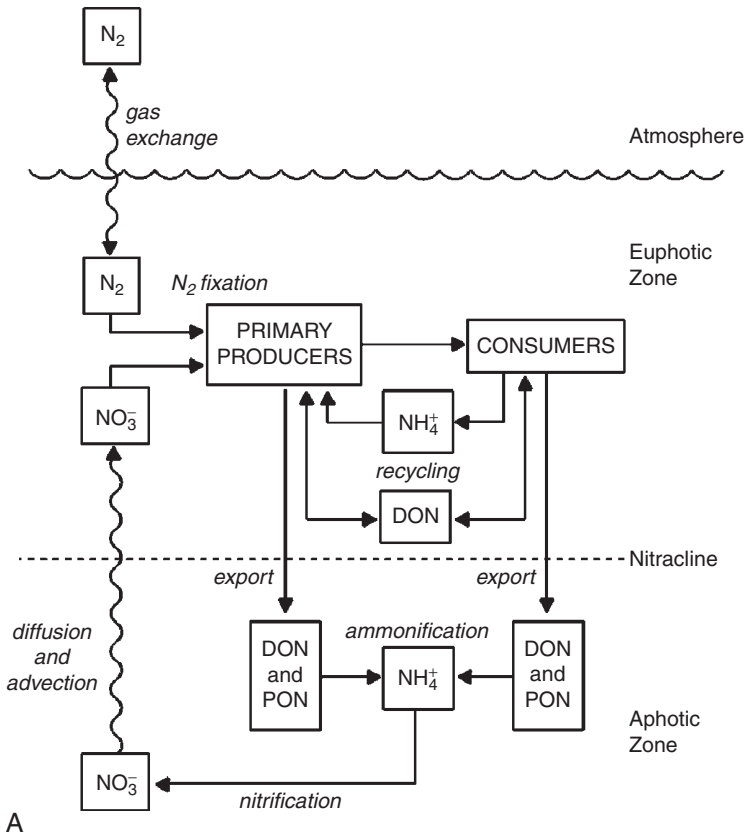
The marine environment is large by any worldly measure. For more than a century, oceanographers have recognized that there are predictable physical and chemical properties, and biotic communities that vary systematically from near-shore environments to the oceanic realm and from the equator to the poles. This has led to a recognition and definition of specific biogeographical provinces, or biomes, within which processes can be scaled in time and space after adequate representative sampling (Longhurst, 1998). With the advent of Earth-orbiting satellites designed to measure key ocean parameters such as sea surface temperature, topography, winds, light and color—the latter as a surrogate of photoautotrophic community biomass—a wealth of information on global ocean environmental conditions as they relate to the ecological geography of the sea now exists. Based on these criteria, there


Figure 16.3 Microbial food web processes sustain the marine N-cycle in the North Pacific trades biome. Shown are: (A) a schematic view of the various sources, transformations and sinks for key N pools and

(Continued)

N Resource Partitioning in the NPSG
Figure 16.3 cont'd (B) a hypothetical microbial N-resource partitioning in the euphotic zone among the various N pools and components of the microbial assemblage.

appear to be four primary biomes in the ocean: a coastal boundary biome and three oceanic zones (polar, westerlies and trades; Longhurst, 1998). Biological processes in both the polar and westerlies regions are characterized by strong seasonal cycles that are established by changes in upper water column stratification and light. As the mixed-layer shoals above a critical depth, a vernal phytoplankton bloom results (Siegel *et al.*, 2002; Sverdrup, 1953), leading to a temporal pulse of carbon and energy through the food web and export of particulate matter to the deep sea. The N-cycle in these seasonally forced biomes is characterized by two distinct phases. At the start of the spring bloom, NO_3^- is present in high concentrations and reduced forms, including NH_4^+ and DON, are low. As the mixed-layer becomes NO_3^- limited for phytoplankton growth because of net uptake in early summer, the system evolves into a lower biomass, nutrient-limited system fueled primarily by locally regenerated NH_4^+ and DON.

In contrast, the trade wind regimes support an N-cycle with fundamentally different dynamics than those observed in the polar and westerlies biomes. A key feature of the physical habitat in the trades biome, which extends from approximately 30°N to 30°S in each ocean basin and collectively represents about 45% of the total area of the ocean, is the presence of a seasonally stable pycnocline/thermocline caused by the radiation balance of positive downward heat flux across the sea surface. The dynamic topography of the North Pacific Ocean reveals systematic basin-scale variations that drive the large scale anticyclonic (clockwise) circulation of water around the core of the trades biome at approximately 20°N (Fig. 16.4A). The anticyclonic circulation effectively isolates the upper portion of the water column from large volume water exchange with the bordering current systems. This stratification leads to a permanent vertical separation of light (above) and nutrients (below), and results in a condition of extreme oligotrophy in near-surface waters including low nutrient flux, low standing stocks of particulate matter, low net rates of organic matter production and low rates of export (e.g., Fig. 16.4B). These are characteristic features of the trades biomes worldwide.

The dynamics of the N-cycle in the trades biomes is distinct from those in other oceanic regions because gross primary production is supported largely by locally recycled NH_4^+ and DON, with a subsidy via local N_2 fixation and stochastic nutrient entrainment events. Due to the rapid and efficient recycling of most N and associated bioelement pools, these oligotrophic regions sustain high N turnover rates despite low ambient pool concentrations and PON standing stocks. The stable vertical structure present in trades biomes may facilitate depth-dependent niche specialization and support the co-existence of a diverse microbiota that contribute to unique metabolic and ecophysiological processes that in many ways epitomize the marine N-cycle (Fig. 16.3B).

1.2. The "new" versus "regenerated" nitrogen paradigm

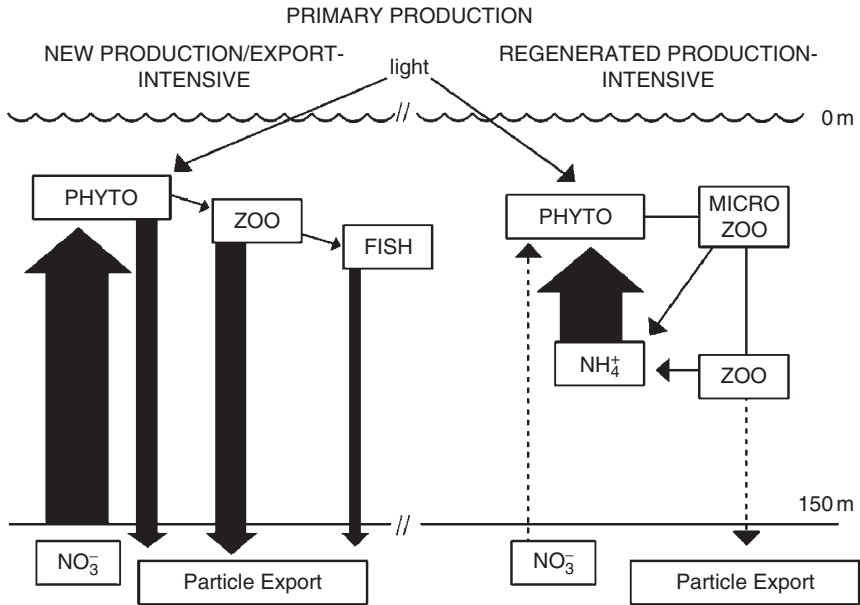
In 1967, Dugdale and Goering formalized their now unifying concept of new and regenerated primary production of organic matter in the sea (Fig. 16.5). In their model, new production was defined as that portion of total primary production that was supported by allochthonous N sources such as upwelled NO_3^- or locally fixed N_2. Regenerated production, which typically ranges from 70 to 90% of total production in most open ocean systems, was defined as that portion of total primary production that was supported by NH_4^+ or DON. They assumed that total N assimilation could, as a first approximation, be treated as the sum of NH_4^+ plus NO_3^- uptake, and that these two rates could be quantitatively measured in separate but simultaneous incubation experiments (a few hours to 1 day in duration) following the addition of the appropriate ^{15}N-labeled substrate. While the uptake of $^{15}NH_4^+$ could be equated to locally regenerated N, the uptake of $^{15}NO_3^-$ represented N that was imported to the euphotic zone by upward advection and diffusion. In their presentation, they were very explicit on several important issues including a warning that if local nitrification or local N_2 fixation were later found to be important processes in the regional N-cycle of interest, then there would be a need to reconsider the model assumptions. N_2 fixation and nitrification fundamentally alter the
Figure 16.4 Map of the North Pacific Ocean basin showing several important features of the trades biome. (A) Dynamic topography of the sea surface in dyn-cm relative to 1000 dbar based on historical hydrographic observations. Arrows show the direction of geostrophic flow. From Wyrtki (1975). (B) Sea surface distributions of chlorophyll (mg m^{-3}) for the Pacific Ocean in 2003 from 15°S to 65°N latitude as derived from the AQUA MODIS satellite-based sensor system (4 km resolution). Superimposed on ocean color, in white contour lines, is the mean annual surface nitrate concentration (mmol NO$_3^-$ m^{-3}) based on the World Ocean Atlas (2001) Ocean Climate Laboratory/NODC. Areas of high NO$_3^-$ (and presumably NO$_3^-$ flux) correspond to areas that are enriched in chlorophyll as a result of net plant growth. The North Pacific trades biome is the central region of low standing stocks of plants (<0.1 mg m^{-3}; blue–purple areas) and low ambient NO$_3^-$ concentrations (<1 mmol m^{-3}).


Figure 16.5 A conceptualized view of the new versus regenerated N model based on the classic work of Dugdale and Goering (1967). Shown are two contrasting marine ecosystems: (Left) an upwelling habitat where allochthonous NO_3^--supported new production dominates total primary productivity, and (Right) an open ocean habitat where locally produced NH_4^+-supported regenerated production dominates total primary productivity. New production-intensive biomes also support much greater export per unit area, usually in the form of sinking particulate matter, than remineralization-intensive systems like the North Pacific trades biome.

conceptual views of new (i.e., NO_3^-) vs. regenerated (i.e., NH_4^+) sources of N. For example, new NH_4^+ excreted during the growth of N_2 fixing microorganisms freely mixes with the pool of regenerated NH_4^+, and regenerated NO_3^- formed locally via nitrification and becomes indistinguishable from truly new NO_3^- imported into the region from allochthonous sources. In addition to the advective-diffusive fluxes of NO_3^- from beneath the euphotic zone and N_2 fixation, new N for the North Pacific trades biome is also derived from continental sources transported great distances as both NO_3^- aerosols and in association with Asian dust.

The new vs. regenerated N conceptual framework led to a convenient field protocol wherein paired incubations using ^{15}N–NH_4^+ and ^{15}N–NO_3^- were used to estimate the fraction of total N assimilation that is supported by new N, the so-called "f-ratio" (Eppley and Peterson, 1979). On less frequent occasion, investigators also included an estimate of the uptake of DON using a "model" compound such as urea. However, it is impossible to relate the uptake of this single compound to the potential assimilation of the entire DON pool which has not yet been fully characterized (Hansell and Carlson, 2002). Ironically, this major "advance" in our conceptualization of the marine N-cycle led to a situation where N_2 fixation was relegated to a "negligible term" in the N assimilation budget and was all but ignored

in most field studies of the marine N-cycle. Only recently has there been a renewed interest in quantitative measurements of N_2 fixation in the North Pacific trades biome. It is now recognized as a significant pathway of new production rivaling the flux of N from NO_3^- in selected oligotrophic regions. Furthermore, euphotic zone nitrification can locally produce "recycled" NO_3^- from NH_4^+. Both processes will be discussed later in this chapter. The time has come for a reconsideration of the new vs. regenerated N paradigm (Karl, 2000; Yool *et al.*, 2007).

1.3. Hawaii Ocean Time-series (HOT) program

In recent years, several long-term oceanic monitoring programs have been established to make systematic repeated observations of key physical and biogeochemical parameters including those related to oceanic N-cycle processes (Karl *et al.*, 2003). One of these programs, the Hawaii Ocean Time-series (HOT), began sampling in October 1988 at a deep ocean station dubbed Station ALOHA (A Long-term Oligotrophic Habitat Assessment) which is located in the trades biome of the North Pacific Ocean at 22°45′N, 158°W (Karl and Lukas, 1996; Karl and Winn, 1991). HOT was built on the foundation of previous field research in the North Pacific gyre dating back to the Challenger expedition in the late 19th century, and including several predecessor time-series programs (Table 16.2). As part of this program, approximately monthly measurements are made to develop a climatology of physical and biogeochemical properties including water mass characteristics, nutrient inventories, microbial community structure, primary/export production and the net metabolic balance of the sea. In this comprehensive on-going study, numerous N-cycle state variables have routinely been measured and others, including several key rate measurements, have been made on a less frequent basis (Table 16.3). This chapter will summarize these HOT program N-cycle accomplishments in the much broader context of microbial ecology and ocean biogeochemistry of the North Pacific subtropical gyre, including the presentation of a research prospectus for the future. We will primarily focus on results obtained during the past two decades, and on earlier "benchmark" achievements that guided us in the experimental designs and interpretations of our observations.

2. Distributions of Major Nitrogen Pools and Selected Nitrogen Fluxes

2.1. Dissolved and particulate nitrogen inventories

Required growth elements, like N, have uneven distributions in the open sea, both in time and in space. Consequently, inventory measurements should ideally integrate over these expected spatial and temporal variations, but this is not usually feasible in most expeditionary style investigations. Remote sensing of selected N species (e.g., NO_3^-) would be highly desirable and is now possible using novel mooring-based instrumentation (Johnson and Coletti, 2002; Johnson *et al.*, 2007).

Table 16.2 List of Selected Key Publications, Programs, Expeditions and Intellectual Breakthroughs that have Contributed to our Current Understanding of the Marine N-cycle in the North Pacific Trades Biome

Date(s)	Program/Person(s)/Event	Discovery, data sets, and ecological significance
1961	R. C. Dugdale, D. W. Menzel and J. H. Ryther	Discovery of N_2 fixation in the sea (*Deep-Sea Res.* 7: 297–300)
1967	R. C. Dugdale and J. J. Goering	Formulation of the new (NO_3^--based) vs. regenerated (NH_4^+-based) paradigm for marine primary productivity (*Limnol. Oceanogr.* 12: 196–206)
1968–1985	J. McGowan, T. Hayward, E. Venrick and others, CLIMAX time-series	Pioneering research on rates and regulation of primary production, including nutrient limitation; studies of environmental heterogeneity and phytoplankton community structure; dynamics of deep chlorophyll maximum layer; studies of N_2 fixation; DON distributions and dynamics; studies of primary NO_2^- maximum layer; analytical methods development and improvement centered at, or near, the CLIMAX site (28°N, 155°W)
1969–1970	K. Gundersen, D. Gordon, R. Fournier and others	Biogeochemical time-series at oceanic site dubbed Sta. Gollum (22°N, 158°W)
1978–1981	P. Bienfang, J. Szyper and others	Biogeochemistry time-series at two Hawaii Ocean Thermal Energy Conversion (OTEC) program sites (20°N, 156°W and 21°N, 158°W)
1979	R. W. Eppley and B. J. Peterson	Refinement of the equivalance of new and export production under steady-state conditions (*Nature* 282: 677–680)
1982–1988	G. A. Knauer, J. H. Martin and others, VERtical Transport and EXchange (VERTEX) program	Pioneering research on the relationships between particulate matter production, export and remineralization; ^{15}N tracer studies; particle-associated nitrification; trace element (Fe) controls on primary production; establishment of an 18-month ocean time-series at 33°N, 139°W

Table 16.3 Selected HOT Program N-cycle Measurements (hahana.soest.hawaii. edu/HOT/methods)

Property/Process	Method
State variables	
NO_3^-/NO_2^-	Surface waters (0–125 m): chemiluminescence
	Deeper waters: segmented-flow autoanalyzer
DON	UV photolysis followed by autoanalyzer
N_2O	Gas chromatography/electron capture
PON	High temperature combustion/gas chromatography
^{15}N-PON	Isotope ratio mass spectrometry
$^{15}N/^{18}O$-N_2O	Isotope ratio mass spectrometry
Dissolved/particulate C:N:P	As above, for DON/PON
Rates	
Autotrophic PON production	^{14}C-HCO_3^- and O_2 based *in situ* incubation, extrapolation to N
Heterotrophic PON production	^{3}H-leucine based *in situ* incubation, extrapolation to N
Total microbial production	^{32}P-phosphate based *in situ* incubation, extrapolation to N
PON export and subeuphotic zone remineralization	Free drifting and moored sediment traps
Nitrification	Substrate changes during timed incubations, ^{14}C-HCO_3^- uptake/inhibitors
N_2 fixation	^{15}N-N_2 based *in situ* incubation

Despite the fact that N is an essential nutrient and potentially the growth rate limiting nutrient in the sea, only NO_3^- exhibits the predicted "nutrient-like" profile (i.e., depleted near the surface with increasing concentrations at depth; Figs. 16.6 and 16.7A). Typically, there are NO_3^- deficits in the euphotic zone (0–175 m) where new organic matter is produced and exported, and NO_3^- excesses in regions below the approximately 0.1% light level where net organic matter decomposition and nitrification occur. Vertical profiles of NO_3^- in the North Pacific trades biome have barely detectable concentrations (<10 nM) in the upper 0–100 m and essentially no vertical gradient; hence, there is no upward diffusion over this depth range. Eppley *et al.* (1990) observed near-surface (0–30 m) enrichments of NO_3^- (28–40 nM) compared to mid-euphotic zone depth (50 m) minima of approximately 10 nM, a feature that they interpreted to be the result of atmospheric deposition of NO_3^-. At Station ALOHA, the 0–100 m inventory of NO_3^- displays both seasonal and interannual variability (Fig. 16.7B) which may be a result of stochastic mixing events.

Below 100 m, NO_3^- increases to a maximum of approximately 42 µM at 800 m, the core of the oxygen minimum zone; at greater depths the NO_3^- concentrations decrease to about 36 µM near the seafloor (Fig. 16.7C). It is important to note that
Figure 16.6 Representative upper ocean profile of NO_3^-, DON and PON at Station ALOHA based on 17-year time-series observations. Note accumulation of reduced N, especially DON in near-surface and decreases with depth. In the near-surface waters at Station ALOHA, DON accounts for nearly 95% of the total fixed N inventory.

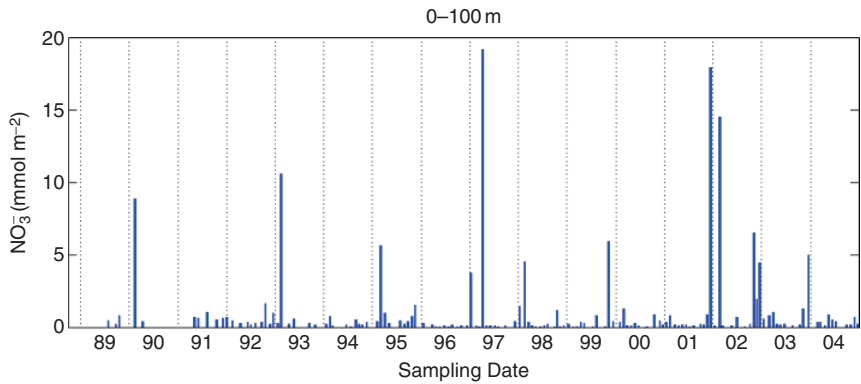
deep water (>2000 m) NO_3^- concentrations in the North Pacific Ocean are nearly twice as high as they are in the North Atlantic Ocean. This is a consequence of the different ages of the water masses and, consequently, the greater amount of time to accumulate NO_3^- from the combined effects of the biological pump and coupled ammonification/nitrification (Fig. 16.7C). In the trades biome of both major ocean basins, the temporal variability in the horizontal and vertical distributions of NO_3^- is relatively low compared to the dynamics observed in the coastal, polar or westerlies biomes. The vertical and horizontal stabilities of NO_3^- in the North Pacific trades biome are manifestations of a finely tuned balance between NO_3^- input (primarily via upward diffusion and local nitrification) and NO_3^- removal (primarily via uptake into living biomass and subsequent export by gravitational settling of particulate matter).


Figure 16.7 Seasonal and interannual variations in NO_3^- concentrations at Station ALOHA. Shown are: (A) the 16–year data set on NO_3^- (nM) in the upper 200 m as well as the summer vs. winter climatologies. Note the log scale in both graphs. (B) integrated (0–100 m) inventories of NO_3^- showing aperiodic injections of NO_3^- into the upper euphotic zone. Note the lower graph presents the data on a log scale to emphasize the extreme temporal variability in NO_3^- inventory which exceeds a factor of 300 over the 16–year observation period,

(Continued)
Figure 16.7 cont'd (C) full water column NO_3^- and dissolved oxygen profiles showing the relationships between the two pools. On the right hand plot is an enlargement of the upper 1000 m where most of the N transformations take place.

In a series of papers, Villareal and colleagues have documented a novel mechanism to supplement the net upward flux of NO_3^- in the trades biome, namely the vertical migration of diatom (*Rhizosolenia*) mats (Pilskaln *et al.*, 2005; Singler and Villareal, 2005; Villareal *et al.*, 1993, 1999). Estimates of the quantitative significance of this process, by their field observations, appear to be increasing over time and currently average 40 μmol N m^{-2} d^{-1} (Pilskaln *et al.*, 2005), a value that approaches 20% of the N export measured using sediment traps (Karl *et al.*, 1996). Because *Rhizosolenia* mats are rare and probably an aperiodic occurrence, it is difficult to estimate the annual flux of N by this process with certainty. Regardless of its quantitative role for the ecosystem as a whole, the evolution of this strategy for NO_3^- acquisition is testament to the acute selective pressures that act on microbial communities under nutrient stressed conditions. This phytoplankton-based vertical migration process, if selective for NO_3^- relative to other inorganic nutrients, would lead to a decoupling of N from the otherwise linked cycles of C and P and would thus have significant ecological implications. However, to our knowledge there are no published data on phosphate co-transport by this or similar mechanism in mat-forming diatoms. Other possible mechanisms for aperiodic enhancements in the rates of N delivery and removal will be examined in greater detail in a subsequent section of this review.

NH_4^+, NO_2^- and DON are also characterized as "nutrients," despite the fact that none of them has a "nutrient-like" profile in the open sea (e.g., DON; Fig. 16.6). The most important reason for this is that NH_4^+, NO_2^- and selected compounds in the DON pool have much shorter residence times in the water column, in part, due to the fact that they are either partially or fully reduced and contain additional potential metabolic energy. Essentially all of the "fixed" or reactive N that is exported from the surface ocean to greater depths, whether in dissolved or particulate form, is in the -3 valence state (R-NH_3 or NH_4^+), whereas essentially all of the fixed N in deep water is in the $+5$ valence state (NO_3^-). This indicates an important role for deep water nitrification (org-N/$NH_4^+ \rightarrow NO_3^-$) as a key metabolic process even though we have not yet identified the site(s) where active nitrification occurs or characterized the diversity of deep water nitrifiers.

DON and PON concentrations are both maximal in near-surface waters where inorganic nutrients are assimilated into organic matter, a process that is ultimately sustained by photosynthesis (Fig. 16.6). The decreasing concentrations of PON and DON with increasing water depth are manifestations of energy limitation of sub-euphotic zone waters and net remineralization processes. In the North Pacific trades biome, DON is usually the larger of these two organic pools, and is the largest reservoir of fixed N in near-surface open ocean habitats (Bronk, 2002; Karl et al., 2001a). As such, it represents both a potential source of N for microbial growth and, because it is in the most reduced (-3) valence state, a potential source of energy for those microbes capable of utilizing it. Consequently, the near-surface enrichments of DON are enigmatic and must be a result of the longer term accumulation of semi-labile or refractory organic compounds.

The total DON pool is poorly characterized at the present time, and is likely to consist of numerous individual compounds or compound classes of varying concentration and bioavailability (Aluwihare et al., 2005; McCarthy et al., 1997, 1998). The most dramatic result was the discovery that most of the HMW-DON is present in the form of amides, rather than the previously-held view of DON as a complex spectrum of heterocyclic compounds formed from condensation reactions. Several candidate amide-containing compounds thought to be important are proteins, chitin and peptidoglycan, the latter being a major constituent of bacterial cell walls. Recently, Aluwihare et al. (2005) have reported that the HMW-DON pool (which accounts for approximately 30% of the total DON at their study site in the North Pacific trades biome) consists of two chemically distinct pools of amide based on selective hydrolysis, ^{15}N-NMR spectroscopy and chemical analysis of degradation products. Their results indicated that nearly half of the HMW-DON pool in surface waters consists of N-acetyl amino polysaccharides (N-AAP). Since peptidoglycan is rich in N-acetyl glucosamine and N-acetyl muramic acid, they were expected to be present in—if not to dominate—the N-AAP pool, but were found in only negligible concintrations (Aluwihare et al., 2005). It is conceivable that the N-AAPs in seawater are resistant to degradation, both chemical and microbiological, due to condensation. Using ^{15}N and molecular techniques, Meador et al. (2007) reported that the $\delta^{15}N$ of surface HMW-DON was relatively invariant throughout the tropical Atlantic (4.1 $\pm$ 0.6‰) and tropical Pacific (5.4 $\pm$ 0.8 ‰) Oceans, and showed little correlation with sources or concentrations of N supporting

primary production. However, the δ^{15}N of the dissolved protein fraction was consistently δ^{15}N-depleted relative to bulk HMW-DON in regions where N$_2$ fixation was the dominant source of new N. This suggests that there is a small, rapidly recycled component of the HMW-DON pool that is more labile than the bulk pool (Meador *et al.*, 2007). This pioneering research continues.

Particulate nitrogen in the open sea is most likely organic in origin (i.e., PON) and is expected to be as complex in molecular structure as DON. Although few data exist on bulk PON characterization (Bronk, 2002), several specific N-containing components of the total PON pool have been measured, some routinely (Table 16.1). Because living microbial cells (biomass) can comprise a major, but variable percentage of total PON in seawater (from ~10 to 80%, depending upon depth and geographical location), a portion of the PON pool must consist of the major cellular N reservoirs, namely protein, nucleic acids and, for bacteria, cell walls. While DON and PON can be interconverted, the two pools are likely to have different sources and sinks. Based on ^{13}C-NMR and δ^{13}C isotopic analyses, the HMW-DOM and POM at Station ALOHA appear to be different in both molecular composition and source (Sannigrahi *et al.*, 2005).

The concentrations and dynamics of the near-surface DON and PON pools have been studied at Station ALOHA since 1988. Church *et al.* (2002) reported that the 0–175 m dissolved organic C (DOC) and DON (but not dissolved organic P) increased at rates of 303 and 33 mmol m^{-2} year^{-1}, respectively, for the period 1993–1999. The accumulated DOM had a mean C:N molar ratio of 27.5. By comparison, the C:N ratio of isolated HMW-DOM in the North Pacific trades biome is 14–15, suggesting that the highly aged (based on ^{14}C content) LMW-DOM is more carbon rich (Loh *et al.*, 2004). However, the true C:N ratio of the DON pool (as opposed to bulk DOM) is neither known nor easily determined because the DOC and DOC-N, DOC-N-P and DOC-P sub-pools cannot currently be separated. For example, the N content of HMW-DOM isolated from Station ALOHA varied between 0.95 and 1.69 wt% with no clear depth trends between 20 and 4000 m; molecular analyses identified carbohydrate and amino acids as major compound classes (Sannigrahi *et al.*, 2005).

With regard to PON, Hebel and Karl (2001) have reported regular seasonal changes in the 0–75 m inventories of PON at Station ALOHA, with significantly greater concentrations in summer and fall and minimum concentrations in winter. The average molar C:N:P stoichiometries for 0–75 m particulate matter were 122:17.1:1 (winter), 119:18.4:1 (spring), 140:20.2:1 (summer), and 143:21.8:1 (fall), indicating a tendency for high C:N and high N:P ratios relative to the canonical Redfield ratio of 106C:16N:1P (Hebel and Karl, 2001). They also reported that the contemporary HOT program data set indicates a 70–100% increase in the POC and PON inventories throughout the euphotic zone in comparison to those reported more than 20 years ago during the GOLLUM program (1969–1970) using similar methods. These long-term trends reported by Hebel and Karl (2001), as well as the sub-decadal variations in DOC and DON reported by Church *et al.* (2002), are consistent with enhanced N$_2$-supported new production and increased retention of N-containing compounds. Additional data on these key processes in the marine N-cycle, and the ecological implications of decade-scale enhancements in N$_2$ fixation are discussed later in this chapter.

2.2. Nitrogen assimilation and particulate nitrogen production

Several comprehensive studies of N assimilation in the North Pacific trades biome have been conducted over the past several decades. Gundersen and his colleagues (1974, 1976) were the first to establish N_2 fixation as a source of new N to the open ocean ecosystem, and concluded that it was a more important source of fixed N than wet deposition from the atmosphere (see Case Studies section). They also made measurements of the rates of nitrification, denitrification and assimilatory nitrate-reduction. These latter experiments involved the addition of fairly high concentrations of exogenous N substrates (NH_4^+, NO_2^-, NO_3^-) and extended incubations (days to months), so the rates reported must be viewed as "potential" rates at best.

Eppley *et al.* (1977) measured *in situ* rates of assimilation of NH_4^+, urea and NO_3^- in the upper photic zone on several expeditions to the central North Pacific gyre near the Climax site using ^{15}N tracer techniques. Their experiments were based on 24-h incubations and did not account for isotope dilution (substrate recycling during the incubation period). Assimilation of NO_3^- in surface waters was negligible due to low ambient NO_3^- concentrations, but potential uptake rates under conditions of NO_3^- saturation were in the range of 1–8 nM d^{-1}.

A decade later, similar ^{15}N tracer measurements were conducted at the Climax site during the PRPOOS expedition (Sahlsten, 1987). The experimental design called for large volume (4 liter), short-term (3–4 h) incubations under simulated (light/temperature) *in situ* conditions; diel variability in N assimilation rates was also determined. Several interesting results were obtained: (1) the average ($n = 3$) percentages of NO_3^-, urea and NH_4^+ to the total N assimilated were 14%, 32%, and 54%, indicating that regenerated N supports approximately 85% of the N demand, (2) the total daily rate of N assimilation was 12.5 mmol N m^{-2} day^{-1} integrated over the euphotic zone and (3) < 3 μm size fraction accounted for approximately 75% of the NH_4^+ uptake.

As one component of the decade-long VERTEX program, an oceanic time-series station (33°N, 139°W) was occupied for an 18-month period from October 1986 to May 1988. During this observation period, the site was visited on 7 occasions (~90-day interval) for approximately 1 week per expedition to retrieve and redeploy a free-drifting sediment trap array, to collect water samples and to conduct experiments relevant to C- and N-cycle processes (Harrison *et al.*, 1992; Knauer *et al.*, 1990). The uptake and assimilation of $^{15}NO_3^-$ and $^{15}NH_4^+$ substrates were measured during incubation experiments that were designed to assess, and correct for, isotope dilution of the added tracers. Photoautotrophic N assimilation was measured using the ^{14}C into protein method, described later in this section. Measurements were also made of the concentrations of NO_3^-, NH_4^+, DON, PON, total microbial biomass, autotrophic biomass, heterotrophic biomass, primary productivity and the export of particulate matter (Harrison *et al.*, 1992). In many ways this was, at that time, the most comprehensive study of the marine N-cycle ever conducted in the North Pacific trades biome.

The total microbial community assimilation of NO_3^- and NH_4^+, as well as total photoautotrophic N uptake all showed significant depth and time dependence, with maximum rates of N assimilation in the near-surface waters during summer (Figs.16.8A and 16.8B, Table 16.4). The f-ratio was consistently low (≤ 0.1 in the
Figure 16.8 N assimilation data from the VERTEX program time-series station at 33°N, 139°W (adapted from Harrison *et al.*, 1992). Shown are: (A) Upper water column density, expressed as "sigma-T" showing changes in stratification of the water column, ^{14}C-HCO_3^--based primary production, autotrophic N-uptake based on the ^{14}C-HCO_3^- into protein method (see text for details) and (B) NO_3^- and NH_4^+ uptake rates based on ^{15}N tracer experiments and calculated f-ratios.

Table 16.4 Selected N Flux Estimates in the North Pacific Trades Biome

Location/Date	*Process*: Method	N-assimilation rates (mg N m^{-2} day^{-1})	Reference
27°58′N, 154°54′W Aug 1973	*Selected substrate assimilation*: Uptake of ^{15}N-labeled substrates at various depths between 0–75 m	NH$_4^+$: 3–22 NO$_3^-$: 0 Urea: 0.8–19 N$_2$: 0.03–0.7	Mague *et al.* (1977)
18°44′N, 157°W Feb 1980	*"Net" Total microbial production:* Conversion of ^{3}H-adenine incorporation into DNA to N using N:DNA ratio of 7.6, integrated to 1% surface irradiance	71.5	Winn and Karl (1984)
26°N, 155°W Mar–Apr 1986 and Oct 1986 (ADIOS)	*Total photo-autotrophic N assimilation:* Uptake of ^{14}C-HCO$_3^-$ into protein, integrated to 1% surface irradiance	58.7–84.9	Laws *et al.* (1989)
33°N, 139°W 7 cruises Oct 1986–May 1988 (VERTEX)	*Selected substrate assimilation*: Uptake of ^{15}N-labeled substrates	NO$_3^-$: 8.26 ± 2.94 (annual = 3080) NH$_4^+$: 83.7 ± 57.3 (annual = 31,220)	Harrison *et al.* (1992)
22°45′N, 158°W various cruises to Sta. ALOHA from Oct 1988 to Dec 2005 (HOT)	*"Net" Total microbial N assimilation:* Conversion of ^{32}P-based production to N using N:P of 16:1	8 cruises 0–75 m: 116 ± 32 75–175 m: 51.8 ± 28	Björkman and Karl (2003)
	"Net" photoautotrophic N assimilation: Conversion of ^{14}C-based production to N using C:N of 6.6:1	Net = 88.2 (annual = 32,193)	Karl *et al.* (2002)
	"Gross" photoautotrophic N assimilation: Conversion of O$_2$-based production to N using a PQ = 1.1 and a C:N of 6.6:1 both integrated to 1% surface irradiance	Gross = 175 (annual = 63,875)	Williams *et al.* (2004)
	"Net" heterotrophic production: Conversion of ^{3}H-leucine incorporation rates to N using 265 g N per mol leucine incorporated	Net = 12.3–19.5	Church *et al.* (2004)
	"Net" N$_2$ fixation: ^{15}N$_2$ assimilation into PON, integrated 0–100 m	0.56–1.62	Dore *et al.* (2002)
	NO$_3^-$ and N$_2$-based new production: Model estimation using δ^{15}N mass balance of exported PON for period 1990–2000	N$_2$-based: mean = 1.89 NO$_3^-$-based: mean = 2.07	Dore *et al.* (2002)
	PON export from euphotic zone: free-floating sediment traps at 150 m	3.1–5.6	Karl *et al.* (1996)

upper 0–50 m) throughout the year, indicating a strong metabolic preference ($\geq$90% of the total) for NH_4^+. The uptake of NO_3^- was less variable than that of NH_4^+, and could account for the annual PN export measured using sediment traps. The seven–cruise mean 0–150 m integrated rates of NO_3^-, NH_4^+ and autotrophic-N assimilation were 8.26, 83.7 and 59.2 mg N m^{-2} day^{-1}, indicating a significant non–photosynthetic uptake (~40%) of [NO_3^- + NH_4^+], presumably chemoorganoheterotrophic assimilation of NH_4^+. Unfortunately, neither DON uptake nor N_2 fixation were measured in this study.

Allen *et al.* (1996) compared NO_3^- uptake rates based on net changes in [NO_3^-] during timed incubations to rates estimated from $^{15}NO_3^-$ tracer experiments, in which approximately 55 nM NO_3^- was added to the samples; ambient [NO_3^-] was $\leq$10 nM. The addition of the ''tracer'' stimulated NO_3^- uptake to rates that approached 25 nM N day^{-1} compared to the measured net NO_3^- uptake rates that were not significantly different from zero for 24-h incubations of unspiked seawater samples. They also concluded that most of the total euphotic zone NO_3^- assimilation probably occurs within a few tens of meters near the top of the nitracline between the 0.1 and 1% light levels, hence, a sampling protocol for NO_3^- assimilation measurements needs to be designed accordingly (Allen *et al.*, 1996).

The rate of ^{14}C-bicarbonate incorporation into protein has also been used to estimate rates of phytoplankton N-assimilation (DiTullio and Laws, 1983). This method, applicable to all N-limited marine ecosystems, builds on the observation that the C:N ratio in protein is remarkably constant and that, under N limitation, a fairly constant percentage (85%) of phytoplankton N is incorporated into protein, with little or no N storage (DiTullio and Laws, 1983). Application of the method involves an incubation with ^{14}C-HCO_3^- followed by extraction and isolation of the ^{14}C-labeled protein fraction. From measurement of the ^{12}C/^{14}C ratio of the total dissolved inorganic carbon pool, the protein C assimilation rates can be estimated. Total phytoplankton N assimilation is then calculated from the theoretical ratios of C:N in protein and protein in phytoplankton under N limitation. In theory, this method has the ability to measure total N assimilation by photoautotrophic plankton regardless of substrate class utilized to support growth (fixed inorganic N plus organic N plus N_2), and the ability to measure phytoplankton N assimilation without interference from co-occurring chemoorganoheterotrophic bacteria. However, it should be emphasized that heterotrophic microorganisms will become partially labeled over time, especially if the microbial food web is active in the incubation bottles. A disadvantage of the method is that it can only be used to measure N assimilation in N-limited ecosystems. Furthermore, at the present time there is limited information whether photoautotrophic prokaryotes, including the two most abundant groups of marine picophytoplankton, *Prochlorococcus* and *Synechococcus*, have protein C:N ratios and protein cell quotas that are similar to the eukaryotic phytoplankton that form the basis for this method.

At a station located in the North Pacific trades biome (18°N, 156°W), DiTullio and Laws (1983) reported autotrophic N uptake rates of 7–11 μmol N m^{-3} h^{-1} for four samples collected in the euphotic zone. The integrated (0–120 m; to the 1% light level) rate of autotrophic N assimilation was 0.93 mmol N m^{-2} h^{-1} and the mean molar C:N assimilation ratio (C assimilation was measured using ^{14}C) was 7.84 ($\pm$0.23), compared

to the Redfield ratio of 6.6. Laws *et al.* (1984) later applied the "^{14}C into protein" method to estimate phytoplankton N assimilation during the PRPOOS program at several stations around the island of Oahu, Hawaii. Rates of assimilation ranged from 0.05 to 0.14 µmol N l^{-1} d^{-1} for near-surface waters, excluding one eutrophic sample (1.8 µg chl a l^{-1}) collected in Kaneohe Bay (Laws *et al.*, 1984). These rates were generally lower than corresponding rates of N assimilation based on the direct incorporation of ^{15}N-labeled NH$_4^+$ with corrections for isotope dilution over time (based on the method of Glibert *et al.*, 1982). The average molar ratio of ^{14}C-bicarbonate assimilation to N assimilation by ^{14}C into protein for these experiments was 7.3 ($\pm$2.1; $n = 6$), not significantly different from the Redfield C:N ratio of 6.6.

In a subsequent report, Laws *et al.* (1985) compared N assimilation based on ^{15}NH$_4^+$ and ^{14}CO$_2$ into protein at three sites near Oahu, Hawaii. Once again the uptake rates of ^{15}NH$_4^+$ exceeded total photoautotrophic N assimilation. They concluded that heterotrophic processes accounted for 50–75% of the NH$_4^+$ uptake, suggesting an intense competition between phototrophs and organotrophs for NH$_4^+$ in these habitats.

In most oceanic environments, including the North Pacific trades biome, primary production of organic matter was traditionally thought to be limited by the supply of fixed N (Caperon and Meyer, 1972; Eppley *et al.*, 1977; Ryther, 1959). This conceptual view of a N-controlled ecosystem assumes that the large reservoir of N$_2$ in the sea is inaccessible to primary producers or that the activities of N$_2$ fixing microorganisms are limited by some other major or trace nutrient (e.g., P or Fe). In most marine environments, nutrient elements are tightly coupled in such a way that alleviation of proximate N, P or Fe limitation will lead to immediate limitation by the next, as predicted by Liebig's Law of the minimum (Karl, 2002; Liebig, 1840). Consequently, single "nutrient addition" experiments may not reveal the fundamental processes controlling the ecosystem carrying capacity and structure; new experimental approaches may be necessary to address this important ecological problem. Suffice it to say that for the multiple required elements likely to limit rates of organic matter production in the sea (N, P and Fe), only N can be converted from a nearly inexhaustible, but relatively inert, pool (N$_2$) to a bioavailable form (NH$_4^+$), provided the required energy is available (either directly as sunlight or as reduced organic matter, which itself is ultimately derived from sunlight) and that N$_2$ fixing microorganisms are present and actively growing. Therefore, from this simple analysis it appears that the marine environment might only be N-limited in areas where energy (light) is also limiting, and in all other regions—including much of the surface ocean in the North Pacific trades biome—organic matter production should ultimately be limited by P or Fe, or both (Karl, 2002).

2.3. Particle export and sub-euphotic zone remineralization of nitrate

Once formed in the near-surface waters, PON has three possible fates. It can be: (1) locally remineralized back to inorganic N (primarily NH$_4^+$) by the combined activities of protozoan and metazoan grazers, bacteria and viruses, (2) converted to

DON and either accumulate or enter into the microbial food web remineralization pathway as in (1), or (3) exported from the local system via advection or gravitational settling.

With the development and extensive use of particle interceptor traps (PITs), also called sediment traps, a new phase of marine biogeochemistry was initiated (Honjo, 1978; Knauer *et al.*, 1979; Soutar *et al.*, 1977). In addition to obtaining "static" measurements of the inventories of DON and PON, oceanographers were now also able to record the downward vertical flux (and upward flux as well if sediment traps are deployed in an inverted configuration), of particulate matter. Returned samples could be interrogated using microscopes, elemental analyzers, mass spectrometers and DNA sequencers, to name a few tools, to characterize the materials collected at a given reference depth or to determine chemical and biological changes that occur as particles sink between selected reference depths. Early models developed to predict particle flux based on surface primary production and water depth (Berger *et al.*, 1987; Pace *et al.*, 1987; Suess, 1980), or particle flux at depth based on particle flux measured at the base of the euphotic zone (~150–200 m; Martin *et al.*, 1987) provided conceptual frameworks for more detailed, mechanistic studies during the VERTEX program and throughout the JGOFS era. Because much of the total global marine export occurs in open ocean habitats (Karl *et al.*, 1996; Martin *et al.*, 1987) it is important to understand the coupling between particle production and downward particle flux, and the factors that cause them to vary over time.

Eppley and Peterson (1979) elaborated further on the Dugdale and Goering (1967) conceptual framework for relating new production to export. If a system is in biological steady-state, or if the measurements are integrated over a sufficiently long period of time (months to years), then new production—*sensu* Dugdale and Goering (1967)—should be equivalent to the amount of primary production that is available for export (Eppley and Peterson, 1979). This export would be quantitatively balanced by the resupply of the production-rate-limiting nutrient(s). Unfortunately, these relationships appear to be much more complex than previously assumed (Karl *et al.*, 1996; Karl *et al.*, 2001b). Data collected during the ongoing HOT program indicate both seasonal and interannual variations in the flux of PON from the euphotic zone, with aperiodic decoupling from primary production that may be partly related to the hypothesized role of N_2 fixation, leading to a systematic alternation between N and P limitation and changes in microbial community structure and ecosystem processes (Karl, 1999; Karl *et al.*, 1996; Karl *et al.*, 2001a, b).

The vertical fluxes of particulate C, N and P at Station ALOHA reveal the following general trends (Christian *et al.*, 1997; Karl *et al.*, 1996): (1) export is maximum near the base of the euphotic zone (mean $\pm$ 1 SD = 2.30 $\pm$ 0.86 mmol C m^{-2} day^{-1}, 0.28 $\pm$ 0.11 mmol N m^{-2} day^{-1} and 0.013 $\pm$ 0.005 mmol P m^{-2} day^{-1} at a reference depth of 150 m), (2) POC flux ranges from 2 to 17% (mean = 6.7%) of the contemporary primary production, (3) C:N:P molar stoichiometry of the exported materials at the 150 m reference depth averages 177:21.5:1, indicating a deficit of N and P, relative to C, compared to the Redfield ratio of 106:16:1, (4) the molar ratios of C:N and C:P of the sinking particulate matter increase by 50% and 35%, respectively, with increasing depth over the range 150–500 m, resulting in a consistently longer solubilization length scale and a concomitant deeper penetration

of particulate C, relative to N or P, and (5) C, N and P fluxes all display both seasonal and interannual variability and may be punctuated by large, aperiodic pulses that are not well sampled or understood, as described in the previous section.

The base of the euphotic zone, approximately 150–200 m in the North Pacific trades biome, represents a key ecosystem boundary below which there is a net loss of sinking N and a net accumulation of NO_3^- with increasing water column depth. While several other processes can contribute to C-N-P bioelement export (Emerson *et al.*, 1997), the gravitational settling of particulate matter ultimately derived from photosynthesis is generally the most important. Sinking particles, containing N in the most reduced amine form (-3), are ultimately oxidized to NO_3^- ($+5$) by the combined activities of macro- and microorganisms, especially the NH_4^+- and NO_2^--oxidizing prokaryotes. However, the exact pathways of conversion, sites of oxidation and organisms involved are not well understood (see Figs.16.1, 16.7C and 16.9A). In one model, microorganisms associated with the sinking particles convert $PON \rightarrow NH_4^+ \rightarrow NO_2^- \rightarrow NO_3^-$. In a second model, sinking particles are consumed by macrofauna who produce a new suite of sinking particles and produce an overlapping ladder or semi-continuous "rain of detritus." In a third conceptual model, sinking particles disaggregate, disintegrate or otherwise alter their sinking rates (and possibly achieve neutral buoyancy) so that free-living microorganisms at depth can catalyze PON remineralization (Fig. 16.9A). Each model has independent rate controls and sensitivities to changes in the nature of the initial sinking particle spectrum. Regardless of the mechanism(s) involved, the sequence of metabolic processes conforms to the von Brand *et al.* (1937) "diatom rotting" experiments (Fig. 16.9B). The coupled processes of ammonification (the production/release of NH_4^+ from PON) and nitrification (the stepwise oxidation of NH_4^+ to NO_2^-/NO_3^-) are the key processes in the conversion of PON to NO_3^-, both in this classic experiment and in the ocean as a whole. Ammonification is a very general and widespread process, whereas nitrification is probably more restricted.

The mesopelagic zone of the world ocean (defined as the habitat between the lower epipelagic zone and the upper bathypelagic zone, approximately 150–1500 m; Hedgpeth, 1957) is sometimes referred to as the "twilight zone" partly because the light flux in this region is—at most—equivalent to twilight and partly because "mystery abounds" as we know so little about it. One of the largest and yet unsolved mysteries involves the process of nitrification. Until recently, it was thought that chemolithoautotrophic nitrifying bacteria (e.g., *Nitrosomonas/Nitrobacter*, and related genera) controlled the oxidation of NH_4^+ to NO_3^- in subeuphotic zone habitats. However, after the pioneering discovery of non-thermophilic *Archaea* in marine ecosystems (Fuhrman *et al.*, 1992; DeLong, 1992), pelagic *Crenarchaeota* and *Euryarchaeota* were recognized as important components of the total microbial assemblage in the North Pacific trades biome, especially within the twilight zone (Karner *et al.*, 2001). And despite the ubiquity of pelagic *Archaea*, their metabolic and biogeochemical roles remained unresolved or, at best, only partially answered. Recently, Pearson *et al.* (2001) and Wuchter *et al.* (2003) provided independent evidence suggesting that mesopelagic zone *Archaea* may have an autotrophic metabolism, and even more recently a chemo-lithoautotrophic NH_4^+-oxidizing marine archaeon has been isolated documenting
Figure 16.9 Coupled euphotic zone PON export and mesopelagic zone remineralization processes. (A) Shown are three conceptual models to account for the net decomposition of sinking POM and coupled nitrification showing the various and, potentially independent, roles of micro- and macroorganisms in the ocean's mesopelagic zone N-cycle (see text for details). (B) The observed stepwise remineralization of diatom-associated biomass (PON) to NH_4^+, NO_2^- and NO_3^- (all shown as arbitrary units of N) in the dark as particles aged over a period of three months. Redrawn from data in von Brand *et al.* (1937).

the first example of nitrification in the domain *Archaea* (Könneke *et al.*, 2005). Laboratory growth of the isolated Crenarachaeote strain SM1, which has been assigned the candidate status, *Nitrosopumilus maritimus*, demonstrated a quantitative conversion of NH_4^+ to NO_2^- as the sole energy source and incorporation of HCO_3^- as the sole carbon source. Furthermore, metagenomic surveys have

revealed that some *Archaea* carry a unique ammonia monooxygenase (*amoA*) gene (Schleper *et al.*, 2005; Venter *et al.*, 2004), and polymerase chain reaction (PCR) primers designed to specifically target archaeal *amoA* have detected its presence in a variety of coastal and open ocean habitats (Francis *et al.*, 2005). Mincer *et al.* (2007) have obtained the quantitative distribution of putative nitrifying genes and phylotypes in a picoplanktonic genome library from Station ALOHA. They report a deeply branching crenarchaeal group related to a hot spring clade indicating that the *amo*A containing archaea in the mesopelagic zone may be more diverse than previously reported. They also found a positive correlation between pelagic *Nitrospina* and crenarchaea suggesting a probable syntrophic relationship between the two. Even with this new discovery of archaeal ammonium oxidation, there still appears to be a division of metabolic labor during the process of nitrification (Costa *et al.*, 2006), despite one report to the contrary (Ram *et al.*, 2001). Consequently, it is tempting to hypothesize that *Archaea* may play a role in, or even control, subeuphotic zone nitrification, at least the oxidation of NH_4^+ (e.g., Ingalls *et al.*, 2006; Nicol and Schleper, 2006; Wuchter *et al.*, 2006; Beman *et al.*, 2008). Well designed *in situ* rate experiments that are able to distinguish between bacterial and archaeal NH_4^+ and NO_2^- oxidation, perhaps using specific inhibitors, will ultimately be necessary to test this novel hypothesis.

3. Selected Trades Biome Ecosystem Processes

3.1. Nitrous oxide production and sea-to-air gas flux

Nitrous oxide (N_2O) is a potent greenhouse gas (approximately 200 times more effective than CO_2 on a molar basis) that has also been implicated in stratospheric ozone depletion (Kim and Craig, 1990; Yoshida *et al.*, 1989) (see Bange, Chapter 2, this volume). Currently, N_2O accounts for about 5.5% of the enhanced radiative forcing attributed to all gases in the atmosphere (IPCC, 2007). Furthermore, while the atmospheric inventory of N_2O is increasing, its sources are not well understood causing a renewed interest in the role of marine ecosystems as a potential source for N_2O.

In the North Pacific trades biome, N_2O is a trace dissolved gas with typical concentrations ranging from 5 to 50 nM (Fig. 16.10A). N_2O concentrations in near-surface waters are generally in slight excess of air saturation, implying both a local source and a sustained ocean-to-atmosphere flux. At Station ALOHA, N_2O concentrations in the surface mixed-layer zone range from 5.1 to 9.3 μmol m^{-3}, equivalent to 83–137% of air saturation; deeper within the euphotic zone, the N_2O concentrations range from 6.8 to 14.4 μmol m^{-3}, equivalent to 95–187% of air saturation (Fig. 16.10B; Dore and Karl, 1996a; Popp *et al.*, 2002; unpublished HOT data). In selected oceanic regions, N_2O can exceed 300% saturation, relative to atmospheric equilibrium. An understanding of the processes maintaining the euphotic zone N_2O supersaturation has received the most interest (Capone, 1991), mainly because of the potential for a significant sea-to-air N_2O flux. Beneath the euphotic zone, at a depth approximately 500–1000 m, there is a peak in N_2O concentration that is usually co-located with the dissolved oxygen minimum (Ostrom *et al.*, 2000).
Figure 16.10 (A) Nitrous oxide (N_2O) concentrations and isotopic composition for water samples collected at Station ALOHA. [Left] Depth profile of N_2O showing a distinct mid-depth maximum of ~60 nM coincident with the dissolved oxygen minimum. [Center] ^{15}N isotope composition of N_2O. [Right] ^{18}O isotope composition of N_2O. Data from Dore *et al.* (1998) and B. Popp and J. Dore (unpublished). (B) N_2O saturation state, expressed as a percentage of air saturation, for the upper portion of the water column at Station ALOHA during the period September 1992–September 1994. The vertical dashed line indicates equilibrium (100% saturation) with atmospheric N_2O. With the exception of one measured value on cruise HOT-45, all determinations indicate significant N_2O saturation relative to the atmosphere which implies both a local source and a net ocean–to–air gas flux. From Dore and Karl (1996a).

The formation of N_2O in seawater has at least two fundamentally distinct pathways: nitrification by *Bacteria* and possibly *Archaea*, and bacterial denitrification (Ritchie and Nicholas, 1972; Vincent *et al.*, 1981; Yoshida *et al.*, 1989). In any given habitat, the relative contributions of these two competing oxidative vs. reductive metabolic pathways can vary spatially and temporally. Although relatively inert, N_2O—once formed—can be reduced to N_2 by selected bacteria. Dore and Karl (1996a) used N_2O concentration data and an empirically determined gas transfer model (Wanninkhof, 1992) to estimate the instantaneous sea-to-air flux of N_2O. They estimated a sea-to-air N_2O flux of 1.83–8.11 µmol m^{-2} day^{-1} for five separate HOT cruises between September 1992 and September 1994. Based on a simple 1-D box model and an eddy-diffusivity coefficient of 3.7×10^{-5} m^2 s^{-1} (Lewis *et al.*, 1986), they calculated that the upward vertical flux of N_2O into the euphotic zone was two to three orders of magnitude lower than would be required to sustain the estimated sea-to-air flux, and concluded that there must be a local, near-surface ocean source of N_2O in the North Pacific trades biome. They hypothesized that NH_4^+ oxidation (the first step in nitrification) was the most likely source and used published laboratory results of the maximum molar yield of N_2O during bacterial nitrification (N_2O production = 0.5% of total NH_4^+ oxidation rate; Goreau *et al.*, 1980; Lipschultz *et al.*, 1981) to conservatively constrain rates of *in situ* nitrification. Their model results yielded NH_4^+ oxidation rates of 0.34–1.59 mmol m^{-2} day^{-1} for the euphotic zone (0–175 m) at Station ALOHA, a range of values that was consistent with measured rates of nitrification based on changes in NO_3^-/NO_2^- during dark incubations (Dore and Karl, 1996a) and with those derived from ^{15}N tracer measurements (Olson, 1981a), all in the lower reaches of the euphotic zone (100–175 m).

In a subsequent study, Dore *et al.* (1998) confirmed the large N_2O source at Station ALOHA using direct measurements of the δ^{15}N and δ^{18}O of water column dissolved N_2O. Combining a 1-D eddy diffusive model with both N_2O concentration and dual isotopic gradient measurements they derived a revised net N_2O sea-to-air flux of 0.4 ± 0.2 µmol m^{-2} day^{-1}, approximately an order of magnitude lower than estimated in the earlier study. The ^{15}N and ^{18}O-depleted isotopic signatures of N_2O at the base of the euphotic zone suggested nitrification as the most probable source of N_2O in the surface ocean, a finding that gained additional support from later measurements of the δ^{18}O of H_2O and dissolved O_2 (Ostrom *et al.*, 2000), the δ^{15}N of NO_3^- (Sutka *et al.*, 2004), and the N-isotopomeric composition of dissolved N_2O (Popp *et al.*, 2002). Popp *et al.* (2002) also used the isotopomer mass balance to constrain the sea-to-air N_2O flux at 0.4–1.0 µmol m^{-2} day^{-1}, a value which agreed well with their gas transfer estimate based on wind speed and surface N_2O saturation state (1.1 ± 0.7 µmol m^{-2} day^{-1}). The differences between the various estimates of sea-air N_2O flux at Station ALOHA may be at least partially explained by differences in the eddy-diffusivity coefficients employed and the considerable temporal variability in the surface ocean N_2O saturation (Fig. 16.10B).

Near-surface ocean nitrification at rates that are likely to exceed the upward eddy-diffusion of NO_3^- from beneath the euphotic zone (e.g., Martin and Pondaven, 2006) has important implications for both the conceptual model of new vs. regenerated production (Dugdale and Goering, 1967) and for the

quantitative relationships between f-ratio (the fraction of total N assimilation that is supported by new N, usually measured as NO_3^-) and system export (see Fig. 16.5). Furthermore, because N_2O production scales on gross rates of NH_4^+ oxidation (rather than on net rates) any environmental variable that leads to an enhancement in the cycling rates of NH_4^+ would be expected to have a corresponding impact on N_2O production and hence on N_2O flux to the atmosphere. For example, N_2 fixation (which produces NH_4^+), Fe/P deposition, or even subtle shifts in microbial community structure or grazing rates could all impact NH_4^+/N_2O inventories.

3.2. Structure and dynamics of the primary and secondary nitrite maximum layers

Nitrite-N (NO_2^-) has an intermediate redox position between that of NH_4^+ and NO_3^-, thus NO_2^- often accumulates in selected depth strata when active N transformations are occurring (Rakestraw, 1936; Vaccaro and Ryther, 1960). In the global ocean, two such zones have been identified and studied (Fig. 16.11): (1) the primary NO_2^- maximum (PNM) zone that is usually located near the base of the euphotic zone worldwide and (2) the secondary NO_2^- maximum (SNM) zone that is most prominent in oxygen depleted waters (Codispoti and Richards, 1976; Fiadeiro and Strickland, 1968).

The formation and maintenance of the PNM appears to be complex, perhaps involving at least three independent and, in part, competing processes that include: (1) chemolithoautotrophic oxidation of NH_4^+ (Brandhorst, 1959; Olson, 1981b), (2) partial (incomplete) assimilatory NO_3^- reduction by phytoplankton (Kiefer *et al.*, 1976; Vaccaro and Ryther, 1960), and (3) partial dissimilatory NO_3^- reduction by chemoorganoheterotrophs (Wada and Hattori, 1972) growing in oxygen-depleted microenvironments or in the guts of mesozooplankton or fishes. This important aspect of the marine N-cycle has recently been reviewed by Lomas and Lipschultz (2006).

The production of significant amounts of extracellular NO_2^- by marine phytoplankton during NO_3^- assimilation was first demonstrated in unialgal cultures by Vaccaro and Ryther (1960). They also found that the highest NO_2^- concentrations appeared in cultures recovering from N deficiency and grown under reduced light. They suggested that in the open ocean near the base of the photic zone, where NO_3^- becomes plentiful but phytoplankton are light-limited, partial assimilatory reduction of NO_3^- to NO_2^- leads to the formation and maintenance of the PNM. Subsequent laboratory studies by Carlucci *et al.* (1970) supported their results, and this hypothesis was re-examined in a field study conducted by Kiefer *et al.* (1976). The latter study employed a simple box model using measured profiles of NO_2^-, NO_3^- and phytoplankton carbon, along with a literature-derived eddy diffusivity constant, to show that rates of NO_2^- production are consistent with the Vaccaro and Ryther phytoplankton assimilatory reduction hypothesis. Kiefer *et al.* (1976) concluded that the PNM "exists at a given depth because the cells above the maximum are depleted of nitrate, while the cells below the maximum receive insufficient radiant energy to maintain intracellular rates of NO_3^- reduction." When light levels are low, the rate of NO_3^- reduction to NO_2^- exceeds the rate of NO_2^- reduction to NH_4^+, the final precursor for N incorporation into cellular
Figure 16.11 Vertical distributions of Chlorophyll *a*, $[NO_2^- + NO_3^-]$, and $[NO_2^-]$ for the water column at Station ALOHA in October 1992. The conspicuous NO_2^- maximum beginning at approximately 100 m is positioned below the deep Chlorophyll *a* maximum layer (DCML) and is coincident with the top of the nitracline. This primary nitrite maximum (PNM) is further divided into upper and lower regions (UPNM and LPNM, respectively) with a tailing of the LPNM. These major features are the result of competing microbiological NO_2^- production and utilization processes as shown in Fig. 16.2. From Dore and Karl (1996b).

materials. An intracellular pooling of NO_2^- occurs, and as a result of the slightly acidic intracellular milieu of phytoplankton, NO_2^- is protonated to HNO_2, a weak acid, which freely diffuses out of the cells as an uncharged molecule, nitrous acid. In seawater (pH ≈ 8.0), the HNO_2 dissociates to produce free NO_2^- and this process produces and sustains the PNM at a selected isolume (Kiefer *et al.*, 1976).

Indirect evidence further supporting the phytoplankton partial assimilatory reduction model was presented by Herbland and Voituriez (1979). They performed a statistical analysis of 123 measurements of the depths of the PNM and the top of the nitracline, and found a strong correlation. They also found a significant offset of

about 11 m between these two features, the PNM falling below the top of the nitracline. Moreover, in an earlier study conducted in tropical waters, they showed that NO_2^- is never detectable when NO_3^- is not present (Herbland and Voituriez, 1977). Thus, they concluded that the PNM "stands where the chlorophyll concentrations decrease in a light-limited regime and where NO_3^- is abundant" (Herbland and Voituriez, 1979).

The condition of low light level for phytoplankton NO_2^- production suggested by Vaccaro and Ryther (1960) is apparently not absolutely necessary. Field work by Wada and Hattori (1971) and laboratory-based culture studies by Olson *et al.* (1980) showed that NO_2^- production by phytoplankton is positively correlated with both NO_3^- concentration and light intensity. Furthermore, in boreal areas rich in surface NO_3^-, an annual accumulation of NO_2^- closely matches the annual depletion of NO_3^- as light levels increase during the spring (e.g., see Dore and Karl, 1992; Olson, 1981a; Verjbinskaya, 1932). It is therefore probable that the phytoplankton contribution to the PNM is not due to low light, but to *sufficient* light and *ample* NO_3^-, enabling phytoplankton cells to maintain a high rate of NO_3^- reduction (Dore, 1995). This view is consistent with the correlation of the depth of the PNM and the nitracline seen by Herbland and Voituriez (1979); indeed, the depth of maximal NO_3^- uptake measured by Eppley and Koeve (1990) for trades biome stations with NO_3^-–depleted surface layers and steep nitraclines was always a few meters below the top of the nitracline.

As mentioned previously, *Prochlorococcus* is the dominant phytoplankton group in the North Pacific trades biome. Recently, the full genome sequences of several representative *Prochlorococcus* ecotypes have been published (Dufresne *et al.*, 2003; Rocap *et al.*, 2003). It is important to point out that none of the three genomes sequenced contain nitrate reductase, the enzyme responsible for the reduction of NO_3^- to NO_2^-, the hypothesized mechanism for the existence of the PNM layer. This is not to say that *Prochlorococcus* does not contribute to the PNM, rather that we have no evidence to date that they can utilize NO_3^-. However, recent results suggest that a yet–to–be–isolated *Prochlorococcus* ecotype may contain nitrate reductase (Casey *et al.*, 2007). Furthermore, the deep living/dark-adapted ecotype of *Prochlorococcus*, as well as other microbes, can utilize NO_2^- as a source of N for biosynthesis so the net effect of phytoplankton/microbe metabolism would be to erode, not to produce or sustain, the PNM.

As an alternative to partial assimilatory NO_3^- reduction by phytoplankton, oxidation of NH_4^+ by *Bacteria* and *Archaea* (the first step in the 2-step process of nitrification) can produce NO_2^- as an intermediate product. Nitrifying bacteria were first isolated from the marine environment by Watson (1965) and are now known to be ubiquitous in the global ocean. Wada and Hattori (1971) used a sensitive chemical assay to measure changes in NO_2^- in incubated samples, to conclude that NH_4^+ was the major source of NO_2^- in the PNM in the central North Pacific Ocean. Miyazaki *et al.* (1973, 1975), using a ^{15}N tracer method, found that, in Sagami Bay and in the western North Pacific, NH_4^+ and NO_3^- were both important sources of NO_2^-.

In a benchmark study, Olson (1981a) used improved ^{15}N tracer methods to measure the production of NO_2^-, independently from NO_3^- and NH_4^+, as well as the simultaneous uptake of NO_3^- and NH_4^+ in a variety of marine habitats. He found

that in the North Pacific trades biome, NH_4^+ was the major source of NO_2^- for the PNM. In addition, he observed that a large fraction of the NH_4^+-oxidizing activity passed through a 0.6 μm filter but was retained on a 0.2 μm filter, suggesting that bacteria were responsible. The rate of NO_2^- production from NH_4^+ for experiments conducted in the North Pacific trades biome was reported to be 2.24–7.30 μmol m^{-3} d^{-1}, yielding a NO_2^- turnover time of 25 ± 10 days in the PNM zone.

In a companion paper, Olson (1981b) proposed a mechanism by which nitrifying bacteria might form and maintain the PNM, involving the differential photoinhibition of the two steps of nitrification, namely NH_4^+ oxidation and NO_2^- oxidation. Based on the observation that NH_4^+ oxidation occurred both within and below the PNM, but that NO_2^- oxidation occurred only below, he concluded that NO_2^- was accumulating because, at the light levels associated with the PNM, NO_2^- oxidation was inhibited while NH_4^+ oxidation was not (Olson, 1981b). In studies of coastal seawater samples, Olson found that NO_2^- oxidation was indeed inhibited by light of an intensity less than that required to inhibit NH_4^+ oxidation, and that the critical intensity was about 1% of surface irradiance, about the light level found at the PNM. The physiological mechanism for this differential inhibition by light on the two independent steps of nitrification is not clear, but may be related to differences in the sensitivity of ammonium oxidizers and nitrite oxidizers to photochemically produced carbon monoxide or to oxidation of intracellular components such as cytochrome C$_{554}$ (Vanzella *et al.*, 1990). Alternatively, differential recovery from photoinhibition, rather than differential photoinhibition, has been proposed as a mechanism for accumulating NO_2^- in the PNM (Guerrero and Jones, 1996).

Dore and Karl (1996b) presented a comprehensive data set on NO_2^- vertical distributions and temporal dynamics at Station ALOHA for the observation period September 1989 to November 1993. Their results revealed a novel double-peaked structure to the PNM, and they separated the previously reported single PNM into an upper and a lower zone (UPNM and LPNM, respectively). Comparisons between monthly cruises showed substantial variability in the vertical structures and NO_2^- concentrations in the UPNM and LPNM features (Figs. 16.12A and 16.12B). The authors suggested that the UPNM was a result of partial assimilatory NO_3^- reduction by phytoplankton (i.e., the Vaccaro and Richards model) while the LPNM was a result of differential nitrification (i.e., the Olson model). Dore (1995) developed a refined steady-state model that combined the processes of phytoplankton reduction of NO_3^- to NO_2^-, as well as bacterial oxidations of NH_4^+ to NO_2^- and NO_2^- to NO_3^-. This "hybrid" model made several simplifying assumptions. For example, it neglected mixing and diffusion, fixed the microbial community composition, assumed that NH_4^+ and NO_2^- oxidizing bacteria were uniform in the upper 200 m of the water column, and used an assumed NH_4^+ profile. Nevertheless the Dore (1995) model was able to simulate the general features of the PNM observed at Station ALOHA, including the large upper PNM (a result of phytoplankton reduction of NO_3^-), the vertical separation of oxidative and reductive processes, and the vertical asymmetry of NO_2^- within the broad PNM in this region (Dore, 1995). The lower portion of the PNM was not always as well reproduced, and sensitivity analysis showed that $[NH_4^+]$ had a large effect on the LPNM, but not on the UPNM, due to the dependence of NH_4^+ oxidation on substrate concentration.

Figure 16.12 Temporal and spatial (depth) variations in the primary nitrite maximum layer at Station ALOHA. (A) Shown are five representative profiles of NO_2^- between 80 and 200 m from February 1990 to September 1992 displaying the two-peaked structure (U = UPNM and L = LPNM) of the general feature. Note concentration variations and changes in reference depths of the key features. A = February 1990, B = July 1990, C = December 1990, D = October 1991, E = September 1992. From Dore and Karl (1996b). (B) Temporal variations in the positions of the UPNM and LPNM relative to the nitracline. Shown also are the mean depths for these features over the observation period. From Dore and Karl (1996b).

Zafiriou *et al.* (1992) reported trace amounts of NO_2^- (0.4–1 nM) in the ''tail'' of the PNM layer in the NW Atlantic Ocean to a depth of at least 1000 m. The NO_2^- inventory in this region was roughly equivalent to that in the PNM feature itself. This mid-water NO_2^- pool was dynamic with an estimated turnover time of a few days. At Station ALOHA, Dore and Karl (1996b) likewise detected an
Figure 16.13 Mesopelagic zone profiles of nitrate from Station ALOHA during 7 cruises from February 1991 to May 1993. From Dore and Karl (1996b).

exponential decay of NO_2^- over the depth range of 200–1000 m with concentrations decreasing from >5 nM at 200 m to <1 nM at 1000 m (Fig. 16.13). The Station ALOHA data set, which included 7 separate profiles over a 2-year period, also displayed temporal variability suggesting that the mesopelagic zone NO_2^- pools are dynamic even at great depths. While the mechanism(s) is not known, fluctuations in $[NO_2^-]$ are undoubtedly biological in origin, most likely a result of coupled particle export–remineralization and nitrification processes.

3.3. New production by nitrogen fixation

Biological N_2 fixation was discovered in the early 20th century in a soil bacterium (Beijerinck, 1908). In his now classic monograph on "Oceanography: Its scope, problems and economic importance," Bigelow (1931) stated that "the possibility that so-called N_2 fixers may also fertilize seawater must be taken into account"; however, systematic investigation did not begin for at least another three decades. In the past decade, there has been an enormous effort to obtain accurate estimates of the rates of N_2 fixation and the controlling mechanisms of this vital ecosystem process (Capone, 2001; Gruber, 2005; Karl *et al.*, 2002; Mahaffey *et al.*, 2005;

Michaels *et al.*, 2001) (see Carpenter & Capone, Chapter 4, this volume). In part because of its sensitivity to climate variability and its potential role in the marine sequestration of carbon.

According to Marumo and Asaoka (1974), the North Pacific trades biome supports the growth of at least five different N_2 fixing cyanobacteria: *Trichodesmium thiebautii*, *Trichodesmium erythraeum*, *Oscillatoria* sp., *Katagnymene spiralis* and *Richelia intracellularis*. Based on observations made during an August–October 1969 expedition from 50°N to 15°S along the 155°W meridian, they reported that *T. thiebautii* and *Rhizosolenia styliformis* had the largest geographical range from 15°S to 40°N; none of the species were found north of 40°N. *T. thiebautii* was the only N_2-fixing cyanobacterium found south of 10°N.

Several pioneering field studies including Mague *et al.* (1974 and 1977) and Gundersen *et al.* (1976) established N_2 fixation as an important metabolic pathway in the marine N–cycle of the North Pacific trades biome. Selected results included: (1) N_2 fixation was widespread in the oligotrophic portions of the North Pacific, both in free-living non-heterocystous *Trichodesmium* assemblages and in diatom-*Richelia intracellularis* symbiotic associations, (2) there were intermittent spatial and temporal distributions of N_2 fixing organisms, with greater average abundance and activity in summer, (3) strong vertical zonation of N_2 fixation with greatest rates in the upper 40 m of the water column, but detectable activity to at least the 1% light level (~100 m), (4) significant O_2 inhibition of N_2 fixation with a pO_2 of 0.4 atm causing an approximately 75% inhibition of activity, (5) when present, *Trichodesmium* could meet 100% of its N requirement via N_2 fixation, and (6) during stratified summer conditions, approximately 3% of the total N assimilated (as determined by the combined uptake of ^{15}N-labeled NH_4^+, NO_3^-, urea and N_2) was supplied via N_2 fixation.

The establishment of HOT, in October 1988, marked the next and current phase of N_2 fixation research in the North Pacific trades biome. The extant HOT program N_2 fixation database now includes biological, biogeochemical and genomic information in addition to direct measurements of rates of N_2 fixation and environmental controls thereof. The HOT program interest in the process of N_2 fixation began during the HOT-9 cruise in August 1989 when a large (approximately 10^3 km^2) *Trichodesmium* "bloom" was encountered near Station ALOHA (Karl *et al.*, 1992). The HOT data set on the role of N_2 fixation was reported at an international symposium on the biology and ecology of diazotrophic microorganisms in the sea, the first special focus event of its kind (Carpenter *et al.*, 1992). Analysis of the near-surface water particulate matter showed concentration enrichments of 3375- to 7787-fold for C, N, ATP and chlorophyll *a* compared to non-bloom HOT climatologies; P was enriched only 583-fold, leading to unusually high C:P and N:P ratios (particulate matter C:N:P = 891:125:1 for bloom compared to 142:20:1 for non-bloom conditions; Karl *et al.*, 1992). In addition, dissolved N pools (NH_4^+, [$NO_2^- + NO_3^-$], DON) were all enriched within the bloom, in the case of NH_4^+, by 27-fold, whereas dissolved phosphate and silicic acid were not enriched. Although no rate measurements of N_2 fixation were made during this serendipitous encounter, these dissolved and particulate matter indices were all consistent with high rates of new N input. Based on measured ^{14}C assimilation and measured particulate C:N molar ratio of 7.1 in the bloom, and assuming a 2-m thick

near-surface layer of *Trichodesmium* that was active at this site for only 1 day per year, the authors concluded that N_2 fixation could supply 80–100 mmol N m^{-2} year^{-1}, compared to the primary production total N assimilation of approximately 2326 mmol N m^{-2} year^{-1} (Karl *et al.*, 1992). If these assumptions are reasonable, then N_2 fixation at Station ALOHA would equate to 3–4% of the total N demand for the microorganisms that inhabit that ecosystem, similar to all previous studies. However, when compared to estimates of new production (140–256 mmol N m^{-2} year^{-1}) or to N exports by sinking particles and migrant zooplankton (159–203 mmol N m^{-2} year^{-1}), N_2 fixation appears to be a significant (40–60%) source of new N.

A key to the renewed interest in N_2 fixation was a better appreciation for the quantitative role of export production and a shift in research focus from gross to net and export pelagic production. While it had been known for at least two decades that N_2 fixation could supply ~2–5% of the daily N quota of the microbial assemblage, it was only more recently realized that this was a *large* percentage of the total new N for systems like the North Pacific trades biome which export from the euphotic zone <10% of their daily organic matter production, rather than being a *negligible* source. Not since the discovery of marine N_2 fixation in 1961 (Dugdale *et al.*, 1961) had there been so much interest in this key ecosystem process, and it quickly emerged as one of the primary research foci of the HOT program.

The initial HOT investigations of marine N_2 fixation had a deliberate focus on the large filamentous, colony-forming *Trichodesmium*. This was, in part, because it forms spectacular near-surface accumulations (sometimes called "blooms") in warm subtropical and tropical seawaters worldwide, especially during periods of extreme calm (Capone *et al.*, 1997). The encounter with the 1989 *Trichodesmium* bloom near Station ALOHA led to three basic questions that, to date, remain only partially resolved (Letelier, 1994): (1) What are the mechanisms that lead to aperiodic, enhanced *Trichodesmium* biomass near the sea surface (*in situ* growth vs. physical aggregation/accumulation)?, (2) What are the fates of that *Trichodesmium* biomass?, and (3) What roles does *Trichodesmium* play in upper water column biogeochemistry and ecology? A unique aspect of this research prospectus was that it was embedded in the systematic time-series study with comprehensive ancillary data sets to place observations of *Trichodesmium* into a broader ecological context. If *Trichodesmium*, and perhaps other diazotrophic microorganisms, constitute a significant source of new N for the North Pacific trades biome, this would lead to changes in the dynamics of the N and P cycles unless there was an alternate source of P to sustain the balanced growth of the plankton assemblage. Therefore, detailed ecosystem study of the N-cycle, N_2 fixation specifically, is incomplete unless comprehensive analysis of the P-cycle is also achieved. For this reason, N_2 fixation studies at Station ALOHA were designed within a more comprehensive framework of C, P and associated bioelemental cycles. Two conceptual models were initially devised to account for the spatial N and P decoupling: (1) the upward P-flux model and (2) *Trichodesmium* P-transport model (Karl *et al.*, 1992). Alternatively, changes in the N and P cell quotas, specifically a reduction in P under P-limited growth, could decouple N and P cycles.

In the upward P-flux model, P derived from the upward transport of low density, low N:P content organic matter (e.g., lipid–P enriched organic matter; Yayanos and

Nevenzel, 1978) is taken up and assimilated by *Trichodesmium* at or near the ocean's surface. In the *Trichodesmium* P-transport model, unique physiological attributes, including the ability to store "ballast" carbohydrate, under conditions of P-limited/light-saturated metabolism near the surface, and polyphosphate under conditions of carbohydrate-based/P-saturated metabolism near or below the base of the euphotic zone, combined with their ability to alter buoyancy by gas vacuole formation, provides the mechanism for the vertical transport of *Trichodesmium* colonies based on P status (Karl *et al.*, 1992). Both models, as well as the atmospheric deposition of low N:P particles (Karl and Tien, 1997) or meridional advection of labile DOP without similar flux of labile DON (Abell *et al.*, 2000), would lead to an eventual decoupling of N and P dynamics and selection for N_2 fixing microorganisms. The observation of high frequency variations in the soluble reactive P pools in the surface waters near Station ALOHA (Karl and Tien, 1997) is consistent with the existence of one or more of these (or some other) dynamic processes at this site.

Letelier and Karl (1998) field tested the *Trichodesmium* P-transport model, or "P-shuttle hypothesis" by collecting and analyzing "rising" and "sinking" colonies at a reference depth of 100 m. The lowest N:P ratio was found in rising *Trichodesmium* colonies, which is consistent with the prediction of the *Trichodesmium* P-shuttle hypothesis. Sinking colonies were also shown to actively assimilate phosphate equivalent to 35–57% of their total cellular P content in the dark during the first 12–24 h of post-collection incubation; this result is also consistent with the hypothesis (Letelier and Karl, 1998). A subsequent analysis of the *Trichodesmium* shuttle hypothesis suggested that while limited vertical excursions in the upper 70 m of the water column are possible, deeper migrations appear unlikely unless respiration rates decrease significantly (Villareal and Carpenter, 2003). However, significant differences in the N:P ratios of sinking (N:P = 87:1) vs. ascending (N:P = 43.5:1) colonies at their study site in the western Gulf of Mexico were consistent with the P-shuttle model predictions. More recently, White *et al.* (2006a) have conducted laboratory experiments to examine the ability of *Trichodesmium* spp. to alter its C–N–P stoichiometry in response to variable P in the growth medium, and have incorporated these results into a numerical model (White *et al.*, 2006b). Their results indicate that *Trichodesmium* is capable of P-sparing under P-depleted conditions. The bulk C–N–P elemental composition of the cells was $C_{585\pm56}$: $N_{90\pm10}$:P_1, approximately six times more C and N, relative to P, than the Redfield prediction. When exposed to high external P concentrations, luxury uptake of P was observed and the stoichiometry changed significantly, approaching the Redfield ratio ($C_{96\pm8}$:$N_{16\pm1}$:P_1). They also showed that *Trichodesmium* can survive in dark, P-replete medium for periods of 3–6 days, after which they cannot recover (White *et al.*, 2006a). These data on elemental plasticity and dark survival help to constrain the temporal scale of vertical migration. Based on these and other laboratory and field observations, White *et al.* (2006b) concluded that *Trichodesmium* migrations represent as much as 10% of the P-based export flux at Station ALOHA.

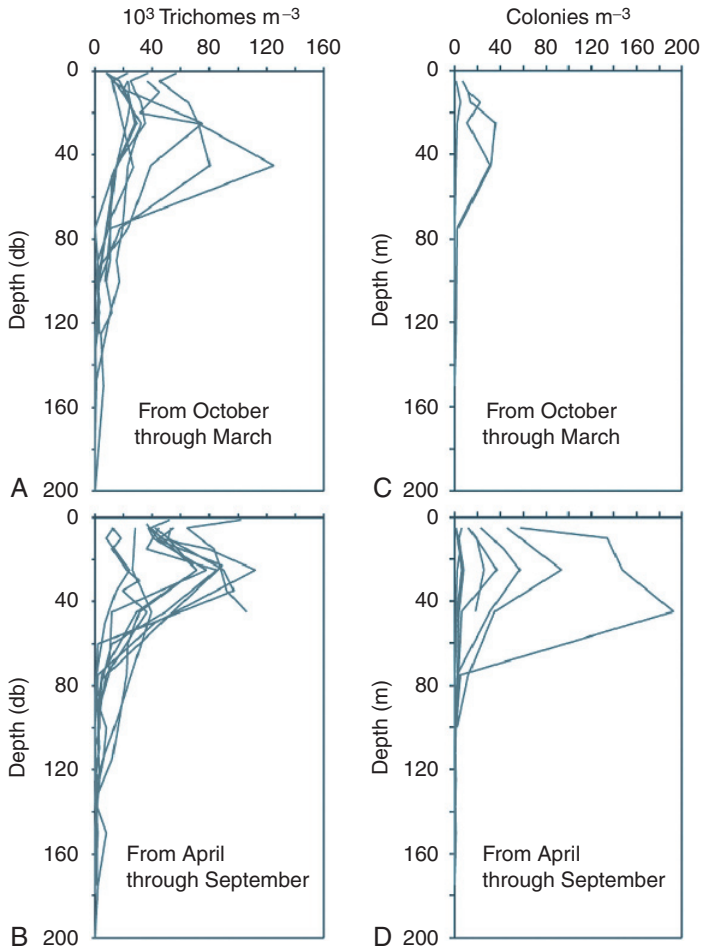
Soon after the HOT time-series began, Letelier and Karl (1996) confirmed that a key N_2 fixing species, *Trichodesmium*, exists *in situ* as both free trichomes (single filaments) and in the more commonly reported colonial trichome morphologies (fusiform or "tuft" and spherical or "puff"), at Station ALOHA. Based on approximately monthly sampling between October 1989 and December 1992, the average


Figure 16.14 *Trichodesmium* spp. vertical distribution of single trichomes (A, C) and colonies (B, D) at Station ALOHA between October 1989 and December 1992. From Letelier and Karl (1996).

abundance of free trichomes in the upper 45 m of the water column was reported to be temporally variable ranging from 1.1 to 7.4×10^4 trichomes m^{-3}, and from 0.02 to 1.4×10^2 colonies m^{-3} (Fig. 16.14). Each colony consisted of an average of 182 filaments, and collectively colonies accounted for approximately 12% of the total biomass of *Trichodesmium* (Letelier and Karl, 1996). While the existence of free trichomes had been reported previously in the North Pacific Ocean (Marumo and Asaoka, 1974; Marumo and Nagasawa, 1976), very little attention had been paid to them because it was thought that only colonial forms of *Trichodesmium* could fix N$_2$ due to the perceived need to sustain local sub-oxic habitats within colonies (Carpenter and Price, 1976, and related papers; but also see Saino and Hattori, 1982 and Letelier and Karl, 1998 for evidence of aerobic N$_2$ fixation in single *Trichodesmium* filaments). Letelier and Karl (1996) also reported a systematic seasonal

variation in *Trichodesmium*, with higher concentrations of both free trichomes and colonies in the spring–summer period (April to September) compared to the fall–winter period (October to March). It was also reported (Letelier and Karl, 1996) that hand–sorted *Trichodesmium* filaments and colonies from the North Pacific trades biome habitat had molar C:N ratios that were indistinguishable from the Redfield ratio of 6.6, but had N:P ratios that were 250–300% higher, approaching 50:1 (compared to the Redfield N:P stoichiometry of 16:1). This P–sparing is predicted for diazotrophs growing under conditions of P limitation. Measurements of *Trichodesmium* production made during March 1990 and August 1991, based on uptake of $^{14}C\text{-}HCO_3^-$ and measured C:N stoichiometry, indicated that it may account for approximately 30% of total ecosystem new production (Letelier and Karl, 1996). The authors cautioned that this estimate should be viewed as a lower bound because these experiments were conducted under non–bloom conditions and also did not consider the potential extracellular release of NH_4^+/DON which has been observed for *Trichodesmium* during active N_2 fixation (Capone *et al.*, 1994; Glibert and Bronk, 1994; Mulholland *et al.*, 2004). This comprehensive time–series study of *Trichodesmium* (Letelier and Karl, 1996), the first of its kind in the North Pacific trades biome, lent support to the N_2 fixation–based, new production hypothesis.

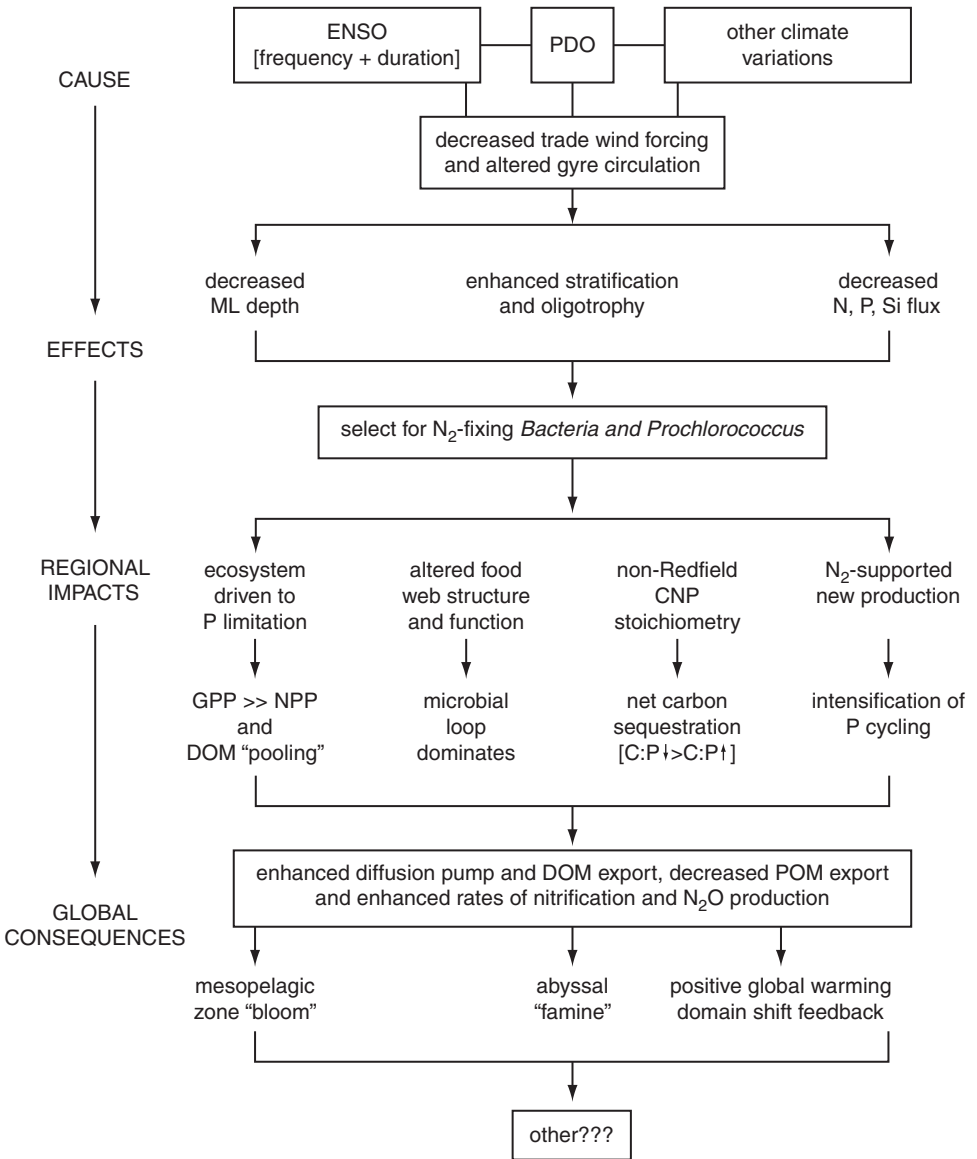
The Station ALOHA investigation led eventually to a more general N-P alternation hypothesis for control of plankton rate processes, with attribution of enhanced rates of N_2 fixation to El Niño induced climate variability (Karl, 1999; Karl *et al.*, 1995; Karl *et al.*, 1997). The conceptual model (Fig. 16.15) suggested that decreased upper ocean mixing and changes in the intensity of water circulation led to enhanced nutrient limitation, increased abundance and activity of N_2-fixing microorganisms and a shift from a primarily N–limited to a primarily P–limited habitat with attendant changes in total, new and export production and nutrient cycling pathways and rates. A number of associated physical, biological and biogeochemical habitat properties and processes displayed significant change during the 1991–1992 El Niño period, and these were all consistent with enhanced N_2 fixation activity despite the lack of any direct rate measurements. A synthesis of seven years of continuous monthly measurements based on several independent data sets including (1) *Trichodesmium* abundances and estimates of their potential rates of N_2 fixation, (2) assessments of the molar N:P stoichiometries of surface ocean dissolved and particulate matter pools and a development of a 1-D model to calculate N and P mass balances, (3) seasonal variations in the natural ^{15}N isotopic abundances of particulate matter exported to the deep sea and collected in bottom–moored sediment traps, and (4) observations on the secular changes in dissolved phosphate, DOP and DON pools during the period of enhanced N_2 fixation, all strengthened the hypothesis that N_2 fixation is a significant source of new N in the North Pacific trades biome (Dore *et al.*, 2002; Karl *et al.*, 1997). From these analyses the authors concluded that N_2 fixation may contribute up to half of the N required to sustain total annual export production at Station ALOHA, a previously neglected source of new N. They further speculated that enhanced input of new N by this mechanism might result from relaxation of upper ocean mixing, the direct opposite of that derived from existing conceptual models of oceanic ecosystems (Karl *et al.*, 1997), which has profound implications for the potential impact of natural or


Figure 16.15 Hypothetical view of the effects of climate variability on ecosystem structure and function in the NPSG based, in part, on results obtained during the decade-long HOT research program. Changes in the stratification of the surface ocean have affected nutrient and trace element budgets and have selected for N_2-fixing bacteria and *Prochlorococcus* resulting in a domain shift from predominantly *Eukarya* to predominantly *Bacteria*. Numerous biological consequences have been observed and others are expected. From Karl (1999).

human-induced environmental change. Finally, the sources of P and Fe needed to sustain the continued production of new N supported by N_2 fixation were acknowledged as key unresolved issues (Karl, 2002).

As interest in the role of N_2 fixation was growing in the HOT program, it also emerged as a potentially important ecosystem process at the Bermuda Atlantic Time-series Study (BATS) site in the oligotrophic North Atlantic Ocean (Sargasso Sea) near the location where Dugdale *et al.* (1961) had first reported active marine N_2 fixation. The evidence was based on the observation of anomalously high nitrate:phosphate ratios in the mesopelagic zone, with a relative excess of N termed $N\star$ ($N\star$ = excess nitrate = $[NO_3^-] - 16 \times [PO_4^{-3}]$; Michaels *et al.*, 1996), and with an observed dissolved inorganic C drawdown in the summer in the apparent absence of nitrate (Bates *et al.*, 1996; Michaels *et al.*, 1994). Local N_2 fixation could explain both "mysteries" (Karl *et al.*, 2003; Michaels *et al.*, 2000), so it appeared that N_2 fixation might have been systematically underappreciated in both ocean basins. Because the HOT and BATS programs were part of the Joint Global Ocean Flux Study (JGOFS) program, there was community interest in N_2 fixation rates and controls, and various ecosystem models soon emerged to account for N_2 fixation as a potentially important source of new N for the oligotrophic regions of the global ocean (e.g., Hood *et al.*, 2001 for *Trichodesmium* at the BATS site in the North Atlantic Ocean, Fennel *et al.*, 2002 for *Trichodesmium* at Station ALOHA in the North Pacific trades biome, and Goebel *et al.*, 2007 for three types of diazotrophs also at Station ALOHA). The Fennel *et al.* (2002) model employed a mechanistic parameterization of N_2 fixation based on known or hypothesized physiological responses of *Trichodesmium* to physical conditions of the environment. The model also allowed for variable N:P stoichiometry and shifts from N- to P-control of plankton communities. The biological model was coupled to a modified Price *et al.* (1986) 1-D physical model of the upper ocean that simulated vertical profiles of temperature, salinity, evolution of the mixed layer in response to wind stress and surface heat fluxes, and mixing. The Station ALOHA simulation captured many of the key features of the environment including the vertical structure of and seasonal changes in chlorophyll a, a seasonal cycle and interannual variations in *Trichodesmium* biomass and particulate matter export, and the hypothesized N_2 fixation-driven alternation between N- and P-limitation (Fennel *et al.*, 2002).

Several research teams were also investigating basin-scale and even global-scale consequences of N_2 fixation. Gruber and Sarmiento (1997) used variations in the N:P stoichiometry of the dissolved nutrient pools (with a modified $N\star$ parameter) to estimate rates of N_2 fixation in the tropical and subtropical North Atlantic Ocean and Mediterranean Sea. They derived an estimate of 28 Tg N_2 fixed year^{-1} for these regions and suggested the global ocean rate might be as high as 110 Tg N year^{-1} (Gruber and Sarmiento, 1997). Deutsch *et al.* (2001) applied a similar $N\star$ model to the Pacific Ocean. Based on their primary assumption of N steady-state (N_2 fixation equals denitrification on the basin scale) they concluded that N_2 fixation north of $32°S$ is 59 ± 14 Tg N year^{-1}, with intensification in the western boundaries of the gyres near regional sources of Fe from atmospheric dust deposition (Deutsch *et al.*, 2001). Finally, Lee *et al.* (2002) investigated and mapped regions of the global ocean where DIC concentrations appear to be drawn down in the absence of measurable nitrate. They hypothesized, as Michaels *et al.* (1996) and others had before them, that

N_2 fixation is the mechanism for organic matter production (DIC removal) in these oligotrophic regions. Based on their analysis, the Pacific Ocean ($40°S-40°N$) had the greatest N_2 fixation-supported carbon production (0.5 Pg C $year^{-1}$), equivalent to approximately 63% of the global ocean estimate. The regional distribution within the Pacific basin again showed enhanced rates near known sources of Fe, primarily from dust deposition, re-emphasizing the probable role of Fe as a control on N_2 fixation in the global ocean.

No sooner were the new *Trichodesmium*-centric models up and running when a major discovery was reported, namely the existence of a diverse assemblage of N_2 fixing microorganisms in the North Pacific trades biome, including unicellular cyanobacteria (Zehr *et al.*, 1998, 2000, 2001). Prior to these reports, *Trichodesmium* and, to a lesser extent, the endosymbiotic associations of the N_2 fixing cyanobacterium *Richelia* with several different diatom species, had become the primary foci of marine N_2 fixation research (Capone *et al.*, 1997; Carpenter *et al.*, 1992). Nitrogenase activity by phototrophic unicells in the N-starved North Pacific trades biome might have been predicted from an evolutionary-ecological perspective, but this process was not seriously considered because it was generally thought that high O_2 concentrations would preclude diazotrophic growth of unicells in this habitat. An indication of the ecological potential of unicellular diazotrophs came when RNA was extracted to determine which organisms were expressing the *nifH* gene under *in situ* conditions. Nitrogenase gene transcripts (messenger RNA) attributable to organisms other than *Trichodesmium* and *Richelia* were detected in all samples that were analyzed from the upper portion of the euphotic zone near Station ALOHA (Zehr *et al.*, 2001); little or no *nifH* transcription was observed at depths of 150 m, and greater. This pattern of transcription could be a result of energy (light) limitation or the presence of a sufficient supply of fixed N at depth, or both. Nitrogenase gene fragments from microorganisms in the pico/nano (0.2–10 μm) size class were amplified, cloned and sequenced to establish their phylogenetic relationships to each other and to other known N_2 fixing microorganisms (Fig. 16.17). Results indicated the presence of two different cyanobacteria (termed Group A and Group B) whose *nifH* sequences were most similar to *Crocosphaera* a unicellular cyanobacterium that has been isolated from marine environments but not previously considered to be important in the sea or to the marine N-cycle in general. The ability of these unicells to fix N_2 under *in situ* conditions was suggested by experimental determination of $^{15}N_2$ assimilation into the 0.2–10 μm size fraction (Zehr *et al.*, 2001). N_2 fixation from a sample collected at Station ALOHA (25 m) in July 2000 was 10–16 pmol N L^{-1} h^{-1}, suggesting that the role of small (unicells) N_2 fixers may have been systematically underestimated and underappreciated, if not totally ignored. With the publication of these new field data from Zehr and colleagues, excitement in N_2 fixation research at Station ALOHA was at an all time high; a redirection of the research agenda, to include the possibility of N_2 fixation by the novel unicellular cyanobacterial populations, was now mandatory.

Dore *et al.* (2002) were the first to report euphotic zone depth-integrated measurements of the relative contributions of "small" (<10 μm) and "large" diazotrophs to total N_2 fixation in the North Pacific trades biome. Based on $^{15}N_2$ assimilation rate measurements from HOT cruises conducted in November 2000

and June 2001, they reported a significant contribution by <10 μm cells, ranging from 46 to 50% of the total integrated rate over the upper 0–100 m of the water column and up to 100% of the total rate for individual samples (Dore *et al.*, 2002). Because the whole water was collected using standard CTD-rosette bottle methods, it is likely that the sampling protocol selected against the very large *Trichodesmium* colonies and *Rhizosolenia* aggregates, if present, while quantitatively sampling the unicellular cyanobacteria, diazotrophic proteobacteria and free *Trichodesmium* trichomes, so in some ways this sampling/experimental design may have been biased towards detection and relative importance of the small diazotrophs. Furthermore, a full quantitative assessment could not be achieved without proper accounting of the N_2 fixation that occurs during the sometimes massive, but stochastic blooms of the larger diazotrophic assemblages which are undersampled even with the approximately monthly HOT program sampling frequency. It came as no surprise then, that the measured rates of N_2 fixation were considerably less than those estimated using a model based on the measured sediment trap derived PN export flux and its stable N isotopic composition, a value which they estimate to be 40 mmol N m^{-2} $year^{-1}$ (Dore *et al.*, 2002). Results from the latter data sets indicated that N_2 fixation accounted for 48% of the new N over the 11-year period (1990–2000) with considerable interannual variation (minimum 36% in 1992, maximum 69% in 1999; also see Fig. 16.16). They concluded that, although discrete $^{15}N_2$ bottle incubations are valuable for elucidating patterns and size distribution of N_2 fixation with time and, perhaps, for evaluating nutrient controls of *in situ* N_2 fixation, they are inadequate for assessing time- and space-integrated rates of N_2 fixation in the biome as a whole. Nevertheless, the results of Dore *et al.* (2002), and several subsequent studies (Grabowski *et al.*, 2008; Zehr *et al.*, 2007; Montoya *et al.*, 2004), documented an active population of <10 μm N_2 fixing microorganisms that had not previously been considered in North Pacific trades biome N budgets (see Table 16.5).

Church *et al.* (2005a) used the emerging information about *nifH* diversity and the probable role of unicellular cyanobacteria to design specific oligonucleotide primers and probes that facilitated an enumeration of the various diazotrophs using quantitative polymerase chain reaction (QPCR) of *nifH* phylotypes at Station ALOHA. Initial targets for this analysis included *Trichodesmium*, the unicellular cyanobacterial Groups A (closely related to *Cyanothece*) and B (closely related to *Crocosphaera/Synechocystis*; Fig. 16.17), and a novel "Cluster III" bacterial group that was phylogenetically similar to strict anaerobes. Analysis of total particulate DNA, and specific size fractions thereof, provided a quantitative estimation of the abundances of the various diazotroph groups, at least in terms of *nifH* genes. As with previous studies of cell enumeration and N_2 fixation rates, the vertical distributions of *nifH* genes were most abundant in the near-surface waters (approximately 2×10^5 *nifH* copies per liter at 25 m), but decreased by several orders of magnitude throughout the euphotic zone (Fig. 16.18A). Unicellular cyanobacteria (sum of Groups A plus B plus Cluster III) *nifH* gene copies exceeded *Trichodesmium* gene copies by 1–2 orders of magnitude. The Cluster III *nifH* phylotype was most dominant in the lower euphotic zone (>100 m). The use of QPCR to enumerate *nifH* gene abundances and to establish diazotroph population structure and dynamics is a novel technique that relies upon several as yet untested assumptions regarding uniform
Figure 16.16 Time series of particulate nitrogen (PN) export and isotopic composition determined from 150-m floating sediment trap collections at Station ALOHA. (Top) PN flux (μmol N $m^{-2} d^{-1}$). Error bars represent $\pm$SE of three to six individual trap measurements. (Bottom) Stable nitrogen isotopic composition ($\delta^{15}N$) of trap-collected material ($^o/_{oo}$ vs. air N_2). Error bars, where shown, represent $\pm$SE of two to three individual trap measurements. Dotted lines represent the isotopic compositions of exported PN expected when supported entirely by nitrate ($6.5^o/_{oo}$) or entirely by dinitrogen gas ($0 ^o/_{oo}$). The solid line indicates a decreasing trend determined by linear regression. The trend break at the end of 2002 remains to be explained. Updated and revised from Dore *et al.* (2002).

DNA extraction and amplification efficiencies, and identification of the number of gene copies per cell among the disparate diazotroph groups. However, these gene-based techniques provide a quantitative approach to the important question of diazotroph diversity. Their initial field results opened a new window of observation for the study of N_2 fixation in the North Pacific trades biome.

In a follow-on study, Church *et al.* (2005b) examined both the presence and expression of specific N_2 fixing microorganisms at Station ALOHA. Temporal patterns of nitrogenase expression were estimated by reverse-transcribed QPCR (RT-QPCR) of the phylotype-specific *nifH* gene transcripts. Their results revealed unexpected and complex, but highly ordered, diel patterns with certain phylotypes exhibiting maximum expression around mid-day and others around midnight (Fig. 16.18B). The concentrations of selected *nifH* cDNA copies (e.g., Heterocyst-1 and Group B cyanobacteria) varied by more than 3–4 orders of magnitude over a 6-h period (Church *et al.*, 2005b). While the authors did not confirm a quantitative

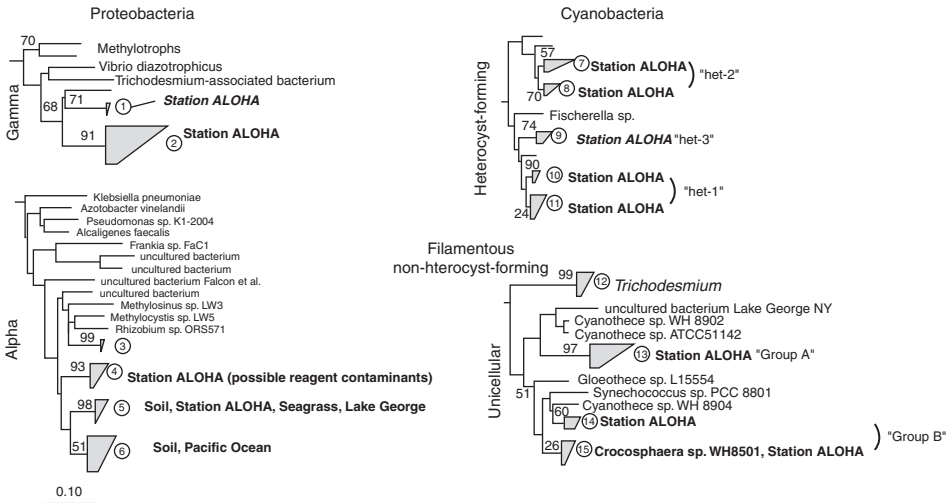

Figure 16.17 Phylogenetic tree showing major *nifH* DNA sequence phylotypes found at Station ALOHA. Cyanobacterial lineages include three heterocyst-forming groups that are associated with diatoms, free-living filamentous nonheterocyst forming *Trichodesmium*, and the two unicellular cyanobacterial groups (Groups A and B). Bootstrap values of 100 replicates are shown at nodes. Scale bars = 0.1 substitutions per site. From Zehr *et al.* (2007).

coupling between *nifH* gene transcription and *in situ* rates of N$_2$ fixation, the former is ultimately required for the latter and, at least for *Trichodesmium*, the diel transcription pattern with highest activity during daylight hours (Church *et al.*, 2005b) is identical to diel N$_2$ fixation patterns that have been reported for *Trichodesmium* cultures (Letelier and Karl, 1998). There are at least two important implications of this work. First, and foremost, different *nifH*-containing phylotypes appear to have different responses to daily fluctuations in irradiance for physiological reasons that are not entirely clear at the present time. These distinct responses may have implications for *in situ* growth and removal processes and, ultimately, for energy flow and food web dynamics. Previous field observations presented conflicting data on the relationships between light and N$_2$ fixation, and on the rates of N$_2$ fixation in the dark. In retrospect, these variable results may have derived, in part, from variations in the *nifH*-containing phylotypes in the microbial assemblages under investigation, or in the design and duration of the incubation experiments. Second is the potential problem of sampling, measurement and scaling. If certain phylotypes alter their *nifH* transcription by 3–4 orders of magnitude over diel time scales, it may be difficult to constrain *in situ* rates of N$_2$ fixation from short-term (1–2 h for C$_2$H$_2$ reduction) assays or to reconcile the results of short- (C$_2$H$_2$) or even longer-term (^{15}N$_2$) incubation studies with geochemical indicators of N$_2$ fixation (e.g., Dore *et al.*, 2002). Accurate scaling from hourly to daily to annual rates of N$_2$ fixation, and from discrete water samples to basin scales clearly has not yet been achieved.
Figure 16.18 Distribution, abundance and temporal dynamics of N$_2$ fixing bacteria at Station ALOHA. (A) Vertical profiles of <10 μm (left) and >10 μm (right) *nifH* phylotypes in December 2002 relative to upper mixed-layer depth (dashed line) and 1% surface radiance isopleth (dotted line). Error bars are ±1 SD of triplicate QPCR (45 cycles) reactions. From Church *et al.* (2005a).

Figure 16.18 cont'd (B) Temporal patterns of *nifH* transcription (*nifH* cDNA copies per liter) by five unique phylotypes at a reference depth of 25 m in December 2002. Error bars are ± 1 SD of mean cDNA concentrations from triplicate QPCR reactions. From Church *et al.* (2005b).

The current paradigm for N_2 fixation in the North Pacific trades biome is one where at least two independent microbial assemblages and ecosystem processes contribute to new production, namely the "background state" wherein a relatively low but relatively constant rate of new N import is supported by the combined activities of pico- and nano-diazotrophs, and the aperiodic "bloom state" wherein large filamentous, colonial and aggregate forming diazotrophs (*Trichodesmium* and/or endosymbiont-containing diatoms) dominate the new N-cycle. Despite the fact that the latter may be more "noteworthy" than the former, and have received a disproportionate

amount of research effort to date (Capone *et al.*, 1997, 1998, 2005), it is not possible to provide an accurate accounting of the relative importance of the two pathways because of inadequate sampling of the blooms in time and in space (White *et al.*, 2007; Dore *et al.*, 2008). Both pathways are important to the N economy of the sea and both are worthy of additional investigation. Because size matters among the planktonic assemblages of the open sea, the short- and perhaps long-term fates of the new N delivered by these two independent pathways are likely to be very different and may require refined models that have an explicit representation of diazotrophy by the two alternate pathways (Fig. 16.19). This remains one of the contemporary challenges in marine N-cycle research.
Figure 16.19 Conceptual view of a revised version of the new vs. regenerated nutrient paradigm for primary production in the trades biome. On the left is the background or normal state (low Fe) where allochthonous inputs of N are dominated by upward diffusive flux of NO_3^- from below with a variable subsidy from N_2 fixation by small, unicellular cyanobacteria. N resource partitioning among the dominant phototrophs is a key to species co-existence, especially for *Synechococcus* and *Prochlorococcus*. The (N) and (R) designations refer to new and regenerated N, respectively. A fundamental difference between this view and the one originally proposed by Dugdale and Goering (1967) is the novel sources of "new" N ($NH_4^+/DON/NO_3^-$) from N_2 fixation and subsequent nitrification. In this revised view, much of the NH_4^+ is "new" N and much of the NO_3^- is "recycled" N which makes a straightforward accounting very difficult. Following a dust deposition event (right) there is a selection for rapidly growing, bloom-forming N_2-fixing cyanobacteria (including the "diatomic diatoms", the large diatoms with endosymbiotic N_2 fixing cyanobacteria) and a transient shift in the source of new N to a N_2 fixation dominated system. Following bloom termination there is a large export event that is a key to net carbon sequestration. From Karl (2002).

3.4. Aperiodic delivery of nutrients and consequences for ecosystem metabolism

Long-term time-series studies are ideally suited for investigations of subtle habitat changes, stochastic events and complex interdependent ecological phenomena that affect oceanic biogeochemical cycles, especially N dynamics. Despite their acknowledged importance, oceanic time-series investigations are rare. In the North Pacific trades biome, four time-series programs have been initiated over the past four decades but only one, HOT, is ongoing (Karl and Lukas, 1996). The Climax series ran for nearly two decades, from approximately 1968 to 1985. Of the 22 research cruises that were completed during the 17-year observation period, four were in 1973, three in 1985, two each in 1971, 1972, 1974, 1976, and 1983 and one each in 1968, 1969, 1977, 1982, and none in 1970, 1975, 1978, 1979, 1981, and 1984. Two shorter time-series programs, Gollum and VERTEX, lasted less than two years with thirteen, 2-day cruises on approximately monthly intervals and seven, 7-day cruises on approximately 3-month intervals, respectively (Karl and Lukas, 1996). None of these time-series programs supported a cruise frequency sufficient to observe either the high frequency event scale phenomena (days to weeks) or the lower frequency (subdecadal) regime shifts that are now considered crucial for a comprehensive understanding of the marine N-cycle (Karl *et al.*, 2001b). Furthermore, none of these programs seriously considered material exchange with the atmosphere, a process that is emerging as potentially important for the delivery of fixed N to open ocean ecosystems.

Prospero and Savoie (1989) reported total atmospheric concentrations of 0.3–0.4 µg NO_3^- m^{-3} for the North Pacific trades biome. Seasonal and regional variability in atmospheric NO_3^- was directly related to dust concentrations with maxima in spring. These continental sources of dust, and associated excess N, are predominantly anthropogenic and, therefore, highly susceptible to changes associated with industrial emissions and land use practices (Galloway *et al.*, 2004). Prospero and Savoie (1989) estimated that approximately 1.0 Tg (Tg = 10^{12} g) of NO_3^--N derived from continental sources is deposited annually into the North Pacific Ocean lying outside the coastal and equatorial regions. If we assume that approximately 50% of the total is delivered to the North Pacific trades biome (15°N–35°N and 135°E–135°W, an area of approximately 2×10^7 km^2) then the mean atmosphere to ocean flux of NO_3^- in this region would be 25 mg N m^{-2} year^{-1}, which is lower by approximately an order of magnitude than the fixed N delivery rate reported by Duce (1986), based on direct measurements of wet and dry deposition at a station near Hawaii.

In addition to NO_3^-, delivery to the surface ocean of atmospheric NH_4^+ is also potentially important though poorly documented for the North Pacific trades biome at the present time. Clarke and Porter (1993) reported significant NH_4^+ concentrations in aerosols coincident with local enrichments in near-surface chlorophyll, suggesting a biogenic source or control. Estimates of the sea-to-air flux of NH_4^+ in the equatorial Pacific biome were 10 µmol N m^{-2} day^{-1}, a value that is comparable to the downward flux of PON from the euphotic zone. Presumably, high rates of net primary production and coupled ammonification leads to changes

in local pH and increases in pNH_3 resulting in a net flux of NH_3 out of the surface ocean. Atmospheric NH_3 eventually reacts to form NH_4^+-enriched aerosols that partly reflux back into the more oligotrophic regions of the North Pacific trades biome north of 5°N latitude (Clarke and Porter, 1993). This translocation of fixed N, to our knowledge, has not been considered in the North Pacific basin-scale marine N-cycle nor in the ecology of the trades biome.

During the ADIOS I expedition in March–April 1986, DiTullio and Laws (1991) observed a dust deposition event that was coincident with, and perhaps caused by, a significant low pressure disturbance at 26°N, 155′W in the North Pacific trades biome. This stochastic event resulted in a 72% increase in submicron-sized autotrophic N-assimilation, and a change in the f-ratio from 0.1 before the storm to 0.28 after the dust deposition event. Turbulent mixing of NO_3^- from below the euphotic zone was determined not to be the source of the new N required to support this PON production pulse. Rather this picoplankton bloom was triggered by the simultaneous delivery of NO_3^- and iron from the atmosphere (DiTullio and Laws, 1991). Although they observed near-surface water (0–40 m) enrichments of NO_3^-, no NO_3^- uptake rates were reported. The enhanced total N assimilation could have resulted from NO_3^- deposition, as they suggested, or alternatively could have been a consequence of dust-derived NH_4^+ (with local nitrification accounting for the NO_3^- enrichments) or iron-stimulated N_2 fixation (again with local nitrification to explain the NO_3^- enrichments). Karl et al. (1992) previously reported elevated NO_3^- concentrations during a Trichodesmium bloom event near Station ALOHA suggesting a coupled N_2 fixation-nitrification pathway (i.e., $N_2 \rightarrow NH_4^+ \rightarrow NO_3^-$). Because Prochlorococcus, the dominant phytoplankter in these waters, may not be able to assimilate NO_3^- (Moore et al., 2002; Rocap et al., 2003; but see Casey et al., 2007), the conceptual model presented by DiTullio and Laws (1991) may be in need of revision. The delivery of iron rather than N per se may have been the ultimate cause of the enhanced rates of production and export.

Since late 1988, the approximately monthly HOT program cruises have successfully established robust climatologies for many of the basic physical, chemical and biochemical parameters in the region of Station ALOHA, but more needs to be done. The use of remote instrumentation deployed on Earth-orbiting satellites, geostationary deep-sea moorings, Lagranian drifters and autonomous gliders and vehicles have supplemented the mostly ship-based observations, especially over the past few years of HOT. It has recently been hypothesized that high frequency, aperiodic net autotrophic "bloom" events sustain what otherwise appears to be net heterotrophy in the North Pacific trades biome (Karl et al., 2003; Williams et al., 2004), and perhaps elsewhere. Neither the cause, nor the full ecological consequences of these stochastic events are known at the present time. Net autotrophic events, similar to those seen in moored ocean observing platform data sets (Emerson et al., 2002; Karl et al., 2003), can be reproduced in shipboard perturbation experiments by allochthonous nutrient additions (McAndrew et al., 2006), so stochastic additions of critical growth-limiting nutrients from deep waters below or from the atmosphere above could result in short-term "greening" of the gyre.

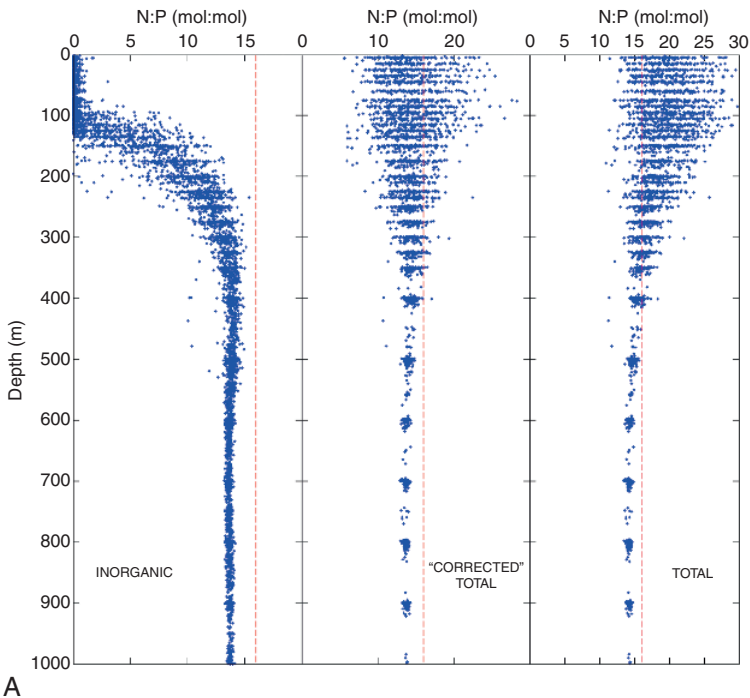
In the North Pacific trades biome, the N:P ratios of dissolved inorganic nutrients (i.e., NO_3^-, PO_4^{3-}) and total dissolved nutrients (i.e., the sum of inorganic plus organic TDN:TDP) are significantly different from each other and from the mean assimilation ratio required for net biomass production (Karl *et al.*, 2001a). Whereas the NO_3^-:PO_4^{3-} ratios in the upper 300 m of the water column (and especially the upper 0–100 m where dissolved organic nutrients comprise a significant proportion of the total inventory; Fig. 16.20A), are well below 16N:1P and in the upper water column well below 1N:1P, the corresponding TDN:TDP ratios are well above, averaging approximately 20–25N:1P. While it is generally assumed that NO_3^- and PO_4^{3-} are available to most plankton, the bioavailability of the DON and DOP pools is unknown due to the fact that they remain poorly characterized at the present time. There are systematic and opposing depth-dependent changes in nutrient concentrations and bulk stoichiometry. The greatest changes are observed at, or


Figure 16.20 Nitrogen–to–phosphorus (N:P) ratios at Station ALOHA. (A) Depth profiles of N:P for inorganic (NO_3^-:PO_4^{3-}) and total (TDN:TDP) pools showing fundamentally different depth trends relative to the 16N:1P Redfield ratio, which is shown as a vertical dashed line in each plot. The elevated N:P (>16) for the total dissolved pool, especially in the upper 100 m of the water column, indicates an excess of N relative to the P requirements for biomass production, if all DON and DOP are biologically available. The middle plot shows the depth dependence for the stoichiometric relationships if the DON and DOP pools are "corrected" for residual deep water concentrations (DON = 2.23 μM and DOP = 0.04 μM, respectively) to remove the contribution of the recalcitrant pools. After this correction, the near-surface N:P appears to converge near the Redfield ratio with a broader envelope of values near the surface. This stoichiometry of the DOM pool may be an important factor in the selection for, or against, N_2 fixing microorganisms. From Karl *et al.* (2001a).

(Continued)
Figure 16.20 cont'd (B) Near-surface distributions (log₁₀ concentrations) of NO_3^- and PO_4^{3-} and the NO_3^-:PO_4^{3-} ratios at Station ALOHA for the period 1989–2004. The large solid circles are the mean values observed and the smaller data points indicate all observations. The dotted vertical line in the plot on the far right is the Redfield reference ratio of 16N:1P.

just below, the water depth where net nutrient delivery occurs mainly by the process of turbulent diffusion. Phototrophic microorganisms that inhabit the zone between the energy-limited/nutrient-sufficient deeper water and energy-sufficient/nutrient-limited shallower waters are among the first to assimilate and reduce NO_3^-, thereby re-setting the N-cycle.

Much has been written on phytoplankton bloom phenomena, mostly in the context of the vernal light–nutrient dynamics (e.g., Sverdrup's critical-depth model; Sverdrup, 1953), and to a lesser extent about fall blooms resulting from density destratification-induced nutrient injections. However, North Pacific trades biome blooms—when they occur—appear mostly in late summer or early fall when the water column is well stratified and mean light levels are declining, not increasing. These blooms have been grossly undersampled, except by ocean color satellites that have consistently observed them, especially in the eastern portion of the gyre (Wilson, 2003; Wilson et al., 2008; Dore et al., 2008). These are significant events; some open ocean blooms cover more than 350,000 km² and last 4 months (Wilson, 2003). Various potential mechanisms have been proposed, including nutrient injection by local atmospheric disturbance, breaking internal waves, nutricline shoaling from passing Rossby waves, cyclonic eddy pumping of nutrient-enriched deep water, atmospheric deposition of Fe and/or P (e.g., Cipollini et al., 2001; DiTullio and Laws,

1991; Leonard *et al.*, 2001; Letelier *et al.*, 2000; McGowan and Hayward, 1978; Sakamoto *et al.*, 2004; Wilson, 2003), and the possibility of vertically migrating phytoplankton (Villareal *et al.*, 1999), as previously mentioned.

Regardless of the mechanism(s) involved, it is almost certain that nutrient loading is a necessary prerequisite to biomass accumulation because the background nutrient state is not sufficient to allow for the net accumulation of plankton biomass. The possible exception to this rule may be the physical accumulation, near the surface, of an otherwise dispersed assemblage of chlorophyll-containing microorganisms, but a physical accumulation of plankton would preclude net growth of the aggregated cells in the nutrient-depleted near-surface habitat. The response of the microbial assemblage to aperiodic nutrient injections will depend on both their frequency and duration, and may result in either a local enrichment of species that are already abundant (e.g., *Synechococcus*; Glover *et al.*, 1988) or a shift in the species composition of the community, especially a selection for large rapidly growing diatoms and other eukaryotes (Cullen *et al.*, 2002). Indeed, it has recently been reported that eddy-induced upwelling of nutrients near Hawaii stimulated a diatom bloom but led to the selective export of particulate silica to depth relative to carbon and nitrogen for reasons yet unexplained (Benitez-Nelson *et al.*, 2007). This overprinting of the microbial food web by the classical diatom-copepod-fish food chain has significant consequences for energy transduction and the export of organic matter.

The trajectory of processes in the perturbed ecosystem state depends critically on the physical delivery mechanism and whether N, P and Fe are co-delivered or not (Karl, 2002). If, for example, Fe and P are deposited by atmospheric dust then the system will most likely select for diazotrophs near the ocean's surface. Excess N_2 fixation could lead to the accumulation of NH_4^+, bioavailable DON (e.g., amino acids) and, via nitrification, NO_3^- (Karl *et al.*, 1992). These new sources of fixed N could trigger a secondary bloom of non-diazotrophic phototrophs. Alternatively, if deep water is the source of the nutrients, then biological processes near the top of the nutricline (~100 m) may be the first to respond. For example, Goldman (1993) has shown that very large phytoplankton cells, particularly diatoms, normally found in low abundances are among the most successful competitors at low light levels following the episodic injection of new nutrients from beneath the euphotic zone. These large, rare, potentially rapidly growing species have few predators in the background ecosystem state, so their biomass can accumulate rapidly following the introduction of new nutrients. With time, these cells can aggregate into very large masses (Alldredge and Gotschalk, 1989; Carpenter *et al.*, 1977) and either sink or be grazed by larger predators normally feeding at a much higher trophic position (Goldman, 1993). In their "wake," these subsurface diatom blooms would leave behind a new production oxygen signal, an inorganic carbon deficit and any residual non-limiting nutrients. Because the $NO_3^-:PO_4^{3-}$ ratio of the upwelled waters at Station ALOHA is much lower than the 16N:1P assimilation ratio in diatoms, excess P would tend to accumulate. This selective retention would lead to the upward diffusion of P, relative to N, and would eventually decouple N–P dynamics. Selective P retention would lead to a habitat that is conducive for the growth and proliferation of diazotrophs, and to a secondary N_2–based new production bloom in the well-lit regions of the euphotic zone (Fig. 16.20B). The N_2 fixing assemblages would import new N and eventually alter the N:P stoichiometry of sinking particulate matter,

in favor of N (i.e., molar N:P ratio of exported POM = 25–40 compared to the expected Redfield ratio of 16N:1P; Karl *et al.*, 2001a). Over time, the subeuphotic zone remineralization of this high N:P sinking flux would be expected to increase the $NO_3^-:PO_4^{3-}$ ratio at the top of the nutricline to an extent that subsequent upwelling events of these regenerated nutrients might result in fundamentally different successional patterns for the planktonic assemblages (Karl, 2002).

Wiegert and Penas-Lado (1995) compared the effects of upwelled pulses of nutrients to a constant supply of an equivalent annual flux. In their simulation of an open ocean pelagic community, nutrient pulsing produced a rich dynamical behavior and complex trophic structure that was not present under constant nutrient supply. Furthermore, reduced mixing can also lead to complex behavior and ''advection-diffusion instability'' for phytoplankton assemblages located in the deep chlorophyll maximum zone at Station ALOHA (Huisman *et al.*, 2006). Based on model results, changes in mixing rate which could result from greenhouse gas-induced warming of the global ocean can generate oscillations and chaos in phytoplankton biomass and species composition, thereby impacting food web structure, primary production and export. Thus aperiodic fertilization of the North Pacific trades biome can be expected to create boom and bust cycles that, depending upon their frequency and duration, may not be adequately sampled even by field-intensive time-series programs like HOT (Gaines and Denny, 1993; Katz *et al.*, 2005).

4. Epilogue

A major, but currently underappreciated, feature of the marine N-cycle is that it is solar-powered. Energy, ultimately derived from sunlight, is used to reduce all partially or fully reduced forms of N (e.g., NO_3^-, NO_2^-, N_2) to the level of NH_4^+ either directly by phototrophic microorganisms or indirectly via heterotrophs that depend upon the phototrophs for a continued supply of energy in the form of organic carbon. Upon death by grazing, viral lysis or autolysis, and during the remineralization of the POM, reduced dissolved N compounds including both organics (e.g., proteins and nucleic acids and their respective monomeric constituents, urea, vitamins) and NH_4^+ are released to the surrounding waters. A large proportion of the total flux of reduced N fuels the next round of combined photo- and heterotrophy, especially in near-surface waters. By utilizing NH_4^+/DON rather than a more oxidized form of N, an organism conserves energy and conducts a more efficient metabolism which would be of selective value in an energy-limited habitat like the open sea. Eventually, reduced N is oxidized back to N_2/N_2O or NO_3^-. During this coupled ammonification/nitrification process the remaining bioavailable energy is extracted from the reduced N by specialized *Bacteria* and *Archaea* that can sustain chemolithoautotrophic growth in the absence of energy in the form of sunlight or reduced carbon compounds.

Based on the cumulative data base of N pools and fluxes in the North Pacific trades biome, but relying largely on the HOT program accomplishments over the past two decades, a quantitative N budget is beginning to emerge. This contemporary view should be considered a ''work in progress'' and may change as new discoveries are made and new methodologies are developed and employed. In particular, high

frequency and, perhaps, unattended measurements of key N-cycle components will be necessary to ensure that time-integrated fluxes properly account for stochastic or seasonally-phased phenomena. The physical and biogeochemical consequences of climate variability and human–induced change may be especially difficult to observe and interpret due to the possibility of non–linear, complex interactions. Models, be they conceptual, statistical or numerical simulations, will be absolutely required for addressing the challenges ahead (Rothstein *et al.*, 2006).

In his review on N_2 fixation published more than 30 years ago, W. D. P. Stewart (1973) declared, ''the days of making gross extrapolations of rates of N_2 fixation based on a few spoonfuls of soil or a bucket of lake water are past. What is urgently required now are detailed studies based on well-established ecological principles where sampling error and distribution in space and time (including both diurnal and seasonal variations) are investigated.'' This suggestion was then, and still is today, sage advice. Future research on the marine N-cycle should consider the following: (1) we only see what we see, hence our current level of understanding is incomplete and we should expect new discoveries in both the near- and long-term, (2) the marine N-cycle is a solar-powered, time-variable, non steady-state, climate sensitive array of mostly microbiological processes, (3) microbial diversity and changes in community structure (e.g., selection for or against N_2-fixing micro-organisms or *Prochlorococcus*) can have profound effects on the marine N-cycle, (4) the marine N-cycle is closely coupled to the availability and flow of other elements through pelagic ecosystems and must be studied in the full context of other bioelemental cycles, especially C, P and Fe, and (5) humans have already begun to influence the global N-cycle primarily by the production and mobilization of excess fixed N through industrial processes. This accumulation of fixed N leads to a catalytic ''N cascade'' with yet to be determined ecological consequences (Galloway *et al.*, 2003). Over time, these anthropogenic impacts will begin to be detected even in the most remote oceanic habitats like the North Pacific trades biome. Furthermore, because of the close balance between N, P and potentially Fe limitation in the trades biome, the ecosystems supported in these regions, which collectively comprise the largest portion of our planet, may be particularly susceptible to this ''N cascade.''

Finally, the establishment of Station ALOHA as an oceanic outpost for the comprehensive study of microbial biogeochemistry has promoted the collaboration of scientists who otherwise do not frequently interact. This field-intensive research program will, hopefully, continue to provide access to the North Pacific trades biome to further enhance our knowledge of the marine N-cycle for years to come.

Coastal Upwelling

Frances Wilkerson *and* Richard C. Dugdale

Contents

1. Introduction

Although contemporary research has focused on the flux of biogenic elements between the upper and deep ocean, or ocean and atmosphere with an emphasis on open ocean systems (e.g., JGOFS studies 1996, Murray, 1995; 1996; Smith, 1999; Smith *et al.*, 2000), it has become apparent that the ocean margins play an important role in global ocean flux. A significant proportion of the global production occurs in the coastal ocean (Chavez and Toggweiler, 1995; Walsh, 1991) where wind-driven coastal upwelling results in surface waters rich in nutrients including nitrate (NO_3). As a consequence, phytoplankton in this well lit, eutrophic environment assimilate

the dissolved inorganic nitrogen (DIN) supplied, photosynthesize and grow. Eventually they sink out or are eaten and end up in fecal pellets. This biological pump acts to export carbon to deep water and lowers the pCO_2 in surface waters (Volk and Hoffert, 1985).

The pump's efficiency depends on the fraction of carbon fixation that escapes recycling within the mixed layer (Berger *et al.*, 1988), i.e., the amount of new production (Dugdale and Goering, 1967), which is supported by nutrient influx (typically NO_3) to the euphotic zone. Eastern boundary ocean margins, fueled by episodes of nutrient enrichment due to coastal upwelling, have high rates of new production (e.g., Dugdale and Wilkerson, 1989a; Dugdale, 1985; MacIsaac *et al.*, 1985). The aim of this chapter is to describe the nitrogen concentrations and the nitrogen assimilation by the resident phytoplankton communities that result in these regions being ecosystems crucial to the flux of nitrogen in the sea. Our focus will be on the supply of inorganic nitrogen as NO_3 in these areas and the new production processes that result from autotrophic cells rather than heterotrophic organisms that also mediate the nitrogen cycle, through regenerated production. Other chapters in this volume deal with nitrogen fixation processes (Chapter 4 by Carpenter and Capone, this volume), dissolved organic nitrogen as a nitrogen source (Chapter 7 by Mulholland and Lomas, this volume) and regeneration processes (Chapter 8 by Bronk and Steinberg, this volume).

In the original volume of ''Nitrogen in the Marine Environment'' the chapter concerning Nitrogen in Upwelling Ecosystems (Codispoti, 1983) reviewed the physical and chemical processes in upwelling areas that lead to high nitrogen supply rates and uptake rates. They did not discuss phytoplankton physiological aspects or ecosystem models involving nitrogen cycling in upwelling areas. Since then, there have been many more field studies of upwelling regions that have continued to describe distributions of nitrogenous nutrients and their uptake by phytoplankton. These have resulted in numerous review or synthesis volumes specific to coastal upwelling such as Bas *et al.* (1985) reporting the presentations given at ''The International Symposium on the Most Important Upwelling Areas off Western Africa'' and Payne *et al.* (1992) summarizing the ''Benguela Trophic Functioning Symposium.'' A Dahlem Workshop ''Upwelling in the Ocean'' discussed both coastal and equatorial upwelling on modern and ancient time scales and resulted in Summerhayes *et al.* (1995). Dedicated special issues of scientific journals have been produced that include a number of associated papers from a specific upwelling region or program. For example, the Lagrangian studies of the Iberian upwelling system (Joint and Wassmann, 2001, Progress in Oceanography), the Coastal Ocean Advances in Shelf Transport (COAST) program off the Oregon coast (Barth and Wheeler, 2005), and the Wind Events and Shelf Transport (WEST) study of the Bodega upwelling area (Largier *et al.*, 2006). Included within these are studies concerning the nitrogen cycle such as nitrogen assimilation measurements using Eulerian and Lagrangian approaches, experiments with shipboard enclosures and simulated upwelling studies in the laboratory.

Our views of how and which phytoplankton in coastal upwelling areas respond to the high supply rates of nitrogen (mostly in the form of NO_3) have progressed from the original chapter (Codispoti, 1983). Information included in this update

include descriptions of cell size-fractionated nitrogen uptake, DIN uptake kinetics, the interaction of other upwelled nutrients with DIN uptake, and how fluxes of nitrogen in upwelling systems can be modeled with this new information. However, many of the new data obtained since the original chapter, collected in coastal upwelling areas that were previously unstudied, confirm the earlier observations in Codispoti (1983) and serve to illustrate the common features of coastal upwelling systems. Since 1983 there have also been many technological advances that have been applied to the study of nitrogen flux and we review some preliminary studies pertinent to our knowledge of nitrogen in upwelling areas made using remote sensing and molecular genetics approaches. First the supply of nitrogen in coastal upwelling areas will be reviewed and compared among different sites. Then the available data on the uptake of nitrogen and new production rates in different upwelling areas will be summarized. The major phytoplankton groups contributing to these levels of new production will be discussed, followed by our view of how these phytoplankton (typically diatoms) are physiologically adapted to injections of NO_3 that accompany upwelling favorable winds. Some simulation models of new production in these ecosystems, along with some preliminary molecular studies appropriate for studying nitrogen flux in upwelling areas will be outlined, concluding with a look to future studies and approaches that might be addressed.

For sake of space we have limited ourselves to coastal upwelling areas and will not discuss equatorial upwelling. However equatorial upwelling is an important source of NO_3 in this high nutrient low chlorophyll region (see Chapter 37 by Kudela, this volume) and equatorial NO_3 flux and new production have been the focus of many field studies (e.g., WEC 88, JGOFS EqPac) as summarized in Barber (1992), Chavez and Smith (1995), Murray (1995, 1996), Murray *et al.* (1997), Turk *et al.* (2001a,b), and others. We cannot review everything that has happened since 1983 in all coastal upwelling regions, but have tried to provide a representative review of the major studies that have involved nitrogen flux measurements.

2. Inputs and Concentrations of Dissolved Nitrogen

2.1. Source of dissolved inorganic nitrogen

The surface waters of most of the ocean, in the absence of upwelling, are stripped of the nutrients used by phytoplankton, including dissolved inorganic nitrogen as NO_3, nitrite (NO_2) and ammonium (NH_4). Below a certain depth (the nutricline or ∼nitracline), NO_3 concentrations are elevated as the result of oxidation of organic material of biological origin containing nitrogen. This occurs in a series of steps, i.e., nitrification which converts NH_4 to NO_2 and then to NO_3 (Chapter 5 by Ward, this volume) resulting in low or undetectable concentrations of NH_4 and NO_2 in the sub–nutricline waters. When NH_4 and NO_2 do occur near the nutricline, it is the result of the other transformations in progress. They may be intermediates of either nitrification, assimilatory NO_3 reduction (NO_3 to NO_2 to NH_4), or denitrification (NO_3 to NO_2 to N_2) (Chapter 6 by Devol, this volume). Oxidation of organic N is complete at relatively shallow depths, *ca.* 500 m in the North

Pacific leading to a relatively constant concentration of NO_3 below that depth. The large reservoir of nitrogen, in the form of NO_3, is unavailable for primary production until uplifted into the euphotic zone by some mechanism, the most effective of which is upwelling, the vertical advection of deep water from below the nutricline. Along eastern boundary coasts the upwelling is wind driven and surface water is advected equatorward and replaced by sub-surface water resulting in high concentrations of NO_3 (and silicate, $Si(OH)_4$) over the coastal shelf (Fig. 17.1). This example from the upwelling center off Bodega Bay, California shows the uplifted NO_3 isopleths (paralleled by the $Si(OH)_4$ isopleths), with surface NO_3 reaching over 20 μM.

Vertical profiles of NO_3 may be modified in regions of low oxygen, or anoxia that can occur in conjunction with highly productive coastal upwelling systems, e.g., the low oxygen regions north and south of the equator in the Pacific (Codispoti, 1983; Codispoti *et al.*, 1986). Denitrification can result in a region of low NO_3 accompanying the subsurface low oxygen zone. In the upwelling region of 15°S, Peru, besides low NO_3 at depth there can be a maximum in NO_2 as a result of NO_3 reduction and low oxygen concentrations. Complete NO_3 reduction will result in a profile with zero NO_3, zero NO_2 and a maximum in NH_4 from the oxidation of organic material (Dugdale *et al.*, 1977). H_2S will usually be detectable in such fully denitrified water as bacteria use sulfate as electron donors for denitrification. In the highly productive Benguela upwelling system additional conversion of inorganic N to N_2 has been shown to occur through the anammox reaction (Kuypers *et al.*, 2005). The anammox process occurs under anaerobic conditions by bacterial mediated combination of NO_2 with NH_4. The reaction was first suggested by Richards (1965) and first shown directly to occur in wastewater bioreactors (Mulder *et al.*, 1995). The anammox reaction uses NH_4 produced during oxidation of organic matter required for denitrification. As a result, when the anammox reaction is combined with denitrification, the total production of N_2 from inorganic nitrogen is increased by as much as 29% compared to only denitrification (Dalsgaard *et al.*, 2003).

2.2. Characteristic NO_3 concentrations in different upwelling regions

Upwelled water in coastal systems is usually derived from maximum depths of 100–200 m (Hutchings *et al.*, 1995). The maximum depth of upwelling is a function of the wind stress and the degree of stratification so it will vary in time and space. The maximum NO_3 concentrations achieved during strong upwelling events are important for two reasons: (1) to determine the rate of specific NO_3 uptake (i.e., growth rate as nitrogen), and (2) to determine the total new production (NO_3 uptake) that can be realized from the particular event. The first effect is on algal physiology, the second on biomass accumulation or production.

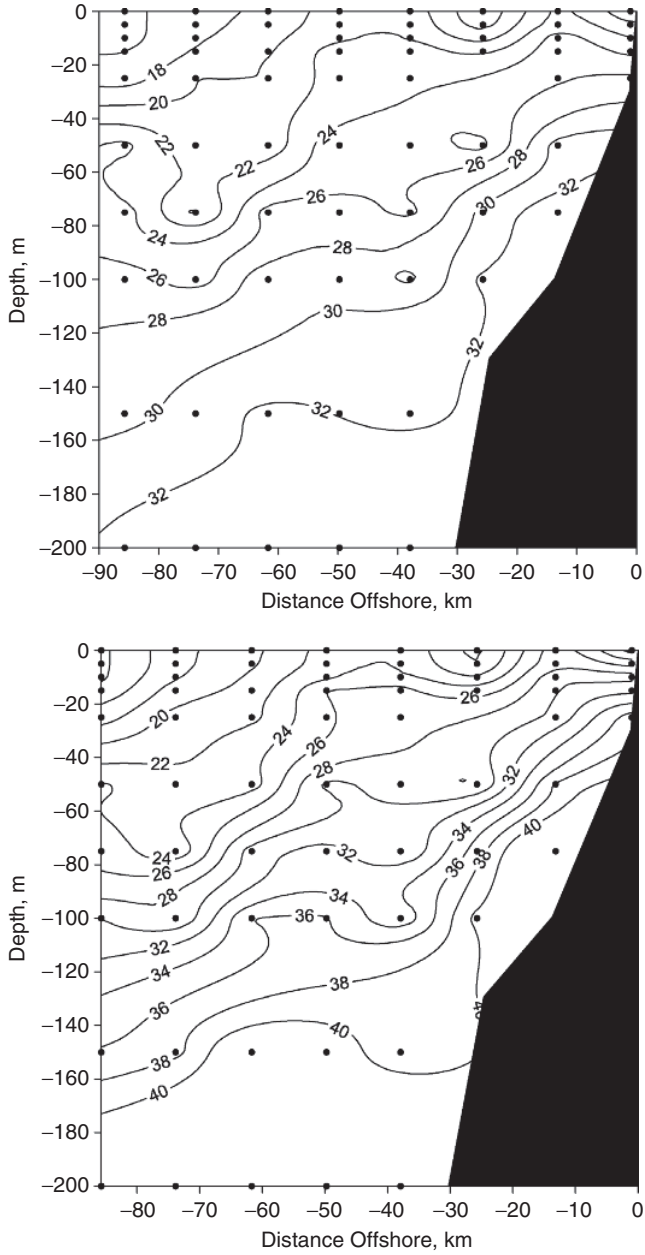
The NO_3 content of upwelling water is strongly influenced by the location of a system (Codispoti *et al.*, 1982) in the global oceanic conveyer belt that transports deep water through the ocean basins (Broecker and Peng, 1982, their Fig. 1.12). From the North Atlantic to the Pacific and Indian Oceans through the Antarctic Circumpolar Current, there are increasing nutrients, from the fallout of surface productivity.


Figure 17.1 Distribution of nitrate (upper panel) and silicate (lower panel) (μM) at the upwelling area off Bodega Bay, CA during WEST 2000 cruise.

This oceanic conveyer belt is essentially a counter–current concentration system in which the Atlantic Ocean is continually stripped of nutrients that eventually find their way to the North Pacific and Indian Ocean. The conveyor belt suggests that newly upwelled waters in the Atlantic Ocean will have lower surface nutrients than in Pacific upwelled waters. Maximum NO_3 concentrations observed during ocean-ographic cruises to selected upwelling systems (Table 17.1) support this with the Pacific systems having the highest maximum concentrations, 32–49 µM for the northern hemisphere sites (note, the Baja California values represent weak, spring upwelling conditions). The Indian Ocean (Somali Coast) concentration is lower, 25.6 µM. The South Atlantic Benguela system has a concentration, 24.35 µM, about the same as the Indian Ocean value. The North Atlantic site, Cap Blanc, northwest Africa has a value that is much lower, 12.0 µM. This series of high Pacific, lower Indian Ocean and South Atlantic and low North Atlantic concentrations (Table 17.1) are the result of the characteristic nutrient concentrations of these basins brought about by the effect of the oceanic conveyer belt system (Broecker and Peng, 1982).

In addition there is a local influence on nutrient concentrations. The local source of upwelled water in coastal upwelling centers is in part from the poleward undercurrents that underlie virtually every coastal upwelling system. The original concentration of the water entrained in the undercurrent is enhanced by the counter–current exchange process (Dugdale, 1972; Hart and Currie, 1960) in which the poleward undercurrent receives and processes detrital material from the equatorward surface waters containing high algal material produced from the upwelled nutrients (Barber and Smith, 1981).

Upwelled NO_3 concentrations are usually reduced during El Niño conditions (e.g. Corwith and Wheeler, 2002), by as much as 50% in the upwelling areas of Peru (e.g., data for 1976) and Baja California (e.g., in 1972) (Wilkerson et al., 1987). Point Conception, California in the El Niño year 1983 experienced about a 30%

Table 17.1 Maximum surface nitrate and silicate concentrations from selected upwelling systems

reduction (Dugdale, 1985; Wilkerson *et al.*, 1987). NO_3 concentrations in Monterey Bay, California were also reduced during the 1992 El Niño to about 30% of 1993 values (Chavez, 1996) and even more during the 1998 El Niño (Chavez *et al.*, 2002).

In coastal upwelling systems, maximum silicate $(Si(OH)_4)$ concentrations are generally equal or greater than NO_3 concentrations (Table 17.1, Jones *et al.*, 1983). Diatoms, the major producers in upwelling systems (reviewed in Section 17.4 and Brink *et al.*, 1995), require silica for construction of their shells in about a 1:1 ratio of N:Si (Brzezinski, 1985). Generally, in coastal upwelling regions, the supply of Si is adequate for diatoms so NO_3 will run out first during biomass production. However, in the Peru system variation in the ratio of N:Si brought about by intensive denitrification, may result in alternating N and Si limitation of diatom production (Dugdale, 1983).

2.3. Dissolved organic nitrogen

DON concentrations of 4–8 µM have been observed in the relatively weak upwelling area off the northwest coast of Spain (Álvarez-Salgado *et al.*, 1999). Hill and Wheeler (2002) reported values of ~7 µM DON in upwelled waters off the Oregon coast. These are similar DON concentrations to the open ocean as summarized Table 17.3 of Hill and Wheeler (2002). Some of this DON is upwelled; e.g., water at 50 m depth off Oregon had a mean value of 5.98 (Hill and Wheeler, 2002). Another source is from production by phytoplankton as they partition newly assimilated NO_3 into particulate nitrogen and DON that is released (Bronk *et al.*, 2006; Wetz and Wheeler, 2003).

3. DISSOLVED INORGANIC NITROGEN UPTAKE IN UPWELLING AREAS

3.1. NO_3 uptake and new production

The incorporation of new inputs of nitrogen into phytoplankton biomass—i.e., NO_3 advected from depth (e.g., Dugdale and Goering, 1967) as occurs in coastal upwelling regions or from atmospheric inputs through rain (e.g., Paerl, 1985; 1997; Chapter 9 by Seitzinger and Harrison, this volume) or through nitrogen fixation (Chapter 4 by Carpenter and Capone, this volume) has been termed new production to differentiate from regenerated productivity that is based upon nitrogen that has come from a recycled source. Typically the regenerated source is NH_4 resulting from meso or micro zooplankton grazing. The concept of new production was used to describe the potential loss rates—i.e., the export of nitrogen as sinking particles (Eppley and Peterson, 1979) or loss to upper trophic levels and ultimately fishery yields (Dugdale and Goering, 1970). New production in upwelling areas can be compared using the percent new production or *f*-ratio. This is typically calculated from the uptake of NO_3 into the particulate nitrogen pool, compared to the uptake of NO_3 plus regenerated N sources, usually NH_4 and sometimes including urea and other DON. It is also used as a way to parse total productivity, i.e., carbon fixation usually measured with the radio-isotope ^{14}C, into total and new fractions. New

production plays a major role in the biological pump as it determines the amount of carbon (and nitrogen) that can be pumped from atmosphere to the deep ocean. Regions with high f-ratios (i.e., >0.5) are areas with an efficient biological pump (Eppley and Peterson, 1979). There may be other sources of nitrogen that may at first glance appear to be regenerated nutrients but are also new to the system (e.g., NH_4 runoff, Dugdale and Wilkerson, 1988; Paerl, 1997). Consequently the term new production and the calculation of f-ratio should be defined carefully when used (see discussion in Chapter 7 by Mullholland and Lomas, this volume). A re-evaluation of new production measurements was made to include DON produced during NO_3 uptake (Bronk $et\ al.$, 1994; Bronk and Ward, 2005). This diverted new production will contribute to the flux of particles (export production) but is not represented in the f-ratio measured as ^{15}N uptake into the particulate N pool. Bronk and Ward (2005) suggested that the DON pool acts as an intermediate between DIN assimilation and the net formation of particles for export and so will influence the export production of the system.

Typically new and regenerated production rates have been measured using tracers—mostly the stable isotope ^{15}N and mass spectrometry. The different sources of nitrogen for phytoplankton can be labeled and incubated with the phytoplankton to measure uptake of the different forms of DIN or DON (e.g., Wilkerson and Grunseich, 1990). In this chapter we will limit ourselves to DIN. Having the uptake rates for $^{15}NO_3$ and $^{15}NH_4$, estimates of percent new production and f-ratio can be made. Phytoplankton incorporation of ^{15}N labeled compounds was first carried out in the Sargasso Sea by Dugdale and Goering (1967) and with the advent of mass spectrometers designed specifically for tracer use of stable isotopes, this approach has now become a standard oceanographic technique (e.g., Dugdale and Wilkerson, 1986; JGOFS, 1996). Other approaches have used the radio-isotope ^{13}N that has a very short half life of 10 min (e.g., Collos $et\ al.$, 1992; Zehr and Falkowski, 1988; Zehr $et\ al.$, 1988). One limitation with this is that studies must be carried out in close proximity to a cyclotron that can supply the isotope for the incubations. Another approach is to use ^{14}C labeled methyl-ammonium, an analog of NH_4 to measure regenerated production (Balch, 1986; Wheeler, 1980). Alternatively NO_3 and NH_4 depletion can be followed in incubations but these do not provide direct incorporation of N and so have their limitations (Dugdale and Wilkerson, 1986; Price $et\ al.$, 1985).

The uptake of NO_3 into the particulate N pool can be expressed as a transport rate, with a volume specific unit, ρNO_3 as $\mu mol\ N\ l^{-1}\ h^{-1}$ (or integrated throughout the water column, to get $\mu mol\ m^{-2}\ h^{-1}$) or as a biomass specific rate V usually based upon the particulate nitrogen (PON) of the sample or the chlorophyll content of the sample (Dugdale and Wilkerson, 1986). Dickson and Wheeler (1995a) proposed that V_{Chl} was a better measure in the Oregon upwelling system, although chlorophyll per cell will change with photoadaptation. Kudela (1995) and Kudela and Dugdale (2000) compared specific uptake rates for NO_3 normalized to PON and to chlorophyll in the Monterey Bay upwelling area and found no difference except during winter when detrital N diluted the values of VNO_3 normalized to PON.

Coastal upwelling areas show high NO_3 uptake rates, with maximal rates of ρNO_3 on the order of $0.5\ \mu mol\ l^{-1}\ h^{-1}$ (Table 17.2). The only data available for

Point Conception, California was obtained during an extreme El Niño year (1983) when nutrients (and uptake) were lower than more normal years (Wilkerson *et al.*, 1987). Accompanying the high transport rates are high specific uptake rates (VNO$_3$ based upon PON) up to 0.1 h^{-1} [µmol l^{-1} h^{-1} (µmol l^{-1})$^{-1}$], that can be approximated to a maximal growth rate of the phytoplankton of 0.1 h^{-1}. High *f*-ratios are also characteristic of coastal upwelling areas, with values of >0.7 (Table 17.1), except for the low Point Conception value which was likely due to the El Niño conditions. These uptake rates translate to a rapid ability to drawdown ambient nutrients. For example in the Bodega Bay, California upwelling area (Fig. 17.2), ambient upwelled NO$_3$ of 23 µM was drawn down to zero within four days, VNO$_3$ reached 0.05 h^{-1}, with an accompanying accumulation of biomass of 14 µg l^{-1} chlorophyll (Dugdale *et al.*, 2006; Wilkerson *et al.*, 2006).

Light is required for NO$_3$ uptake so the high rates of uptake in upwelling areas are limited to the upper euphotic zone near the surface (Fig. 17.3) and during the daytime (Cochlan *et al.*, 1991a), although subphotic uptake has been described in the Benguela upwelling (Probyn *et al.*, 1996). The response of NO$_3$ uptake to ambient irradiance in natural phytoplankton was originally described for the upwelling systems of Peru (MacIsaac and Dugdale, 1972; MacIsaac *et al.*, 1985; Wilkerson and Grunseich, 1990), northwest Africa (MacIsaac *et al.*, 1974; Nelson and Conway, 1979) and Baja (MacIsaac, 1978; Nelson and Conway, 1979), summarized in Wilkerson and Grunseich (1990), using a Michaelis-Menten hyperbola to obtain uptake parameters. More recently it has been described by Cochlan *et al.* (1991b) for the frontal high NO$_3$ regions of the Strait of Georgia. Kudela *et al.* (1997), working in the upwelling area of Monterey Bay, California confirmed the use of a hyperbola to describe the response, but indicated that it should be modified for dark uptake of NO$_3$ that can occur. Rarely is there photoinhibition of NO$_3$ uptake (Kudela *et al.*, 1997). In their study the uptake parameter, K_{LT}—the half saturation constant for light—similar to the derived photosynthetic parameter I_K, ranged from 35.7 to 123.5 µmol m^{-2} s^{-1}, (high to low sensitivity to light) as upwelling progressed, showing physiological adaptation from the low light conditions of the source water to the high light expected in a stratified water column.

3.2. NH$_4$ uptake and regenerated production

In upwelling regions, NH$_4$ is usually close to undetectable in deep water, having been oxidized to NO$_3$ by bacterial activity. It may be present in low concentrations in euphotic waters, a result of either regeneration through grazing or bacterial activity, or advected from outside the upwelling center. However, NH$_4$ and other products of grazing, e.g., urea and creatine (Whitledge, 1981; 1982, Whitledge and Packard, 1971) appear in the surface regions as upwelled water ages and is depleted of NO$_3$. Zooplankton and nekton are major sources of NH$_4$ and urea in upwelling systems. Whitledge (1978; 1981) measured equal amounts of NH$_4$ excretion by both in the northwest Africa upwelling system, the sum about equal to the uptake by phytoplankton. There was a higher rate of urea excretion by the nekton than by the zooplankton. The smallest size fraction of zooplankton included was 102–223 µm. The Peru upwelling system at 15°S was unique in that anchovy excretion provided
Figure 17.2 Time series of surface nutrients, nitrate uptake and chlorophyll at a shelf station at the upwelling area off Bodega Bay, CA during WEST 2001. From Wilkerson *et al.* (2006) and Dugdale *et al.* (2006).
Figure 17.3 Two vertical profiles of nitrate uptake at the upwelling area off Bodega Bay, CA during May (open triangles) and June (closed triangles) during WEST 2001. From Dugdale *et al.* (2006).

the major source of NH_4, creatine and urea (Whitledge and Packard, 1971). They calculated that the daily NH_4 uptake requirement of the phytoplankton would be met by excretion of a school of anchovy in two hours. The unique property of anchovy is that as nekton they occupy a position near shore and regenerate nitrogen there, so acting as a nutrient trap to maintain upwelled nitrogen close to the coast rather than exported away.

NH$_4$ is preferentially used by the smaller phytoplankton (e.g., Probyn, 1985). In aged upwelled water in the Benguela upwelling system in the presence of 5 μM NO_3 the picoplankton (<2 μm) and nanoplankton (2–20 μm) took up mostly NH_4 (Probyn *et al.*, 1990). The larger fraction (>20 μm cell size) utilized NO_3 more under the same conditions. Urea was also detected in the aged water and was taken up by all size fractions. In the upwelling area of Monterey Bay urea uptake did not contribute significantly to total N uptake (Kudela 1995) and NH_4 uptake was less than NO_3 uptake during early and mid upwelling but dominated N assimilation in older upwelled water (Kudela *et al.*, 1997). For the upwelling area off Oregon, Dickson and Wheeler (1995b) reported the lowest rates of NH_4 uptake during an active upwelling event and the fastest rates in aged upwelled water. Regeneration rates for both NH_4 and urea were about equal to the measured uptake rates in the Benguela upwelling system (Probyn *et al.*, 1990). In the upwelling area of northwest Spain, NH_4 did not accumulate suggesting a daily time scale coupling between re-generation and uptake (Varela *et al.*, 2003). Their measurements of NH_4 and DON regeneration by microplankton were minimal during active upwelling and maximal

during relaxation (Varela *et al.*, 2003). Microheterotrophs may play a role in upwelling nitrogen cycles. Sherr and Sherr (1994) noted that microzooplankton (protists) routinely consume 25–100% of daily phytoplankton production, even in diatom dominated upwelling blooms. Sherr *et al.* (2005) described a high abundance of ciliates and heterotrophic dinoflagellates in the Oregon upwelling region that would contribute to the regeneration of nitrogen.

4. Phytoplankton Functional Groups and Nitrogen Assimilation

The composition and size structure of the phytoplankton assemblage in the coastal upwelling ecosystems play an important part in determining the amount of NO_3 assimilation (new production) that occurs (Hutchings *et al.*, 1995; Michaels and Silver, 1988; Probyn, 1992; Chavez, 1996). In most coastal upwelling areas the larger sized cells dominate the chlorophyll biomass (Brink *et al.*, 1995; Estrada and Blasco, 1985; Wilkerson *et al.*, 2006). Stolte *et al.* (1994) describe how larger phytoplankton cells only become dominant when NO_3 is the major nitrogen source available and NH_4 is typically low or at detection levels, as in coastal upwelling ecosystems. The larger net (or micro-) plankton size fractions of the phytoplankton community are more effective than the smaller size classes of the microbial web at using recently upwelled NO_3 (Brink *et al.*, 1995; Chang *et al.*, 1992, 1995; Probyn, 1985, 1992; Probyn *et al.*, 1990; Varela *et al.*, 1991; Wilkerson *et al.*, 2000) and are the major new producers. Size fractionated uptake measurements made using ^{15}N in a variety of upwelling regions using different size fractions show that greater than 65% and up to 90% of the total NO_3 uptake by the phytoplankton community can be attributed to the larger phytoplankton (Table 17.3).

Taxonomic studies show that these larger cells in upwelling waters are chain-forming and colonial diatoms (e.g., Chavez *et al.*, 1991; Estrada and Blasco, 1985; Lassiter, 2003; Lassiter *et al.*, 2006) with individual cell diameters of typically 5–30 µm (Estrada and Blasco, 1985). Margalef (1978) was one of the first to observe that the diatom genera *Chaetoceros, Thalassiosira, Rhizosolenia* and *Nitzschia* dominated in coastal upwelling regions and are apparently well suited to both the high turbulence and high nutrient conditions there. Diatoms have been described as the dominant marine phytoplankton species to occur when external ''new'' nitrogen enters the euphotic zone (Malone, 1980; Bode *et al.*, 1997). Diatom physiology is well adapted to exploit increased nutrient availability (Hutchings *et al.*, 1995; Sarthou *et al.*, 2005) as occurs in wind driven upwelling. Phytoplankton cells in upwelling situations have greater intracellular pools of NO_3 than those from non-upwelling situations (Bode *et al.*, 1997). They have large vacuoles (e.g., Antia *et al.*, 1963) that may take up to 90% of the total cell volume in diatoms >5 µm in diameter (Smayda, 1970) and are capable of storing large amounts of NO_3 (Collos *et al.*, 1997; Lomas and Glibert 2000). Diatoms have fast division rates (Furnas, 1991) and a favorable respiration to photosynthesis ratio (Harris, 1978), enabling photosynthetic carbon to be used in growth rather than completely used in respiration. They are also well adapted to

thrive in cold waters as occurs in recently upwelled water. Lomas and Glibert (1999a, 2000) describe how diatoms in colder water have higher uptake capacity for NO_3, and lower optimal temperatures for nitrate reduction enzymes than flagellates (Lomas and Glibert, 1999b).

Consequently rates of new production in many coastal upwelling areas with high NO_3 concentrations are dominated by NO_3 assimilation by diatoms (Franck et al., 2005; Wilkerson et al., 2000), resulting in short diatom-based food chains (e.g., Ryther, 1969). The role of diatoms in downward nitrogen flux (from surface to deep ocean) is also important in these areas where they are the key players in biological export (e.g., Pilskaln et al., 1996). However in some upwelling areas, when the water conditions are less turbulent, dinoflagellates may also use upwelled NO_3 sweeping the euphotic zone clear of NO_3 as they migrate vertically daily. Such conditions were encountered in the upwelling region of the Baja California coast during weak upwelling (MacIsaac, 1978; Walsh et al., 1974). Dominance of the dinoflagellates over the diatoms in this situation was apparent from the high $Si(OH)_4$ concentrations with near zero NO_3 concentrations (Huntsman et al., 1981). In 1977, at 15°S, Peru, there was dominance by patches/blooms of the motile symbiotic ciliate Mesodinium (=Myrionecta) rubrum that were able to exploit the high DIN conditions (Wilkerson and Grunseich, 1990). In some upwelling areas with lower levels of NO_3, such as the Iberian upwelling system (Joint et al., 2001b) picoplankton may play the most important role in NO_3 uptake (Joint et al., 2001a) and consequently new production in these areas has less potential for sedimentation (Joint and Wassmann, 2001) and downward flux of N.

5. PHYSIOLOGICAL ADAPTATION OF NITROGEN ASSIMILATION

The sequence of events that occurs when upwelled phytoplankton respond to the favorable irradiance and nutrient conditions has been described as a conveyor belt (Fig. 17.4; Dugdale et al., 1990; MacIsaac et al., 1974, 1985; Wilkerson and Dugdale, 1987) or cycle of events. Along this conveyor, with sufficient residence time and relaxed winds, phytoplankton cells go through a series of physiological changes (Bode et al., 1997). The productivity cycle begins with upwelling of low levels of seed stocks of phytoplankton cells that have minimal phytoplankton rate processes (Slawyk et al., 1997). The upwelled surface waters are cold with high nutrient concentrations and low phytoplankton biomass (chlorophyll). Then as the water is advected downstream, with relaxed wind conditions, the phytoplankton increase their physiological processes in response to the high light and nutrients. First nutrient uptake mechanisms are turned on and then photosynthesis. This up-regulation or acceleration of rate processes (Fig. 17.4) has been termed shift-up (MacIsaac et al., 1974) and used to model plankton responses to upwelling conditions by Dugdale et al. (1997), Botsford et al. (2003), and Zimmerman et al. (1987). As the cells continue along the conveyor or cycle they reach balanced growth as uptake of C and N approach the Redfield ratio (Kudela et al., 1997). At this stage (often near an upwelling frontal area) chlorophyll biomass begins to accumulate due to the high uptake rates and the surface nutrient
Figure 17.4 Conceptual cycle (conveyor belt) of phytoplankton nitrogen and carbon processes in an upwelling center. From Wilkerson and Dugdale (1987).

concentrations are lower due to phytoplankton drawdown. As the cells continue downstream the larger phytoplankton cells do not have sufficient nutrients, their rate processes down-regulate or shift down. Zooplankton grazing in this region responds to the increased chlorophyll biomass (e.g., Smith and Whitledge, 1977), with regeneration of NH_4 that feeds a small celled phytoplankton community and a microbial loop (Chang et al., 1992; 1995; Kudela et al., 1997; Painting et al., 1993; Probyn et al., 1990; Wilkerson et al., 2000). Sinking algal cells or fecal pellets carry the C and N below the euphotic zone. Any living cells will act as seed stock for the next cycle or conveyor when the winds are upwelling favorable.

Field studies show this cycle (conveyor) for cells to go through high light shift-up to balanced growth and finally to low nutrient shift-down (Fig. 17.4) to take between 5–7 days (e.g., MacIsaac et al., 1985 in Peru; Dugdale and Wilkerson, 1989b in Point Conception, California, Wilkerson et al., 2006 for Bodega, California). These temporal changes described above as chronological changes since upwelling, are translated into spatial changes as newly upwelled water is advected offshore or downstream. The greatest bloom development and spatial extent occurs when upwelling ceases and there is an optimal period of water column stability due to relaxation of the winds. An alternative explanation to physiological adaptation by the phytoplankton along a conveyor was put forward by Garside (1991) and Dickson and Wheeler (1995), who explained the increase in NO_3 uptake (=depletion) that occurs following upwelling to result from increased biomass of phytoplankton, and that an adjustment of metabolism by the phytoplankton was not necessary. However, Kokkinakis and Wheeler (1987) showed data with specific nitrate uptake VNO_3 (based on chlorophyll, V_{Chl}) increasing daily at high NO_3 concentrations

in the Oregon upwelling system. Shift-up of phytoplankton metabolism was also confirmed by Berges *et al.* (2004) who showed that the physiological indicators of nitrogen and carbon metabolisms (nitrate reductase activity and variable fluorescence, Fv:Fm) responded quickly and with great sensitivity to changes in irradiance in simulated upwelling conditions.

Zimmerman *et al.* (1987) and Dugdale *et al.* (1990) used simple models (see section 7 below) based upon the initial NO_3 concentration in the upwelled water and the acceleration rate (a term used to describe the increased uptake rate of NO_3 by upwelled phytoplankton that is directly related to the available NO_3) to predict the time it would take for upwelled phytoplankton to respond and deplete the upwelled nutrients. They showed that, regardless of how much nutrient is upwelled during the upwelling phase, with a suitable period of relaxation, all upwelled NO_3 was taken up within 72 h, i.e., 3 days. This sets the minimum relaxation period for full utilization of upwelled nutrients: a conceptual framework for understanding the phytoplankton response in upwelling regions. Field studies support this time frame (e.g., Wilkerson *et al.*, 2006).

6. Factors Affecting Nitrogen Assimilation in Coastal Upwelling Areas

6.1. Kinetics of NO_3 and NH_4 uptake

NO_3 and NH_4 uptake by phytoplankton in eutrophic systems were initially shown to follow Michaelis-Menten kinetics yielding a saturation curve (MacIsaac and Dugdale, 1972) according to the equation:

$$VNO_3 = V_{max}NO_3{}^*[NO_3]/K_{S(NO3)} + [NO_3]$$

using NO_3 uptake as the example, where VNO_3 is the biomass specific NO_3 uptake rate, $[NO_3]$ is the NO_3 concentration, and $K_{S(NO3)}$ is the half saturation constant for NO_3 uptake (i.e., the concentration of NO_3 at which $VNO_3 = \frac{1}{2} V_{max}NO_3$.

Early values of K_S obtained using ^{15}N incubations in upwelling areas were on the order of 1 μM for both forms of DIN (MacIsaac and Dugdale, 1969); 0.98 μM for NO_3 in the Costa Rica Dome, 4.21 μM for NO_3 and 1.3 μM for NH_4 in the Aleutian Islands. Subsequent measurements of nutrient uptake have largely confirmed the applicability of the Michaelis–Menten formulation at relatively low substrate concentrations. There have been relatively few measurements of NO_3 uptake kinetics in upwelling systems (Table 17.4), in part because NO_3 concentrations are typically high, at levels that would suggest saturated uptake rates to occur. Also experimentally it is often difficult to get low nutrient water (to make substrate additions to) with sufficiently high phytoplankton biomass to be able to measure uptake rates efficiently. Under weak upwelling conditions off the coast of Portugal with surface NO_3 concentrations of 0 to 1 μM, Slawyk *et al.* (1997) measured $K_{S(NO3)}$ values of 0.17–0.39 μM and $K_{S(NH4)}$ values of 0.08–0.3 μM.

Table 17.4   Examples of Michaelis–Menten parameters of DIN uptake for upwelling areas

Upwelling Area	$K_{S(NO3)}$ µM	$K_{S(NH4)}$ µM	Reference

Westland, New Zealand	0.2–1.1	0.2–0.5	Chang et al. (1995)

Chang et al. (1995) measured K_S values for NO_3 and NH_4 uptake by different size classes of phytoplankton in Westland, New Zealand. For >100 µm sized cells, $K_{S(NO3)}$ ranged from 0.4–1.1 µM, for <20 µm cells, 0.3–0.8 µM and for <2 µm cells, 0.2–0.5 µM. $K_{S(NH4)}$ for <200 µm cells ranged from 0.4–0.5 µM, for <20 µm cells from 0.3–0.4 µM and for <2 µm cells, 0.2–0.3 µM. K_S values for urea uptake were in the same range as for NH_4. Kudela (1995) reported values of 1.22 and 4.14 µM NO_3 in Monterey Bay. Dickson and Wheeler (1995b) studying the Oregon coastal upwelling system reported a $K_{S(NO3)} = 1.26$ µM. The value of $K_{S(NO3)} = 2.02$ µM for the Benguela upwelling system (Probyn et al., 1995) falls within the range of the Monterey Bay values, both high NO_3 coastal upwelling systems.

Two complications tend to blur this relatively simple view of NO_3 uptake kinetics. The first is the existence of multi-phasic uptake systems in some algae (see Chapter 7 by Mullholand and Lomas, this volume), and the second is the shift-up process (acceleration of uptake in upwelling systems) in which the maximum specific uptake rate, is a function of both time since upwelling and initial NO_3 concentration. Consequently if a series of upwelled water masses with varying initial NO_3 concentrations were followed and the peak VNO_3 determined for each, the plot of $V_{max}NO_3$ versus initial NO_3 would be linear (see Dugdale et al., 1990, Fig. 4b). An example of linear kinetics resulting from this shift-up response in which VNO_3 is determined both by NO_3 and time since upwelling (Fig. 17.5) is shown for nearshore stations at the Bodega Bay upwelling area. The data include both periods of increasing and decreasing NO_3 concentration with time, from just before and after an upwelling event.

The multi-phasic phenomenon was first suggested by Serra et al. (1978) who observed NO_3 uptake in nutrient deficient cultures of the diatom *Skeletonema costatum* to follow Michaelis-Menten kinetics up to 6 µM NO_3 but at higher concentrations, a linear increase in uptake with increased NO_3 concentration.
Figure 17.5 Nitrate uptake versus nitrate concentration, at a shelf station at the upwelling area off Bodega Bay, CA during WEST 2000. Circles are stations sampled during upwelling, crosses during decreased upwelling conditions. From Dugdale *et al.* (2006).

They suggested the existence of two uptake systems, a carrier mediated uptake that would result in Michaelis-Menten kinetics, and a linear diffusion mediated system. Later work by Collos *et al.* (1992) showed two plateaus of NO_3 uptake by *S. costatum*, the second at very high NO_3 concentrations (50–100 μM). Since that publication, numerous examples of multi-phasic uptake have been discovered. Collos *et al.* (2005) reviewed K_S values for NO_3 uptake and reported low affinity uptake systems with $K_{S(NO3)}$ values ranging from 18–120 μM among the diatom genera *Rhizosolenia, Skeletonema,* and *Thalassiosira*. A linear system in *S. costatum* appeared above a threshold NO_3 concentration of 30 μM. Collos *et al.* (2005) also reported the existence of multiple thresholds and suggested that coastal upwelling productivity models should incorporate multi-phasic kinetics. Kokkinakis and Wheeler (1987) provide data from the Oregon upwelling system that indicate a threshold for different kinetics beginning at about 20 μM NO_3.

6.2. Interaction of NH_4 and NO_3 uptake

NH_4 may inhibit NO_3 uptake and reduction (e.g., Conway, 1977; Chapter 7 by Mulholland and Lomas, this volume). When NH_4 is present at concentrations of *ca.* >1 μM, NO_3 uptake is often inhibited (Cochlan and Harrison, 1991; Dortch, 1990). Although uncommon, when this occurs in upwelling systems, the phytoplankton first lower the NH_4 concentration by uptake and then access the NO_3; so adding some time delay before the phytoplankton population can take up NO_3 at
Figure 17.6 Nitrate uptake versus ammonium concentration for all stations sampled at the upwelling area off Bodega Bay, CA during WEST 2001. From Dugdale *et al.* (2006).

increasingly high rates. Upwelling systems therefore typically show a pattern of increasing specific NO_3 uptake with decreasing NH_4 concentrations. An example from recent studies in the upwelling center off Bodega Bay, California is shown in Fig. 17.6 where VNO_3 shows higher uptake when NH_4 concentrations are <2 μM. The elevated NH_4 (up to 6 μM) was contained in cold, high salinity, recently upwelled water and may have been added during contact with sediments. NH_4 inhibition of NO_3 uptake was also observed and modeled in the Peru upwelling center (MacIsaac and Dugdale, 1972; Dugdale and MacIsaac, 1971).

6.3. Interaction of $Si(OH)_4$ and NO_3 uptake

The way in which $Si(OH)_4$ affects NO_3 dynamics is discussed in detail in Chapter 37 by Kudela, this volume. Concentrations of $Si(OH)_4$ in upwelled water are usually sufficient to match NO_3 concentrations and uptake in the 1:1 Si:N ratio required on the average by diatoms (Brzezinski, 1985) provided upwelling is from depths greater than the crossover depth where the ratio of NO_3:$Si(OH)_4 \geq 1$. Under very strong upwelling $Si(OH)_4$ is likely to exceed NO_3 by a considerable amount, e.g., Bodega Bay, Monterey Bay and Aleutian Islands (Table 17.1). In low oxygen regions where denitrification has reduced the NO_3 content of upwelling water and $Si(OH)_4$ concentration has been augmented by the undercurrent in contact with the sediments, e.g., at 15°S Peru, the limiting nutrient may switch back and forth between NO_3 and $Si(OH)_4$ (Dugdale and Goering, 1970). Since diatoms are the major consumers of NO_3 in upwelling systems, low $Si(OH)_4$ concentrations relative to NO_3 become the primary limiting nutrient, controlling $Si(OH)_4$ uptake and NO_3

uptake as well (Dugdale and Goering 1970). White and Dugdale (1997) measured $Si(OH)_4$ and NO_3 uptake simultaneously in the Monterey Bay upwelling during 1992 and 1993 and showed that VNO_3 was stimulated by the addition of $Si(OH)_4$ in 20-L shipboard enclosure experiments. However Kudela and Dugdale (2000) determined that although $Si(OH)_4$ additions increased VNO_3 they did not result in accumulation of biomass. They described this upwelling region to be limited in the Liebig sense on NO_3 availability during most of the year and $Si(OH)_4$ to be regulating but not limiting. $Si(OH)_4$ concentrations in the surface water can become limiting when grazing or sinking occurs over a sufficiently long time due to the slower regeneration of $Si(OH)_4$ at the surface compared to N, the biologically active silicate pump (Dugdale *et al.*, 1995; Ragueneau *et al.*, 2002).

6.4. Interaction of iron and NO_3 uptake

The enhancement of diatom populations by addition of Fe to some oceanic regions with low Fe concentrations are well known. Some enclosure or grow out experiments carried out in coastal upwelling systems (e.g., Big Sur, California and some parts of the Peru coast) show similar effects, (Bruland *et al.*, 2005; Hutchins and Bruland, 1998; Hutchins *et al.*, 2002). Enhancement of NO_3 uptake with the addition of Fe is typically observed in these grow–out experiments in which NO_3 disappearance is followed (Chapter 38 by Hutchins and Fu, this volume). Some direct measurements in the field using ^{15}N incorporation have been made by Franck *et al.* (2005) who reported that upwelling areas with higher ambient Fe (i.e., Monterey Bay) had more $^{15}NO_3$ uptake by the larger phytoplankton (diatoms) than areas with less Fe (i.e., the eastern tropical Pacific). Studies of the effects of Fe on NO_3 uptake kinetics in upwelling areas are rare. Franck *et al* (2003) measured the effect of Fe on the kinetics of NO_3 and $Si(OH)_4$ uptake in water sampled from central California and showed a direct effect of Fe on V_{max} for both uptake systems (i.e., an effect on transporter synthesis). In the Pacific equatorial upwelling system, a co-limitation of new production by $Si(OH)_4$ and Fe was inferred since Si uptake kinetics were shown in the field to follow Michaelis–Menten (Leynaert *et al.*, 2001) and culture studies revealed Fe modification downward of the Michaelis–Menten hyperbolae (Leynaert *et al.*, 2004). More data on the effect of Fe on NO_3 uptake kinetics would be useful in understanding situations where co-limitation of NO_3 and Fe are likely to occur. If the effect of Fe is found consistently to affect the V_{max} for NO_3 uptake and is a general property of trace metal action (Dugdale, 1967) the problem of modeling co-limitation of primary and trace elements would be greatly simplified.

7. MODELING NITROGEN PRODUCTIVITY IN UPWELLING SYSTEMS

7.1. Ecosystem models of nitrogen flux

New production models in upwelling systems usually are constructed with nitrogen as the currency. Earliest simple models evolved from studies of the Peru upwelling system. For example, Dugdale and MacIsaac (1971) used a relationship between

specific NO_3 uptake (VNO_3) and NH_4 concentration to predict N-based growth rates. Walsh and Dugdale (1971) and Walsh (1975) employed a series of box-models trending offshore in simulating nitrogen flow in the 15°S, Peru upwelling plume, as was also used by Botsford *et al.* (2003) for the Bodega upwelling area. Wroblewski (1977) coupled a numerical model of upwelling circulation with one of NO_3 assimilation by phytoplankton to model nitrogen dynamics in the Oregon coastal upwelling region. Many models of nitrogen (and carbon) flux in coastal upwelling now include at least two forms of DIN (i.e., NO_3 and NH_4) (e.g., Ianson and Allen, 2002) usually incorporated through a Michaelis-Menten function and sometimes the inhibition of NO_3 uptake by NH_4 (e.g., Spitz *et al.*, 2003, 2005) and inclusion of DON (Olivieri and Chavez, 2000). Few include more than one size of autotrophic phytoplankton (Chai *et al.*, 2003).

Measurements made during drifter-following studies and experiments in large shipboard enclosures resulted in the shift-up concept (Fig. 17.4) and a conceptual model of algal physiological responses from upwelling to NO_3 exhaustion (see Section 17.4; MacIsaac *et al.*, 1974, 1985; Wilkerson and Dugdale, 1987). Model simulations by Zimmerman *et al.* (1987) showed the concept of acceleration (shift-up) of VNO_3 to be necessary to predict realistic time courses of NO_3 utilization. Their model gave boundaries where low NO_3 concentrations and high mixed layer depth precluded shift-up and high new production rates, as nutrients or light were insufficient for the up-regulation of physiological responses. The different boundaries measured in upwelling systems were used to estimate the optimal conditions for each.

Dugdale *et al.* (1990) then quantified the nitrogen-based physiological shift-up model of Zimmerman *et al.* (1987) to compare the uptake efficiency/performance of different upwelling systems. Using the initial (maximum) NO_3 concentration characteristic of each system, the maximum NO_3 uptake that could be achieved was calculated, following acceleration of uptake. This enabled the ''r'' or realization of maximal new production to be evaluated and compared amongst upwelling areas.

Until very recently, the resolution of physical models for coastal upwelling was too coarse to be useful for modeling biological processes. However, with increased computer power now available, physical models can resolve the plumes produced by topographical variations along upwelling coasts and are being combined with biologically derived models to predict nitrogen fluxes. For example, the regional NCOM-CCS (Navy Coastal Ocean Model-California Current System) model for the United States West Coast (Shulman *et al.*, 2004); a global circulation model used for ocean prediction now includes a one dimensional biological model (Chai *et al.*, 2003) based mainly upon the biological flux of nitrogen. This biological model was modified from the CoSINE (Carbon, Silicon, Nitrogen Ecosystem) ecosystem model originally developed for the equatorial Pacific upwelling system (Chai *et al.*, 2002; Dugdale *et al.*, 2002) that includes different forms of DIN, Si $(OH)_4$, different sized phytoplankton and interactions of NH_4 and Fe on phytoplankton metabolism. It has also been applied to the California coastal upwelling system (Klein 2003). In the next decade, with increased computing power and more ecophysiological information (e.g., nutrient-nutrient interactions, uptake

versus light relationships, species specific fluxes) available, accurate forecasting of new production and phytoplankton blooms for different eastern boundary upwelling systems will be possible.

7.2. Physical models to estimate new production

Rates of new production have been measured indirectly in upwelling areas from physical estimates of NO_3 fluxes into the euphotic zone (i.e., using the volume of water upwelled and the NO_3 it contains). This was first applied to equatorial upwelling (e.g., Carr et al., 1995; Chavez and Barber, 1987; Lewis et al., 1986), but has also been used in the Peru upwelling region (Chavez and Barber, 1987) and globally for all coastal upwelling systems by Walsh (1991). This approach was also used by Chavez and Toggweiler (1995) to estimate the global fraction of new production that is tied directly to upwelling, by differentiating NO_3 input attributed to wind driven upwelling (coastal) from that supported by vertical mixing or other processes. Their ''crude'' calculations suggest that 11% of global new production is supported directly by coastal upwelling.

7.3. Models to estimate new production from remotely-sensed data

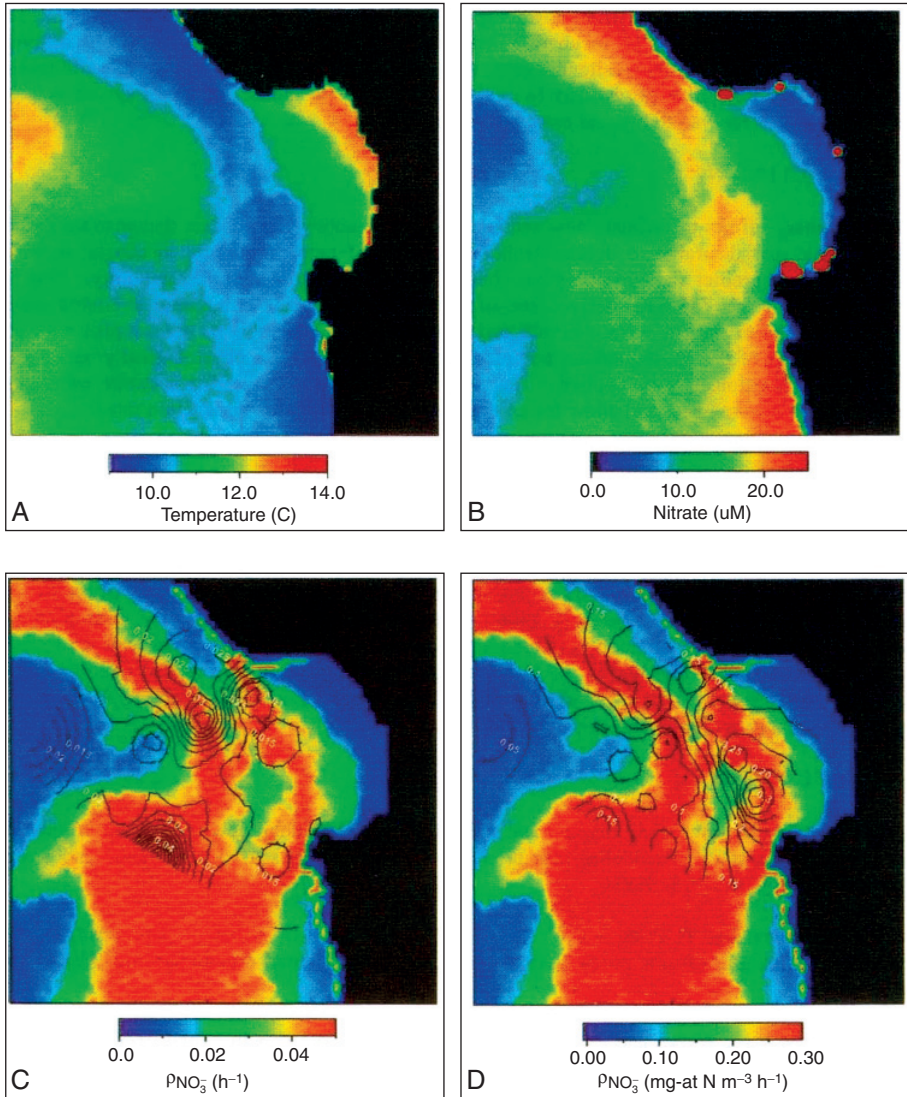
The highly dynamic nature of coastal upwelling, in which the driving meteoro- logical conditions change on short time scales, days and weeks, makes it difficult to sample the system synoptically with ships. One solution is to employ remote sensing and there have been many models developed for estimating primary production in coastal upwelling areas from satellite data (e.g., Bricaud et al., 1987; Carr, 2002; Carr and Kearns, 2003; Gabric et al., 1993). Most depend upon estimation of chlorophyll concentrations at the surface and a series of assumptions about vertical distribution of chlorophyll and incident irradiance. However models of new production have been developed using the relationship of NO_3 and temperature in upwelling areas (e.g., Sathyendranath et al., 1991). An early version (Dugdale et al., 1994) of such a nutrient oriented remote sensing model for an upwelling system used the relationship between remotely sensed sea–surface temperature (from AVHRR imagery) and NO_3 concentrations, combined with a mean value of NO_3 uptake from existing ^{15}N uptake measurements. A similar approach (combined with temperature versus $Si(OH)_4$ relationships) calculated $NO_3:Si(OH)_4$ ratios based upon AVHRR derived surface temperatures and showed that new production in the eastern equatorial Pacific might be limited by $Si(OH)_4$ (Wilkerson and Dugdale, 1996). More complex models were devel- oped for coastal upwelling areas to estimate new production from remotely sensed temperature and ocean color. These employed temperature to estimate nutrient concentrations and time since upwelling, and incorporated the shift–up concept (Dugdale et al., 1990). The first such model was generated for the northwest Africa upwelling center at Cap Blanc (Dugdale et al., 1989) and later applied to the upwelling areas of Monterey Bay (Fig. 17.7; Kudela, 1995; Kudela and Dugdale, 1996) and Point Conception, California (Dugdale et al., 1997). Kudela and Chavez (2000) input temperature and chlorophyll from moorings, rather than from


Figure 17.7 New production modeled from remotely sensed sea surface temperature, a 3 day composite for Monterey Bay, California. (A) AVHRR derived temperature, °C, (B) modeled surface NO$_3$, μM, (C) VNO$_3$, h^{-1} and (D) ρNO3, μmol l^{-1} h^{-1} with superimposed contours of shipboard ^{15}N uptake data. From Kudela and Dugdale (1996).

satellites, into the same model to evaluate the spatial impact of the 1992 El Niño on new production in Monterey Bay. Both satellite observations and mooring data were used later (Kudela and Chavez, 2002) to compare new production in Monterey Bay during the 1997–8 El Niño and subsequent La Niña conditions. Models that ignore the phytoplankton nutrient processes in upwelling are unlikely

to be successful, since the new production in upwelling systems will be proportional to the flux of new nutrient to the surface regions, the product of the upwelling rate and the concentration of source nutrients which may vary by factors of three or more (Table 17.1).

8. MOLECULAR APPROACH TO STUDYING NITROGEN ASSIMILATION

The uptake and metabolism of N is controlled by a number of key enzymes, which provide good molecular targets for studies of these processes in natural communities (see Chapter 7 by Mulholland and Lomas, this volume). Recent advances in isolating genes and obtaining entire genome sequences have enabled the development of specific gene probes for different members of the phytoplankton community. Molecular approaches can now be used to examine what components of the phytoplankton population have the capacity to synthesize and make the correct enzymes to assimilate different forms of N in response to environmental factors. Before this, our understanding of nitrogen dynamics in upwelling areas was restricted to measuring bulk changes in water constituents by the entire phytoplankton community (i.e., the particulate fraction that is caught on a filter). Traditional methods, such as tracer techniques (Chapter 31 by Lipschultz, this volume) or measuring enzyme assimilation rates (e.g., Berges, 1997; Berges and Harrison, 1995; Berges *et al.,* 1995; Slawyk *et al.*, 1997; Chapter 32 by Berges and Mulholland, this volume) provide nitrogen uptake/assimilation (productivity) rates, but do not identify the major players involved in mass transformation, or the physiology of the phytoplankton involved. Information on the response and physiology of specific phytoplankton groups, or breaking open the phytoplankton ''black box,'' provides a mechanistic understanding of observed rates of biogeochemical transformations. Molecular genetic techniques are beginning to be applied to the study of nitrogen cycling processes in marine systems (for review see Zehr and Ward, 2002; Chapter 30 by Zehr and Jenkins, this volume), where species- and group-specific information on the physiological/biochemical responses of marine microbes can be obtained (e.g., Cooksey 1998; Zehr and Voytek, 1999).

There has been an explosion of molecular genetic technologies becoming available and constantly being improved in the last decade. In particular QPCR (quantitative polymerase chain reaction) used with reverse transcription, can provide quantitative measurements of gene expression of functional genes involved in nitrogen assimilatory processes by specific microbial cells. Such approaches are being developed to study the molecular basis for biogeochemical changes (e.g., Parker and Armbrust, 2005) and variability in acceleration/adaptation of N uptake and new production rates in simulated upwelling studies. Smith *et al.* (1992) in a laboratory study to simulate upwelling measured the response of the gene for the major NO_3 assimilation enzyme, nitrate reductase (NaR) in light- and N-limited diatom cells of *Skeletonema costatum* when given an increase in light and NO_3 availability. They showed increases in levels of

NaR–specific messenger RNA (i.e., showing increased transcription of the gene for NaR) that coincided with the acceleration (shift-up) in NO_3 assimilation measured with ^{15}N. To be able to use gene expression as a proxy for species-specific flux or productivity, there first needs to be sufficient sequence data and identification of genes involved in N uptake in target microbial cells expected in these upwelling systems. Other chapters (e.g., Chapter 30 by Zehr and Jenkins, this volume; Chapter 7 by Mulholland and Lomas, this volume) describe our knowledge to date for prokaryotic members of the microbial community. However, in coastal upwelling areas, since phytoplankton communities are dominated by the eukaryotic diatoms, sequences are required for genes for N assimilation by this eukaryotic group, and these are limited at the present time (see below and Armbrust *et al.*, 2004).

Diatoms take up NO_3 and NH_4 via membrane transporters and assimilate NO_3 using assimilatory nitrate and nitrite reductase (NaR and NiR), and NH_4 using glutamine synthetase (GS) and glutamate synthase (GOGAT) (see Chapter 7 by Mulholland and Lomas, this volume, for detailed descriptions). Genes for a number of diatom nitrogen transporters have been identified. Hildebrand and Dahlin (2000) and Hildebrand (2005) first described NO_3 and NH_4 transporter genes (*hnat* and *amt*, respectively) in *Cylindrotheca fusiformis*. The whole genome analysis of *Thalassiosira pseudonana* yielded a genome that encodes multiple NO_3 and NH_4 transporters (Armbrust *et al.*, 2004). Few gene and protein sequences for nitrate reductase (NaR) have been well characterized from eukaryotic algae. Song and Ward (2004) characterized the gene for nitrate reductase (*nar*) from the eukaryotic green alga *Dunaliella tertiolecta* and showed it to be positively regulated by the presence of NO_3 rather than negatively regulated by NH_4. Allen *et al.* (2005) have sequenced the complete NaR gene for the pennate diatom *Phaeodactylum tricornutum* and designed PCR primer sets that are able to amplify NaR fragments in other diatom strains (including *Skeletonema costatum, Chaetoceros mulleri, Thalassosira pseudonana, T. oceanica, T. weissflogi, Coscinodiscus granii,* and *Asterionellopsis glacialis*). These primer sets were also used to amplify diatom specific NaR fragments in DNA samples collected in Monterey Bay indicating that nitrate reductase specific DNA of diatoms can be tracked in field studies. This demonstrates that DNA and RNA based methods can target diatom specific nitrogen assimilation genes in coastal upwelling ecosystems. Poulsen and Kroger (2005) also showed that NaR expression was inducible in transgenic *Cylindrotheca fusiformis* when cells were given NO_3. This offers a genetic manipulation approach to understand the relative expression of NaR genes in simulated upwelling conditions.

NH_4 assimilation occurs by the action of GS and GOGAT (Wheeler, 1983; Falkowski, 1983). The source of NH_4 may be externally supplied or internally as a product of NO_3 reduction or photorespiration. Consequently GS activity gives a measure of both regenerated (based on NH_4) and total productivity (based on NO_3 and NH_4) and is commonly measured in studies of algal physiology (e.g., Slawyk *et al.*, 1997; Slawyk and Rodier, 1986; Rees *et al.*, 1995). Two different isoforms of eukaryotic algal GS proteins have been described based upon their size: GS II that is found in eukaryotes (Chen and Silflow, 1996 in *Chlamydomonas reinhardtii*; Pesole *et al.*, 1991) and GS III which has been identified in diatoms and some other

eukaryotes (Robertson and Alberte, 1996; Robertson and Tartar, 2006; Robertson et al., 1999; 2001), although it was first described in bacteria (as described in Kumada et al., 1993). It has been suggested that one isoform is found in the cytoplasm of the cell and functions to assimilate external source of NH_4 whereas the other is located in the chloroplast (where nitrate reductase is found) and is responsible for assimilating NH_4 that has resulted from NO_3 reduction (reviewed in Anderson, 1999). To establish whether GS II and GS III might have these different functions in diatoms, Takabayashi et al (2005) measured expression of the gene responsible for GS II (*gln II*) in *Skeletonema costatum* cells grown with either elevated NO_3, or NH_4 or both forms of DIN. GS II gene expression increased in cells taking up NO_3. GS II-specific messenger RNA (i.e., transcript abundance of *gln II*, the gene that encodes for the enzyme isoform GS II) and total GS enzyme activity were increased 2–3.5 times above background in cells taking up NO_3 but not cells taking up NH_4. This confirms that GS II is using NH_4 derived from NO_3. The addition of NO_3 results in *gln II* transcription being induced to express the GS II isoform, which catalyzes assimilation of NH_4 that has been made available by reduction of NO_3 and NO_2 by NaR and NiR. Because of this specific role of GSII in diatoms assimilating NH_4 derived from NO_3 assimilation rather than NH_4 taken up directly from the environment, quantification of GS II gene expression (i.e., *gln II* mRNA) promises to be a useful indication (or proxy) of new production by phytoplankton (Takabayashi et al., 2005). In a simulated upwelling study using *Skeletonema costatum* in which cells were shifted into high light, there was a rapid increase in GS II gene expression measured as *gln II* mRNA using quantitative PCR (Barada, 2006). This indicates that the high light shift-up (Fig. 17.4) of physiological response may have a molecular basis.

9. Conclusions and Directions

The original chapter on ''Nitrogen in Upwelling Ecosystems'' written in 1983 by Codispoti described standing stocks and nutrient concentrations with some limited studies of rates of DIN uptake usually using ^{15}N and some measurements of N assimilation enzyme activities. Researchers were beginning to understand the importance of organic forms of DON (e.g., Whitledge, 1981) and had started to develop biological models of N flux to combine with physical simulation models (e.g., Walsh and Dugdale, 1971). Since then focus has been on understanding what components of the phytoplankton community are doing most of the N assimilation and flux, and how other nutrients interact in N flux. Taxonomic studies (e.g., Blasco et al., 1981; Jimenez, 1981; Rojas de Mendiola, 1981) pointed the way to the importance of diatoms and the larger phytoplankton in the coastal upwelling communities. So in the 1990s, studies of N flux were aimed at measuring size fractionated ^{15}N uptake to evaluate new production (or NO_3 flux) by this component (e.g., Franck et al., 2005; Wilkerson et al., 2000). With new molecular genetics techniques, the diatoms can be specifically targeted and we should expect to see many more studies using molecular probes for N assimilation to discern gene expression by the different components of the alga community. This

will let us understand the mechanisms used by diatoms to outcompete the pico–plankton for NO_3, and whether all phytoplankton (e.g., the picoplankton) have the capacity to assimilate all forms of DIN. With the molecular tools, studies of how different parts of the N assimilatory pathway can also be examined such as how or when transporters are switched on following upwelling of cells into the well lit nutrient rich surface waters, compared to the assimilatory enzymes, nitrate reductase and glutamine synthetase.

Although there was awareness of how DIN uptake could be modulated by other nutrients, such as $Si(OH)_4$ (Dugdale *et al.*, 1981) and micronutrients (Dugdale, 1967), the importance of studying these interactions has increased in recent years. Even so, specific experiments designed to measure the interactions are rare. Future research in upwelling will be sure to include laboratory based experiments and ship board enclosure/mesocosm experiments (e.g., Franck *et al.*, 2005; Joint *et al.*, 2002; Kudela and Dugdale, 2000) to study such interactions. The analysis of kinetics of nitrogen uptake has become more complicated since 1983 as evidence for linear uptake at high substrate concentration has accumulated (e.g., Collos *et al.*, 2005) and earlier evidence of multi–phasic uptake mechanisms corroborated. As expressed by Collos *et al.* (2005) more in-depth studies of DIN uptake kinetics that can occur in upwelling systems and what modulates them are required, both at the physiological and molecular level.

Another aspect of N flux in coastal upwelling studies that has ramped up since 1983 has been our ability to model the biological transformations taking place within the upwelling ecosystem, both so N flux can be measured indirectly from some other parameter such as vertical advection or from remotely sensed sea surface temperature, and also for inclusion in global ocean flux models. Most global ocean flux models use global circulation models with embedded ecosystem models. Since a significant proportion of the global marine biological production and natural carbon burial occurs in eastern boundary coastal upwelling areas (Walsh, 1991) due to the active nature of the biological pump in these eutrophic waters, accurate ecosystem models for these regions are required. Future coastal upwelling models will need to incorporate the results of our proposed future directions: i.e., advanced kinetics for N uptake, N flux capabilities of different components of the autotrophic community and the interaction of N flux with other nutrients and micronutrients. Although many advances have been made in understanding and modeling nitrogen fluxes in upwelling systems there are many more avenues to be explored and questions to answer.

CHAPTER 18

ESTUARIES

Walter R. Boynton *and* W. Michael Kemp

Contents

1. INTRODUCTION

In the first edition of this book, Nixon and Pilson (1983) began their chapter on nitrogen in estuaries by indicating it was an exciting and challenging time to be engaged in such studies. In the two decades since, that assessment continues to apply. In fact, studies of nitrogen (N) in estuarine ecosystems have so greatly expanded, intensified, and diversified that it is a challenge to capture even highlights of progress in this hyperactive area of research.

Why have so much intellectual and other forms of capital been devoted to understanding N in estuarine ecosystems? A case can be made that a central work stimulating N investigations in estuarine systems was Ryther and Dunstan's (1971) paper in Science where they concluded, based on nutrient ratios and bioassay experiments, that N rather than P limited coastal algal growth and eutrophication and that reductions in P inputs to these systems would have little restorative effect. Prior to this, and for many subsequent years in some regions of the world, it was generally believed that P limited primary production, if indeed any essential element was limiting in estuaries. In a limited number of estuaries it was known that relatively large loads of N and P entered these systems. However, light was often thought to be limiting in typically turbid estuarine waters and short water residence times (compared to many lakes) were believed to rapidly transport nutrients from estuaries before biota could make use of these compounds (e.g., Schindler, 1981). A decade later the book Estuaries and Nutrients appeared (Neilson and Cronin, 1981) and for the first time there was a broad examination of nutrients in estuarine ecosystems. Papers included reviews and a few syntheses (e.g., Nixon, 1981), case studies from a limited number of estuarine ecosystems, and a few examples of estuarine responses to nutrient management efforts (Jaworski, 1981; Smith, 1981).

By the early to mid-1980s it became increasingly clear to many government agencies and environmental advocacy groups that something was seriously wrong with some estuarine systems (e.g., D'Elia et al., 2003; Malone et al., 1993). During this time several of the large estuarine restoration programs began in such sites as Long Island Sound, Chesapeake Bay, Tampa Bay and San Francisco Bay. With these programs came ambitious monitoring efforts where nutrient inputs from major rivers were gauged, point sources of nutrients were documented and estuarine nutrient concentrations, as well as other chemical (e.g., dissolved oxygen) and biological (e.g., chlorophyll a) variables, were routinely measured, often at many sites. A real estuarine data avalanche had begun and continues today; however, it also appears that many of these data sets remain severely under-analyzed. Bricker et al. (1999) produced a qualitative evaluation of water quality and habitat conditions in USA estuaries that included some 143 systems, again indicating the broad distribution of activities in these ecosystems. This trend has included sharp increases in the number of reported rate measurements and associated improvements in measurement techniques including measurements for rates of nutrient inputs to estuaries, primary production, denitrification rates, sediment-water exchanges of N, P and C, deposition of organic matter, burial of particulate nutrients, and others.

Given two decades of measurement frenzy since 1984, some have asked, what does all this mean? Are these systems all different or do they share some fundamental similarities? Do they respond to N loads in some understandable fashion, are internal losses of N proportional to loads and are there estuarine features that regulate the magnitude of N export to the coastal ocean? How do nutrients shape the structure and function of estuarine food-webs? There is an emerging, and hopefully accelerating, pattern of estuarine data synthesis taking place and N plays a prominent role in these efforts. Early work along these lines (e.g., Boynton et al., 1982; Nixon, 1981) indicated the importance of N in regulating algal primary production and

biomass, and Nixon substantially expanded comparative estuarine analyses to include aspects of nutrient cycling (Nixon, 1981) and secondary production (Nixon, 1982, 1988, 1992). Monbet (1992) related algal biomass in a large number of European estuaries to N concentrations after classifying sites according to tidal range. More recently, nutrient budgets have been used as a quantitative framework to organize diverse data sets towards testing our understanding of N dynamics at the level of whole ecosystems (e.g., Boynton *et al.*, 1995; Nixon *et al.*, 1996; Wulff *et al.*, 1990).

Degradation of estuarine environments prompted much of the interest in estuarine research and it now appears that nutrient-based eutrophication has become a central estuarine research theme, just as it did in limnology where this theme had the effect of unifying theoretical and applied aspects of that discipline. In recent years several reviews and syntheses have appeared with eutrophication being the core issue and considerations of N playing a very prominent role. Kelly (2001) and Rabalais (2002) reviewed N effects on coastal marine ecosystems, Cloern (2001) proposed several versions of a new eutrophication conceptual model and Smith (2003) reviewed and compared eutrophication responses of primary producers in lake, reservoir, marsh and estuarine systems (see also Chapter 11 by Paerl and Piehler, this volume). While it is clear that much needs to be done, it is equally clear that understanding of N in estuarine ecosystems has improved during the two decades since publication of Nitrogen in the Marine Environment (Nixon and Pilson, 1983).

The goal of this chapter is to provide an overview of advances during the past 20 years in our understanding of N in estuarine ecosystems and to suggest some fruitful directions future research might take. We have taken advantage of recent reviews, added information to several existing syntheses and generated several new summaries and syntheses from the almost overwhelming amounts of estuarine N data available. Three data summaries were developed specifically for this paper and these included N and P concentrations in the water columns of a variety of estuaries (Frank *et al.*, 2007), aquatic denitrification rates (Greene, 2005a), and estuarine sediment-water solute fluxes (Bailey, 2005). In this review we have: (1) examined N concentrations from a wide variety of estuaries to describe distinct spatial-temporal patterns in relation to season and climate, (2) reviewed, compared and expanded reported N-budgets for estuarine systems, (3) compiled extensive data on sediment–water fluxes of N and other solutes and examined regulating factors, (4) summarized and compared annual patterns and rates of phytoplankton primary production in relation to nutrient limitation, and (5) reviewed current concepts concerning interactions between N and both trophic state and secondary production in estuaries.

2. Distribution of Dissolved Nitrogen in Estuarine Waters

During the last twenty years, water column concentrations of dissolved N were probably the most intensively measured feature of N in estuarine environments. For example, about 8000 measurements of each of the common dissolved N species (i.e., NO_2, NO_3, NH_4 and dissolved organic nitrogen) were made per year for the

past twenty years as part of routine monitoring in Chesapeake Bay (Chesapeake Bay Water Quality Monitoring Program, 2004). Similar measurement programs have been gathering N concentration data for a decade or more (e.g., Danish estuaries, Conley *et al.*, 2000; Tampa Bay, Greening and DeGrove, 2001). In this section we review earlier efforts describing N distributions, provide some comparative analyses of N concentrations gleaned from examination of data compiled from many estuaries and conclude with a more detailed description of N distributions in Chesapeake Bay where these compounds have been measured at many sites and under variable climate conditions for several decades.

2.1. Previous examinations of nitrogen distributions

Earlier reviews of N distributions struggled to gather sufficient nutrient data to search for commonalities or differences among estuaries, but the current challenge is to organize the huge number of measurements into some tractable form. Given the enormous increase in the number of observations available, it's appropriate to ask what we have learned. Are there a limited number of N distribution patterns among estuarine systems or is variability in space and time the dominant feature? Estuarine characteristics such as river flow, depth, degree of stratification, water transparency, autotrophic community composition, and water residence time all influence N distributions. Since these characteristics vary widely both within and among estuaries we might expect reactive N-compounds to do the same.

Boynton *et al.* (1982) organized seasonal–scale dissolved inorganic nitrogen (DIN) and dissolved inorganic phosphorus (DIP) data from 28 estuarine systems and reported that concentrations of DIN ranged from <1 to 60 µM at the time of the year when phytoplankton production was at a maximum (generally during summer). In addition, DIN: DIP ratios in 75% of these systems were less than 10 during the period of highest production, suggestive of N-limitation, although ratios varied widely during the year, especially in river dominated estuaries. Nixon and Pilson (1983) examined nutrient concentrations in more detail from about a dozen USA estuarine systems. They also noted an extreme range in N concentrations among estuaries (0.1 to >200 µM) and found estuaries where DIN was very depleted in the water column, always abundant, or seasonally variable; the limited data available in the early 1980s may have largely prevented finding clear patterns of N concentration among estuaries.

In a recent and comprehensive review of 81 Danish estuaries it was reported that nutrient loading rate explained about 70% and 55% of the annual variation in total nitrogen (TN) and total phosphorus (TP) concentrations, respectively (Conley *et al.*, 2000). Concentrations of both DIN and TN were highest during winter and lowest during summer. The relative uniformity in annual patterns of N and P concentration in Danish estuaries is consistent with the similarity in their structure, with most being small and shallow, with relatively short water residence times and heavily loaded with agricultural N and P. A large estuarine characterization was completed by Bricker *et al.* (1999) in which 143 estuaries, representing about 90% of USA estuarine surface area, was examined for symptoms of eutrophication. Nitrogen was identified as a major cause of eutrophication, but this effort stopped short of examining data for patterns of N distribution.

Twenty years ago issues concerning dissolved organic nitrogen (DON) were just emerging onto research agendas, measurement techniques were in early stages of development, little was known concerning the various compounds comprising the DON pool, sources and sinks were not well established, and there were only a limited number of measurements available. Much has changed concerning all of these issues, resulting in the development of several important reviews, one from just over a decade ago (Antia et al., 1991) and two more recent works (Berman and Bronk, 2003; Bronk, 2002). Additionally, Burdige and Zheng (1998) developed a summary of DON exchanges between water and sediments in coastal and estuarine systems. We have added several more total dissolved nitrogen (TDN) and DON concentration measurements to those provided by Berman and Bronk (2003; Table 18.1). Several important points are clear. In most estuaries DON ranges from an important (30–40%) to the dominant (>80%) component of the dissolved N pool. DON is operationally defined but is actually a complex mixture of N-compounds with widely differing chemistries, sources and sinks. We echo here the conclusions of Berman and Bronk (2003) that DON is not just a conservative N pool, can have strong source and sink pathways in estuaries and needs more explicit consideration in evaluations of the N economy of estuaries.

2.2. Comparative examination of nitrogen distributions

We re-visited the issue of water column N distributions to see if we could find distinctive seasonal patterns related to estuarine type, location within an estuary and climate variability (i.e., wet, dry, average inflow conditions). We obtained ammonium (referred to hereafter as NH_4), nitrite (NO_2), nitrate (NO_3), and phosphate (PO_4) concentration data from 44 USA estuarine systems. Several locations (e.g., tidal freshwater, oligohaline, mesohaline, polyhaline) were selected in some systems and in a dozen cases we also obtained concentration data during dry, average and wet years (Frank et al., 2007).

Annual $NO_2 + NO_3$ concentrations in surface waters of 44 estuarine sites ranged from 0.05 to 150 µM (Fig. 18.1). Highest concentrations tended to occur in river dominated estuaries and lowest in dry and sub-tropical systems. As expected, concentrations were highest in tidal freshwater or oligohaline locations and decreased seaward. Despite the fact that all data in Fig. 18.1 were collected during average inflow years the range in concentrations was large. This is likely a reflection of the multiple factors, including N input rates, water residence times, and biological uptake, which influence concentrations. In a smaller set of estuaries, $NO_2 + NO_3$ concentrations were available for dry, average and wet years (Fig. 18.2). In Chesapeake Bay there were large differences in concentration between dry and wet years in the polyhaline and mesohaline sites; $NO_2 + NO_3$ was always high in the oligohaline zone because of proximity to the riverine N-source and limited uptake by phytoplanlton in this turbid portion of the system. Systems as different from Chesapeake Bay as Florida and Tomales Bays exhibited similiar but muted patterns. Differences between wet and dry year $NO_2 + NO_3$ concentration were very small or reversed in four of these systems indicating that generalities, even concerning such a common compound as $NO_2 + NO_3$, are hard to find.

Strong seasonal patterns were evident for $NO_2 + NO_3$ and PO_4 concentrations (Fig. 18.3). Nitrite + nitrate concentrations were highest during winter; if winter and

spring frequencies of maximum concentration are combined, then 80% of all maximum concentrations occurred during these seasons. Seasonal minimum concentrations mainly occurred during summer. Seasonal maximum PO_4 concentrations generally occurred during summer or fall, opposite the pattern observed for $NO_2 + NO_3$. Seasonal minimum concentrations of PO_4 were most frequently observed during spring, the time of the year that P has been found to limit spring diatom blooms (e.g., Fisher *et al.*, 1999). DIN: DIP ratios were also computed and grouped by categories as a frequency histogram (Fig. 18.4). The most frequently encountered category was less than 10:1 (40%) which suggests potential N-limitation, and almost 60% of all ratios were less than 20:1. The seasonal differences in N (high in winter-spring) and P (high in summer-fall) concentrations certainly play into creating this distribution of ratios. Given that nutrient inputs to many estuarine ecosystems are rich to very rich in DIN relative to DIP, net biogeochemical processes tend to reduce dissolved N concentrations relative to dissolved P concentrations.
Figure 18.4 Frequency distribution of DIN:DIP ratios computed for a variety of USA estuarine systems. Data were compiled by Frank *et al.* (2007).

2.3. Detailed distributions in Chesapeake bay

While the analyses presented above suggest a wide range of variability in N distributions among estuarine systems, here we examine temporal and spatial patterns for one well-studied estuarine system. An intensive monitoring program in Chesapeake Bay and its tributaries during the past twenty years has experienced a wide range of hydraulic conditions. We summarized N distribution data to illustrate effects of season, location, depth and hydrology.

Monthly surface water nitrate concentrations in three salinity regions (oligohaline, mesohaline and polyhaline) in Chesapeake Bay are displayed as box and whisker plots and as mean values for wet or dry (i.e., high or low river flow) conditions (Fig. 18.5). Strong seasonal patterns are evident throughout the system for wet years and for dry years in all but the polyhaline. Differences between NO_3 concentrations in wet and dry years were pronounced in winter and spring but disappeared during fall. Differences in NO_3 concentrations with river flow in the mesohaline region were similar to the range in algal biomass observed between wet and dry years (Boynton and Kemp, 2000). Peak concentrations occurred in the polyhaline region only a month after the seasonal peaks occurring 300 km farther up the Bay. Harding and Perry (1997) reported the largest changes in algal biomass in the polyhaline zone during a 50 year period of increased nutrient loading, consistent with the NO_3 distribution pattern found between wet and dry years.

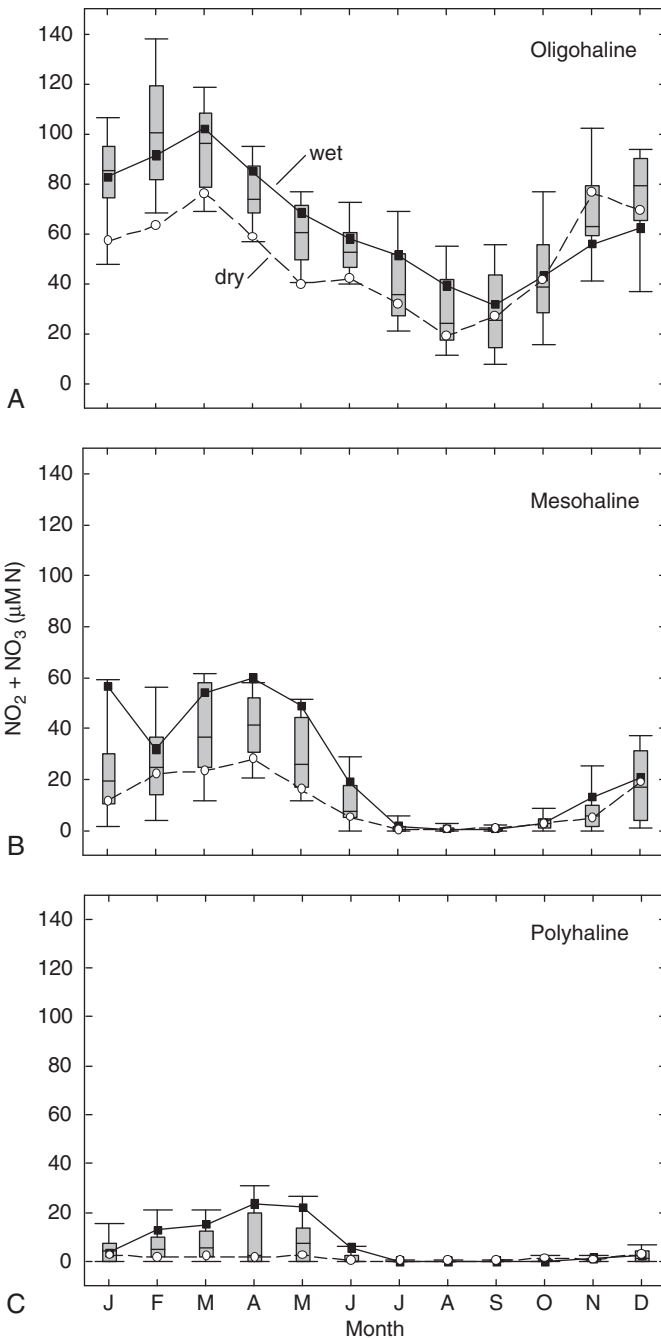
Whereas higher nitrate concentrations in surface (compared to bottom) waters reflect NO_3 sources in watershed runoff, higher concentrations of NH_4 in bottom waters derive from recycling processes occurring in the aphotic sediments (Fig. 18.6; Kemp and Boynton, 1992). Seasonal variations in bottom water NH_4


Figure 18.5 Surface water $NO_2 + NO_3$ concentrations measured at stations located in the oligo–haline (A), mesohaline (B), and polyhaline (C) regions of Chesapeake Bay. The box and whisker plots contain all values for each month in the 20 year data set (1985–2004). Dark squares and circles represent $NO_2 + NO_3$ concentrations during all wet and dry years, respectively, in this 20 year data set. Data were from the Chesapeake Bay Water Quality Monitoring Program (2004).

Figure 18.6 Surface and bottom water NH_4 concentrations measured at stations located in the oligohaline (A), mesohaline (B), and polyhaline (C) regions of Chesapeake Bay. Monthly or bi-monthly data in the 20 year data set (1985–2004) were averaged to seasons. Data were from the Chesapeake Bay Water Quality Monitoring Program (2004).

concentrations were most pronounced in the stratified portions of Chesapeake Bay, particularly in the mesohaline and polyhaline area, where deposited phytoplankton blooms provided labile substrate for decomposition processes. Seasonal patterns and vertical differences in NH_4 were not as evident in the oligohaline portion of the Bay, probably because of stronger vertical mixing and less deposition of labile phytode-tritus. During years of very high river discharge, summer peak NH_4 concentrations in bottom waters of the mesohaline, and even the polyhaline Bay, clearly reflected these flow conditions.

Finally, we examined the seasonal distribution of NO_3 along the salinity gradient of the Patuxent River estuary, a tributary of Chesapeake Bay (Fig. 18.7). While these "mixing diagrams" have inherent interpretive limitations (e.g., Nixon and Pilson, 1983), these plots of nitrate concentration versus salinity provide a format to examine variations in non-conservative processing of NO_3 with seasons and hydro-logic conditions. The most consistent feature of these data is the very rapid disap-pearance of NO_3 in low salinity regions during summer under all flow conditions. In contrast, the non-conservative sink behavior of nitrate clearly evident in summer is barely apparent during winter. In addition, concentrations in the tidal freshwater estuarine zone tend to be higher and lower during dry and wet winters, respectively, suggestive of solute dilution with increasing river flow. These seasonally modulated patterns of NO_3 loss in excess of dilution are not as evident for NH_4 or PO_4, both of which exhibited more spatial variability and strong indications of internal sources, probably related to intense remineralization in the sub-pycnoline water column and bottom sediments (e.g., Kemp and Boynton, 1984).

3. Nitrogen Budgets of Estuarine Systems

Although many data have been collected and reported concerning N in estuaries only a limited portion has been used to support development of quantita-tive N-budgets, at the scale of whole ecosystems. Given the early interest in quantifying the sources and fate of N (e.g., Johnstone, 1908), there have been surprisingly few published quantitative estuarine N-budgets. Most of these report rates of N inputs, internal losses and downstream exports for whole estuaries at annual time scales. Nixon *et al.* (1996) have organized annual-scale nutrient budgets for nine estuarine ecosystems.

3.1. Inputs of nitrogen to estuaries

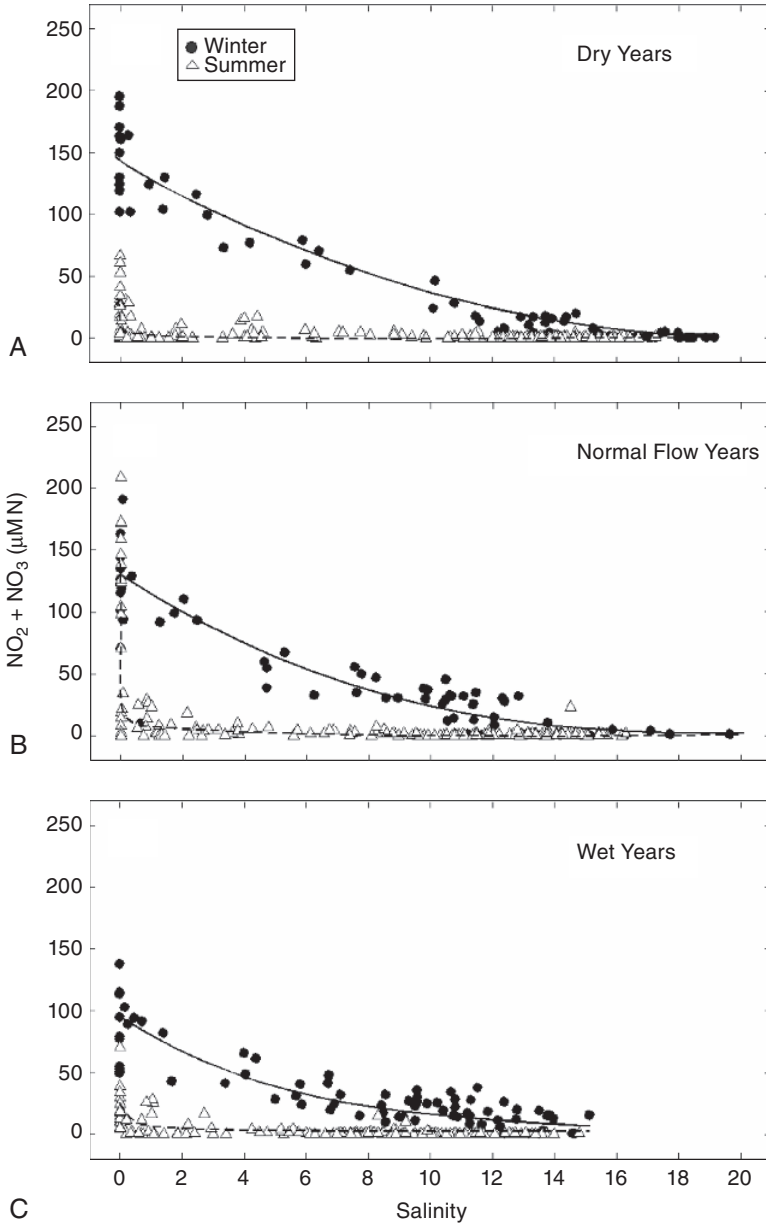
Both the scope and detail of information currently available concerning N inputs to coastal and estuarine waters has changed dramatically since the early work of Meybeck (1982) who reported strong correlations between N concentrations and features of drainage basins (e.g., population density) for 30 rivers. During the late 1980s NOAA organized nutrient load estimates for many estuaries in the USA (e.g., Bricker *et al.*, 1999). More recently, Smith *et al.* (2003) updated the global-scale analysis of Meybeck (1982) using data from 165 rivers to demonstrate that: (1) N and


Figure 18.7 Salinity versus concentration plots for $NO_2 + NO_3$ during dry, average and wet years in the Patuxent River estuary. Summer and winter values are shown in each panel. Data were from the Chesapeake Bay Water Quality Monitoring Program (2004).

P loads were statistically related to population density and runoff per unit land area, (2) N and P loads were closely correlated to each other despite different biogeochemistries, (3) loads to coastal waters had increased by a factor of about three since the 1970s. Estimates of future loads to estuaries and the coastal ocean suggest another doubling by 2050 (e.g., Kroeze and Seitzinger, 1998; Chapter 18 by Seitzinger and Harrison, this volume).

Detailed assessments have been reported for anthropogenic N loads to specific river basins and associated riverine N export to adjacent estuaries and coastal waters. Nitrogen exports from a diverse sampling of coastal landscapes appear to be on the order of 20–25% of anthropogenic inputs (Boyer et al., 2002; Castro et al., 2003; Howarth et al., 2002; Van Breemen et al., 2002). A variety of nutrient load models and techniques have also been developed, ranging from those having complex mechanistic structures and goals of high spatial and temporal resolution (Costanza et al., 2002) to simpler, more tractable models designed for use in particular landscapes (e.g., Carmichael et al., 2004; Jordan et al., 2003; Valiela et al., 1997) to very ambitious statistical models used at continental scales (e.g., Smith et al., 1997).

Several recent analyses of nitrogen loads to estuarine systems have been based on direct measurements of loads from riverine and point sources (possible ocean inputs not considered). For example, Conley et al. (2000) reported N-loading rates to 81 Danish estuaries for a 7 year period, Nedwell et al. (2002) reported DIN loads to 93 mainland United Kingdom estuaries and Carmichael et al. (2004) estimated N loads to 15 small Cape Cod estuaries. In addition, estimates of historical N loads suggest 5-fold or larger increases during the last three centuries for both Narragansett Bay (Nixon, 1997) and Chesapeake Bay (Boynton et al., 1995). Recent estimates for Chesapeake (Hagy et al., 2004) and Waquoit Bay (Bowen and Valiela, 2001) suggest more than a doubling of N loads during the previous half-century. Nixon (2003) estimated Nile River nutrient loads to the adjacent Mediterranean sea coast before and after construction of the Aswan High Dam and argued that the loss of nutrients inputs due to damming of the Nile in the 1960s has largely been replaced by anthropogenic inputs associated with run-off of agricultural fertilizers and sewage discharges. Finally, in many estuaries, the adjacent land and atmosphere are the main sources of N, but the adjacent ocean can serve as the main external source of N in some situations. For example, Kelly (1998) estimated that transport of N from the ocean into Boston Harbor provided about twice as much N as land-derived sources. Bricker et al. (1999) noted, but did not quantify, ocean derived N as a major nutrient source along the USA Maine coast during portions of the year.

It appears that estuaries are among the most heavily fertilized systems on the planet. To examine the distribution of N-loading rates among well-studied estuaries, we organized a frequency histogram of N loads (on an estuarine area basis and including only loads from landside, but not oceanic, sources) for 218 estuarine systems (Fig. 18.8). The distribution that emerged indicated that most N-loading rates fell within the range of 6–50 g N m^{-2} year^{-1}, and only about 15% of the systems had loading rates below 5 g N m^{-2} year^{-1}. It is interesting to note that anthropogenic N dosing to major watersheds of the USA ranged from 0.5 to 3.5 g N m^{-2} year^{-1} (Jordan and Weller, 1996) and from 0.9 to about 6 g N m^{-2} year^{-1} for smaller watersheds of USA coastal areas (Castro et al., 2003; Van Breemen et al.,
Figure 18.8 Frequency distribution of N-loading rates to a variety of estuarine and coastal marine ecosystems. Data were compiled from Boynton *et al.* (1995), Carmichael *et al.* (2004), Conley *et al.* (2000), Nedwell *et al.* (2002), and Nixon *et al.* (1996).

2002). The anthropogenic rates of N-loading to adjacent estuarine systems are clearly much higher; 37% of the sample exceeded 50 g N m^{-2} year^{-1}, almost an order of magnitude greater than most adjacent land areas.

We also assembled data for 34 estuaries where inputs of both TN and TP (g N or P m^{-2} year^{-1}) were available (Fig. 18.9). There is a very large range in N and P inputs among these estuaries. N loads varied by a factor of almost 200 and P by just over 300; the majority of systems in this sample had N and P loading rates ranging from 5 to 50 and 1 to 10, respectively. Despite the different biogeochemistry of N and P, there was an obvious correlation between loading rates of these elements (Smith *et al.*, 2003). Loading rates for a few systems (e.g., Himmerfjarden, Back River) had especially high N: P ratios because sewage was a major nutrient source and P, but not N, was removed at treatment facilities. In others, elevated N: P ratios were the result of diffuse source inputs that were naturally more enriched in N (mainly NO$_3$) than P. Finally, it is important to note that loading rates alone are not generally sufficient to predict the trophic status (*sensu* Nixon, 1995) of an estuary. For example, both the Potomac River estuary and Narragansett Bay had similar annual N-loading rates but the Potomac exhibited severe eutrophication characteristics while these were far less severe in Narragansett Bay. Several authors have noted that estuarine morphology, water residence times, water column mixing rates, light conditions and biological communities all have potentially strong influences on the impact of loading rates (e.g., Boynton *et al.*, 1996; Valiela *et al.*, 2000; Wulff *et al.*, 1990). A 25 year record of annual TN and TP loads to Chesapeake Bay from the Susquehanna River was added as an inset to Fig. 18.9 to serve as a reminder that inputs to some estuaries exhibit considerable inter-annual variability. In this
Figure 18.9 A scatter plot of annual TN versus TP loading rates to a selection of coastal, estuarine and lagoon ecosystems. Figure was re-drawn and expanded from Boynton *et al.* (1995). Systems are coded by number: 1 – Buzzards Bay, MA (NOAA/EPA, 1989); 2 – Sinepuxent Bay, MD (Boynton *et al.*, 1992, 1996); 3 – Kaneohe Bay, HI (post-diversion, Smith, 1981); 4 – Isle of Wight Bay, MD (Boynton *et al.*, 1992, 1996); 5 – Baltic Sea (Nixon *et al.*, 1996); 6 – Chincoteague Bay, MD (Boynton *et al.*, 1992, 1996); 7 – Kaneohe Bay, HI (pre-diversion, Smith, 1981); 8 – Narragansett Bay RI (prehistoric; Nixon, 1997); 9 – Gulf of Riga (Yurkovskis *et al.*, 1993); 10 – Albemarle Sound, NC (Nixon *et al.*, 1986); 11 – Himmerfjarden, Sweden (Engqvist, 1996); 12 – Guadaloupe Bay, TX (dry year, Nixon *et al.*, 1996); 13 – Buttermilk Bay, MA (Valiela and Costa, 1988); 14 – Moreton Bay, Australia (Eyre and McKee, 2002); 15 – Seto Inland Sea (Nixon *et al.*, 1986); 16 – Taylorville Creek, MD (Boynton *et al.*, 1992, 1996); 18 – Newport Bay, MD (Boynton *et al.*, 1992, 1996); 19 – N. Adriatic Sea (Degobbis and Gilmartin, 1990); 20 – Mobile Bay, AL (NOAA/EPA, 1989); 21 – Chesapeake Bay, MD (Boynton *et al.*, 1995); 22 – MERL (1x), RI (Nixon *et al.*, 1986); 23 – Delaware Bay, DE (Nixon *et al.*, 1996); 24 – Narragansett Bay, RI (current, Nixon *et al.*, 1996); 25 – N. San Francisco Bay, CA (Hager and Schemel, 1992); 26 – Guadaloupe Bay, TX (wet year, Nixon *et al.*, 1996); 27 – Potomac River estuary, MD (Boynton *et al.*, 1995); 28 – St Martins River, MD (Boynton *et al.*, 1992, 1996); 29 – Apalachicola Bay, FL (NOAA/EPA, 1989; Mortazavi *et al.*, 2000); 30 – Patapsco River Estuary, MD (Stammerjohn *et al.*, 1991); 31 – Tokyo Bay, Japan (Nixon *et al.*, 1986); 32 – Back River, MD (Boynton *et al.*, 1998); 33 – Boston Harbor, MA (pre-sewage diversion, Nixon *et al.*, 1996); 34 – Western Scheldt, Netherlands (Nixon *et al.*, 1996). The solid diagonal line represents the Redfield ratio of TN:TP inputs (weight basis). The inset shows the same variables from a 25 year time series of loading to Chesapeake Bay from the Susquehanna River. The N:P load ratio in the inset is weight based (Chesapeake Bay Water Quality Monitoring Program, 2004).

example, TN and TP loads varied by factors of about 3 and 5, respectively, and were very rich in N relative to P (TN:TP = 33 by weight). There was a strong indication that the TN:TP load ratio decreased during high load years, probably because more sediment, and sediment-bound P, were eroded and transported during wetter than average conditions. Thus, both the quantity and composition of nutrient inputs can vary by substantial amounts due to climate variability.

In general, variations in N-loading rates are reflected in concentrations of N in receiving water bodies. Although many processes act to modify nutrient concentrations at various rates, mean TN concentrations were significantly correlated to TN loading for five sub-systems of Chesapeake Bay averaged over a decadal period and for interannual variations in annual mean values for the Potomac River estuary (Fig. 18.10; Boynton and Kemp, 2000). Conley *et al.* (2000) reported that on an annual basis about 70% on the variation in TN concentration could be explained by variation in TN loads in a large sample of Danish estuaries.

A review of nitrogen sources to estuaries would not be complete without some discussion of nitrogen fixation, an internal source of nitrogen. A comprehensive review of nitrogen fixation in the world oceans is provided by Carpenter and Capone (Section IIIA, this book). Understanding of the magnitude, factors controlling dinitrogen (N_2) fixation rates and the ecological significance of this process in estuarine ecosystems has received considerable attention in the last few decades.
Figure 18.10 Scatter plot of average annual TN mass versus average annual TN loads for a portion of Chesapeake Bay and a selection of Chesapeake Bay tributary rivers. All concentration data were from sampling stations located in the mesohaline regions of the Bay and tributary rivers. Inset shows annual TN concentrations versus TN loads to the Potomac River estuary for an 8 year period. All data were from the Chesapeake Bay Water Quality Monitoring Program (2004).

It appears that in aphotic sediments and in estuarine water columns, N_2 fixation rates tend to be low and not of ecological significance at the level of whole estuarine systems (e.g., Affourtit *et al.*, 2001; Burns *et al.*, 2002; Howarth *et al.*, 1988a, Marino *et al.*, 2002; Paerl *et al.*, 1987). However, in photic sediments of coral reefs (Capone *et al.*, 1992; Koop *et al.*, 2001), salt marshes (Nielsen *et al.*, 2001) and seagrass communities (McGlathery *et al.*, 1998; Welsh, 2000) N_2 fixation rates tend to be higher and of importance to the nitrogen economy of these localized communities (see also Carpenter and Capone, this volume, O'Neil and Capone, this volume; Hopkinson and Giblin, this volume; McGlathery, this volume).

Howarth *et al.* (1988a) reported N_2 fixation rates to be low (<0.2 g N m^{-2} year^{-1}) in bare estuarine sediments, higher in organic-rich estuarine sediments (0.4–1.6 g N m^{-2} year^{-1}) and higher still in cyanobacterial mats (1–76 g N m^{-2} year^{-1}). Herbert (1999) and Welsh (2000) developed excellent summaries of estuarine N_2 fixation rates for a variety of sub-systems and reached similar conclusions. In these more recent summaries, bare sediment rates ranged from 0.03 to 0.65 g N m^{-2} year^{-1}, rates in cyanobacterial mats associated with salt marshes and reefs ranged from about 1–10 g N m^{-2} year^{-1} in temperate areas and were higher in the tropics and rates in seagrass communities ranged from about 0.1 to 6 g N m^{-2} year^{-1} in temperate areas and from 10 to 40 g N m^{-2} year^{-1} in tropical locations. Comparing these rates to loading rates of N from external sources (Figs. 18.8 and 18.9) indicates that N_2 fixation is not a dominant source of ''new nitrogen'' to most estuaries, although it can be an important feature in some estuarine communities, especially in oligotrophic tropical systems (Welsh, 2000).

Understanding of the factors controlling N_2 fixation rates in estuarine water columns and sediments is also evolving. Suppression of water column N_2 fixation rates by iron limitation and sulfate inhibition of molybdenum uptake have been found to be important features in oxic environments and less so in reducing environments (Howarth and Cole, 1985; Howarth *et al.*, 1988b). Paerl *et al.* (1987) reported increased N_2 fixation rates with the addition of labile organics and suggested that additional substrate and the associated creation of anoxic microzones enhanced rates. In a recent series of papers Marino *et al.* (2002, 2003, 2006) found low N_2 fixation rates by planktonic estuarine cyanobacteria under nitrogen limited conditions to be caused by a combination of intrinsic slow growth, grazing by estuarine zooplankton and sulfate- molybdenum interactions. Thus, estuarine N_2 fixation rates much lower than those typically observed in nitrogen limited lakes appear to be the result of both top-down and bottom-up effects.

3.2. Internal losses of nitrogen

Compared to N inputs, the internal loss terms of estuarine N-budgets are not as well documented. In general, internal losses include burial of PN in accreting sediment columns and denitrification in either the water column or sediments (see also Devol, this volume). A few nutrient budgets have estimated N-extraction in the harvest of fish and shellfish biomass and fish migration from estuaries.

Estimates of long-term PN burial (Table 18.2) illustrate a substantial range in rates from very small values (0.05–0.2 g N m^{-2} year^{-1}) in the deepest systems to

Table 18.2 Summary of Long-Term Particulate Nitrogen (PN) Burial Rates for Several
Tidal Marshes and a Selection of Estuarine and Coastal Marine Ecosystems

Methods used to determine PN burial rates varied but all included an estimate of sediment accumulation rate (^{210}Pb, sediment budget, pollen grain analysis) and an estimate of PN concentration at a depth in the sediment column where concentrations were constant with further depth.

very high rates for river deltas and tidal marshes (>20 g N m^{-2} year^{-1}). Although the small values in deep systems suggest processing of PN during transit through deep water columns (Hargrave, 1973; Kemp *et al.*, 1992), high variability in rates among systems with similar depths indicates other influences. In a synthesis of nutrient (N and P) budgets for 9 estuarine ecosystems, burial of PN was a prominent term in only two systems ($>35\%$ of TN inputs buried) while in the others burial accounted for 12% or much less of TN inputs (see Nixon *et al.*, 1996 for nutrient budget details for 9 estuarine ecosystems). The two systems in which burial was important (Patuxent and Potomac River estuaries) are sediment-rich, eutrophic estuaries, with relatively long water residence time (2–4 months). Of the other systems considered (Nixon *et al.*, 1996), some had high loading rates but short residence times (e.g., Boston Harbor), while others had limited sediment supplies (e.g., Narragansett Bay). We suggest that PN burial can be an important internal loss in some sediment-rich systems, but limited measurements make this conclusion speculative.

Denitrification, which represents a potentially important process for removing fixed N from estuaries, occurs predominantly in the upper stratum of sediments where rates tend to be limited by availability of nitrate. Nitrate is also produced via nitrification near the sediment surface which is, in turn, limited by availability of oxygen. A recent review of denitrification rates in aquatic systems included 1757 measurements from 152 sites over 45 years (Greene, 2005a; Fig. 18.11 insert; see also Chapter 18 by Devol, this volume). Since the 1960s at least nine different techniques were used to measure denitrification. The most frequently used method was the "acetylene block" technique in which acetylene is used to inhibit the reduction of N_2O to N_2, with N_2O accumulation used as a proxy for N_2 production. The acetylene technique was introduced in the 1970s and use peaked in the 1990s. There has been a growing interest in direct measurements of N_2 production since
Figure 18.11 Frequency distribution of denitrification measurements from a variety of estuarine ecosystems. The inset is a frequency histogram using denitrification measurements from all aquatic systems. Both figures used data from the denitrification summary developed by Greene (2005a).

the 1980s. In the mid–1990s, isotope pairing and membrane inlet mass spectrometric (MIMS) techniques were developed and the use of the acetylene technique declined substantially.

Most reported denitrification measurements indicated rates between 11 and 100 μmol N m^{-2} h^{-1}, with few rates <1 μmol N m^{-2} h^{-1} and few in excess of 1000 μmol N m^{-2} h^{-1} (Fig. 18.11). In estuarine systems (Fig. 18.11) the most commonly reported rates were between 1 and 50 μmol N m^{-2} h^{-1}, but almost 40% of measurements were larger. Estuaries were also the most intensively measured systems (56% of all measurements), although many estimates were also available for continental shelves, coastal wetlands, lakes, lagoons, inland wetlands and several other environments (Table 18.3). The lower limit of rates in most environments was <1 μmol N m^{-2} h^{-1} while maximum rates ranged from 167 μmol N m^{-2} h^{-1} in seagrass communities to 24,142 μmol N m^{-2} h^{-1} in human engineered systems. Maximum rates above 1000 μmol N m^{-2} h^{-1} were also measured in freshwater creeks, coral reefs, continental shelf and estuarine environments, with maximum estuarine rates reaching nearly 20,000 μmol N m^{-2} h^{-1} in an area near a sewage treatment plant discharge. Mean rates in most systems were between 50 and 250 μmol N m^{-2} h^{-1}. It is useful to note that denitrification rates of 200 μmol N m^{-2} h^{-1} are equal to about 25 g N m^{-2} year^{-1}, a substantial fraction of TN loading rates to many estuaries (Fig. 18.8).

Several earlier papers helped place denitrification, as an internal loss term, into the context of the N economy of estuaries. Seitzinger (1988) summarized available

Table 18.3 Summary of denitrification rates from a variety of aquatic ecosystems. These data were from a summary developed by Greene (2005a)

| System type | Denitrification rate, μmol N m^{-2} h^{-1} | | | | Number of measurements |
	Minimum	Maximum	Mean	Median	
Lakes	0	490	125	100	91
Freshwater creeks	0	1500	266	13	17
Freshwater wetlands	0	330	39	4	52
Human engineered systems	0	24142	1497	8	55
Tidal mudflats	2.1	213	70	30	62
Coastal wetlands	−200	375	96	71	154
Seagrass communities	8.3	167	51	21	7
Coastal lagoons	0	290	19	5	116
Estuaries (sub-tidal)	−93	19616	182	31	1052
Coral reef communities	0	1351	107	19	38
Continental shelf	0	1657	102	13	113

System types are arranged in geographic sequence from land to sea. Total number of measurements = 1757. Negative values indicate that N-fixation rates exceeded denitrification rates.

data from lakes, rivers and estuaries regarding the ecological significance of this process. Important conclusions were that denitrification rates were higher in systems receiving large, anthropogenic nutrient inputs, most of the NO_3 consumed in denitrification apparently came from sediment-based nitrification rather than from the water column and, from a small sampling of estuaries, denitrification rates were proportional to TN loading rates, removing an average of 40% of N inputs. More recently, Nixon *et al.* (1996) computed the proportion of input N removed via denitrification from a larger selection of estuaries and several lakes, with values ranging from 10% to 74%, again indicating the importance of this process.

Although denitrification is an anaerobic process, estuarine rates are often limited by conditions of low bottom water oxygen and organic enrichment of sediments. Resulting low redox conditions, high sulfide concentrations and shallow penetration of oxygen into sediments inhibit nitrification, and consequently denitrification (e.g., Henriksen and Kemp, 1988; Joye and Hollibaugh, 1995; Vanderborght and Billen, 1975). Under these conditions, sediment recycling of N becomes more efficient in that most of the PN deposited to sediments is returned to the water column as NH_4 (Kemp *et al.*, 1990). We identified a limited number of studies in which bottom water dissolved oxygen varied appreciably during the study period and in which denitrification and net sediment–water fluxes of NH_4, NO_2 and NO_3 were also measured. Such data were available from a Danish site (Rysgaard-Petersen *et al.*, 1994) and from several studies conducted in Chesapeake Bay (Kemp *et al.*, 1990 and Cornwell, unpublished data). We developed an index of N recycling efficiency and examined
Figure 18.12 Bar graph of N-recycling efficiency as a function of bottom water dissolved oxygen concentration. Bars were based on Chesapeake Bay data reported in Kemp *et al.* (1990) and Cornwell (unpublished data). Solid dots were based on data from Rysgaard-Petersen *et al.* (1994) collected from Vilhelmsborg So, Denmark. Terms in the recycling efficiency calculation (γ-axis) are: F_{N_2} = flux of N_2 from sediments; F_{NH_4} = flux of ammonium from sediments; F_{NO_3} = flux of nitrate from sediments.

this as a function of bottom water dissolved oxygen concentrations (Fig. 18.12). For both systems there was a consistent increase in cycling efficiency as dissolved oxygen concentrations decrease. This trend suggests that estuarine eutrophication can seriously inhibit N removal via coupled nitrification-denitrification. Clearly, more sites need to be examined to see if this is a general pattern of response. However, the increase in N cycling efficiency with low dissolved oxygen conditions is consistent with the relatively low percent N removal via denitrification in Chesapeake Bay and adjacent tributary rivers, all of which have hypoxic or anoxic bottom waters for portions of each year (Boynton *et al.*, 1995; Hagy *et al.*, 2004).

3.3. Export of nitrogen to downstream systems

The final term in typical nutrient budgets is the export or import of materials to or from the adjacent downstream system. While we have indicated that there has been significant progress in understanding N in estuarine systems, there are also areas with pressing needs for improvement. Export of materials at the mouths of estuaries is a case in point. In most N-budgets the export term was estimated by subtracting the summation of internal losses from the full suite of inputs. The main reason for this non-independent approach was simply because more direct estimates of net flux were too difficult to accomplish. The basic problem is that water fluxes at the mouths of estuaries are relatively large, circulation patterns are often complex (e.g., Boicourt, 1983; Chao *et al.*, 1996; Kjerfve and Proehl, 1979) and the differences

in nutrient concentrations across this boundary are often small and variable. Thus, it is extremely difficult to develop accurate estimates of net exchange. It appears that this term will remain uncertain until dependable hydrodynamic models become even more widely available and accessible to those interested in nutrient dynamics.

Despite this difficulty, a recent synthesis of nutrient exchanges between estuaries and coastal waters provides some insights (Nixon *et al.*, 1996). Exports of N from 10 estuarine systems and several lakes ranged from 10% to about 90% of inputs and, as suggested earlier (Boynton *et al.*, 1995), N exports were not well correlated with inputs. The percent of N inputs exported to the coastal ocean was inversely correlated with the log mean residence time of water in the system (Nixon *et al.*, 1996), as has been found for lakes (Kirchner and Dillon, 1975). Adding data for four Chesapeake Bay tributaries to this relationship suggests that other factors (e.g., depth, salinity, nutrient levels) also affect relative export of N (Fig. 18.13). However, despite the widely varying environmental character among these systems, water residence time exerts strong control on the ratio of export to loading. If estuarine communities have sufficient time to process nitrogen, they will, in effect, reduce the N exported via N burial or denitrification. Thus it appears that estuaries can act as either "pipes" where N transport rather than transformation is the dominant process or as "sinks" for N, all as a function of how long water remains in the system.
Figure 18.13 Scatter plot of percent N exported versus water residence time for a variety of estuarine ecosystems. Figure was re-drawn from Nixon *et al.* (1996). Patuxent and Choptank Rivers, tributaries of Chesapeake Bay, were not included in the original analysis. Data for those systems were from Boynton *et al.* (1995) and Fisher (unpublished data).

It appears that Chesapeake Bay and its tributary estuaries tend to remove a higher fraction of N loads than expected from the estimated water residence times (Fig. 18.13). Some of these differences may simply be the result of accumulated errors in developing N-budgets. However, Chesapeake Bay is a sediment-rich and eutrophic system with abundant suspended PN and sediment concentrations to facilitate burial. Of the estuaries examined by Nixon et al. (1996), only the Chesapeake systems had substantial N-burial losses, probably because of these features and moderately long water residence times. In addition, many Chesapeake Bay tributaries (e.g., Patuxent and Choptank) that export a small fraction of their N load have large areas of low-salinity tidal marshes which also sequester substantial amounts of both N and P (Greene, 2005b; Merrill, 1999). Thus, it's possible that some estuarine communities, such as those associated with tidal marshes and seagrass beds, may modify relative N export characteristics (Valiela et al., 2001). To expand our understanding of N dynamics in estuaries, there is a clear need for more direct calculations of N exchange with seaward waters and better estimates of other loss terms including burial and denitrification.

3.4. Ecosystem metabolism: Interactions with nitrogen cycling

Under steady-state conditions, the balance between inorganic N inputs and losses for an estuary is directly related to the net production (or consumption) of organic matter in the associated ecosystem, where net organic production and net fluxes of inorganic N are inversely related. Net ecosystem production (NEP) is supported by net uptake of inorganic N, and conversely, net consumption of organic matter results in net release of inorganic N. NEP, which is defined as the balance between gross primary production (P_G) and community respiration (R_C) of organic carbon, provides a measure of the excess production or consumption resulting in changes in internal storage or net export or import across the system boundaries (Fisher and Likens, 1973; Odum, 1956). Ecosystems with positive NEP are considered autotrophic, while those with negative NEP are considered heterotrophic. Although P_G tends to equal R_C (NEP $\approx$ 0) at large scales, imbalances between P_G and R_C at smaller scales support functional coupling between adjacent habitats through exchanges of organic carbon and inorganic nutrients (e.g., Hopkinson and Vallino, 1995; Kemp et al., 1997; Smith and Hollibaugh, 1997).

NEP can be calculated using different methods including long-term continuous records of dissolved oxygen or inorganic carbon (relative to saturation concentrations) at diel or seasonal scales (e.g., Howarth et al., 1992), and summation of individual production and respiration measurements broadly representing temporal and spatial scales and major habitats (e.g., Kemp et al., 1997). NEP can also be computed using estimates of the net balance between imports and exports of DIP (e.g., Smith, 1991), where rates are converted from phosphorus to carbon units assuming a fixed stoichiometry for primary production and nutrient recycling (e.g., C:N:P = 106:16:1). Conversely, NEP can be converted to nitrogen units using these stoichiometric assumptions; however, the net balance of DIN will also be affected by two important processes involving nitrogen gas production and consumption—denitrification and nitrogen fixation, respectively (e.g., Nixon and Pilson, 1984). In fact, rates of NEP and related biogeochemical fluxes have been

estimated for many estuaries and coastal bays worldwide combining simple water- and salt-balance models that compute advective and diffusive solute transport with data for DIN and DIP time-space distributions to infer non–conservative net fluxes as residuals in dynamic nutrient budget calculations (http://wwwold.nioz.nl/loicz/). Comparative analyses of these rates suggest broad regional relationships with hydrology and watershed development (Smith et al., 2003).

Estimates of NEP can also be made using time-varying water/salt balance calculations for an estuarine water volume segmented into two-layers and multiple regions (or boxes) along the salinity gradient (Hagy et al., 2000). Such a "box-model" was used to compute net non-conservative fluxes for nutrients and dissolved oxygen (O_2, corrected for air-sea exchange) in the Patuxent River estuary, USA (Kemp et al., 1999; Testa and Kemp, 2005). The inherently tight coupling between organic production (NEP) and N cycling can be seen in the highly correlated patterns of annual mean rates of net O_2 and DIN flux along the estuarine gradient for surface and bottom layers in hydrologically contrasting years (Fig. 18.14). In surface layers, interannual and longitudinal variations in DIN uptake generally correspond to patterns in net O_2 production, while in bottom layers, trends of net O_2 consumption appear as a mirror image of net DIN production rates. Bottom layer DIN fluxes are inversely correlated to O_2 fluxes ($r^2 = 0.81$); however, trends are complicated because negative fluxes in low salinity estuarine regions are from high water column nitrate concentrations diffusing into sediments to support denitrification, while positive net fluxes in the more saline regions are primarily due to ammonium efflux from decomposing organic matter in sediments.

Whereas annual rates of primary production tend to be regulated by inputs of total nitrogen for many coastal ecosystems (e.g., Boynton et al., 1982; Nixon et al., 1986), it appears that NEP (NEP $= P_G - R_C$) is controlled more by the balance between inputs of DIN and total organic nitrogen (TON) or carbon (TOC), where DIN inputs stimulate P_G, and TON (or TOC) inputs support R_C (Kemp et al., 1997). Comparative analysis of NEP calculations and loading rates for five estuaries and for mesocosms (MERL; Oviatt et al., 1986) at different nutrient treatments reveals a consistent relationship between NEP and the DIN:TOC loading ratio (Fig. 18.15). While strong relationships were evident for NEP from controlled experimental systems and for long term average rates in specific estuaries, substantial year-to-year variations in NEP are often evident for specific estuarine ecosystems. Such variations in metabolic rates may be related to fluctuations in climatic conditions that regulate, for example, inputs of organic matter from adjacent coastal upwelling regions (e.g., Smith and Hollibaugh, 1997), or river flow and associated nutrient loading and water residence time (Fig. 18.15, note differences in net fluxes for high and low flow years, and interannual variability in NEP in figure inset). Values for P_G and R_C computed from continuous diel O_2 measurements for a range of shallow North American coastal ecosystems revealed that NEP was generally negative (i.e., net heterotrophic), was responsive to climatic variations, and was related to N inputs (Caffrey, 2004). The heterotrophic nature of NEP in many coastal ecosystems combined with the correspondence between biogeochemical fluxes of C and N have been interpreted to suggest that N cycling, in general, and denitrification, in particular, may actually be limited by C availability (Smith and Hollibaugh, 1989). This is in contrast to the conventional view that carbon production and consumption are limited by N availability. In summary,
Figure 18.14 Net non-conservative biogeochemical fluxes of dissolved oxygen (O_2) and dissolved inorganic nitrogen (DIN) calculated using a box–model (Hagy *et al.*, 2000) for six regions and two vertical layers defined along the Patuxent River estuary for relatively wet (2000) and dry (2002) hydrologic years. Fluxes were estimated as residuals in mass-balance calculations for monitored O_2 and DIN concentrations (Kemp *et al.*, 1999).
Figure 18.15 Comparative analysis of net ecosystem production for estuaries in relation to loading ratio for DIN:TOC. Data sources are: for MERL mesocosms (Oviatt *et al.*, 1986), for Narragansett Bay (Nixon *et al.*, 1995), for Tomales Bay (Smith and Hollibaugh, 1997), for San Francisco Bay (Jassby *et al.*, 1993), for Chesapeake Bay (Kemp *et al.*, 1997), and for Patuxent River estuary in 1985–1994 (Kemp *et al.*, 1999). Figure was adapted from Kemp *et al.* (1997). The DIN:TOC load ratio was based on external inputs of DIN ($NO_3 + NO_2 + NH_4$) and Total Organic Carbon (TOC) to each site.

we conclude total primary production and net ecosystem production are tightly coupled to inputs and cycling of N in most coastal environments, and that these relationships vary with hydrologic and climatic conditions.

4. Sediment-water Solute Fluxes

One of the distinguishing features of estuarine ecosystems is their relatively shallow water depths compared to many lakes and the coastal ocean. One consequence of a short water column is that the upper photic waters that support primary production are closely connected to zones of nutrient remineralization in estuarine sediments. This results in strong benthic-pelagic (B/P) coupling, which is one of several reasons suggested for the high primary and secondary productivity of estuarine systems (Kemp and Boynton, 1992). While B/P coupling implies bi-directional influences, we focus here on benthic N cycling and the efflux of DIN across the sediment-water interface. During the past twenty years a substantial number of sediment–water flux measurements have been made in diverse estuarine and coastal

marine systems, providing opportunity for a synthetic analysis. In the following section we consider ammonium effluxes because they have been widely measured and because NH_4 is usually the primary N compound released by sediments. However, we also included oxygen and DIP fluxes because they are also widely measured and because O_2, DIP and NH_4 fluxes are stoichiometrically linked in complex ways. We recognize that other N forms, such as NO_3, can occasionally play a significant role in sediment nutrient dynamics. In recent years, a growing number of sediment–water fluxes have been measured in shallow, clear-water systems where sediments are in the photic zone (e.g., Eyre and Ferguson, 2002; McGlathery et al., 2001; Reay et al., 1995; Rizzo et al., 1992; Rysgaard-Petersen et al., 1994; Tyler and McGlathery, 2003). N cycling under those conditions is apparently even more complex, with benthic photosynthesis supporting N-assimilation, shifting redox conditions and associated biogeochemical processes. A detailed discussion of these data can be found elsewhere in this book (Chapter 23 by McGlathery, this volume). Finally, we did not review DON fluxes associated with estuarine sediments because these have not been routinely measured and because Bronk and Steinberg (Chapter 8, this volume) and Joye and Anderson (Chapter 19, this volume) address this issue in detail.

4.1. Overview of flux magnitude

Sediment–water fluxes of ammonium (NH_4), dissolved oxygen (O_2), and dissolved inorganic phosphorus (PO_4) were organized based on data from 52 studies (6, 19, 26, and 1 from the 1970s, 1980s, 1990s and 2000s, respectively) conducted in 48 estuarine and coastal marine areas. A total of 701 flux measurements were included in the summary developed by Bailey (2005). Measurements included those made in situ or with ship–board or laboratory sediment core incubations. In all cases, measurements of analyte concentrations (O_2, NH_4, and PO_4) were made during an incubation period in the dark at ambient water temperature, and fluxes were computed using concentration temporal rates of change. Studies using modeling techniques or fluxes estimated from sediment pore water concentrations were not included.

Mean values of flux magnitudes and ratios exceeded median values (Table 18.4); there were a small number of large values for each of these fluxes (Fig. 18.16A).

Table 18.4 Summary of Net Sediment-Water Oxygen and Nutrient Exchanges and Flux Ratios from 48 Estuarine and Coastal Ecosystems Developed by Bailey (2005)

Type of flux or flux ratio	Minimum	Maximum	Mean	Median	n
NH_4	−83	2700	125	42	641
PO_4	−231	900	22	4.2	506
O_2	0	−18229	−1302	−781	554
N: P	0	193	13	7.8	369
O: N	0	1450	63	24	413

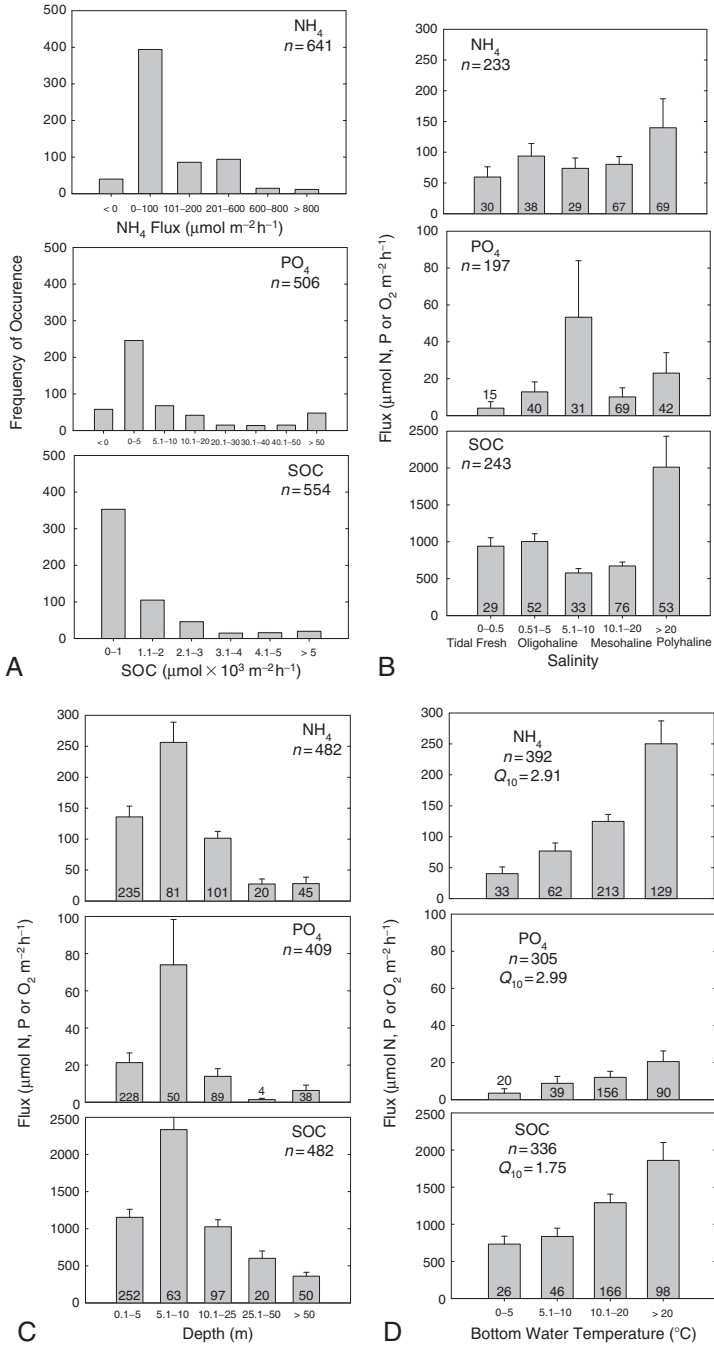
All measurements were made in environments where the sediments were aphotic and all sediment incubations were made in the dark. Flux units are: umol O_2, N or P m^{-2} h^{-1}; N: P and O: N ratios atomic basis. Negative values indicate fluxes into sediments.


Figure 18.16 A summary of sediment-water NH$_4$, PO$_4$ and sediment oxygen consumption (SOC) rates, including: (A) frequency histogram of rates; (B) rates as a function of salinity regime; (C) rates as a function of system depth; (D) rates as a function of temperature. Data were organized by Bailey (2005).

Sediment oxygen consumption (SOC) rates ranged from 0 to 18,229 μmol m^{-2} h^{-}, ammonium fluxes from -83 to 2700 μmol m^{-2} h^{-1} and phosphate fluxes from -231 to 900 μmol m^{-2} h^{-1}. Flux ratios are also of interest because they can provide an indication of active sediment biogeochemical processes. Median values of N: P and O: N flux ratios were lower and higher, respectively, than would be expected based on Redfield phytoplankton composition ratios (N: P $\sim$ 16; O: N $\sim$ 13.3). Both ratios suggest less N being recycled relative to recycled P and to oxygen consumption rates. While several explanations are possible, much of this pattern is probably attributable to loss of N-solutes via nitrification-denitrification in estuarine sediments (e.g., Jenkins and Kemp, 1984; Rysgaard-Petersen et al., 1994; Seitzinger, 1988).

4.2. Spatial patterns of flux

All fluxes tended to be higher in saltier than in fresher waters (Fig. 18.16B). Although one might anticipate that NH_4 and SOC fluxes would be inversely related to salinity with highest values closest to terrestrial organic matter and nutrient sources, this was not the case. Apparently, more phytoplanktonic debris, which is more labile with lower C:N ratios, tends to be the dominant source of organic matter fueling benthic processes in higher salinity zones. On the other hand, DIP efflux from sediments tended to peak in the low mesohaline (salinity = 5–10) region. This is probably a manifestation of both loosely sorbed P being released into solution as a consequence of increased salinity (Froelich, 1988) and of the dissolution of iron–phosphate complexes after chemical reduction of iron and precipitation of iron sulfides in anaerobic sediments (Jensen et al., 1995; Krom and Berner, 1980).

In general, SOC tends to decline with water depth (e.g., Hargrave, 1973; Kemp and Boynton, 1992; Kemp et al., 1992), as plankton respiration causes a smaller percentage of sinking organic matter to reach the bottom due to longer transit times in deeper water columns. Efflux of NH_4 from sediments has previously been related to water column depth (Harrison, 1980) across large gradients (10–2000 m). We found a generally similar response for NH_4, PO_4, and SOC fluxes (Fig. 18.16C) for a relatively small depth range (0.2–50 m). Fluxes were 5 to 10 times higher in water of 5–10 m depth than in waters greater than 50 m depth, consistent with earlier reports for SOC. However, mean fluxes in the dark were lower at very shallow depths (0.2–5 m). The shallow water sediments are typically within the zone where autotrophic processes tend to dominate sediment biogeochemistry, with high rates of N and P assimilation by benthic algae and seagrasses and oxidized sediments which promote adsorbtion and precipitation of PO_4 and coupled nitrification-denitrification of N. Thus, NH_4 and PO_4 effluxes tend to be low in these shallow sediments. In addition, sediments and organic matter may be exposed to resuspension via wave action and the less dense labile organic particulates transported to deeper waters where they are remineralized. The flux-depth pattern observed with our large data set is not consistent with several other analyses including those of Nixon (1981) and Seitzinger and Giblin (1996) where depth ranges of 3–70 m and <200 m, respectively, were examined and did not exhibit strong relationships with depth.

4.3. Regulation of sediment–water fluxes

There are many factors that may play important roles in regulating sediment biogeochemical processes and associated solute exchanges. There is a substantial literature concerning this topic, extending back several decades. The list of potential influencing factors includes temperature, activities of infaunal communities, redox conditions near the sediment-water interface, solute concentrations in overlying water, and rates of organic matter supply. Effects of infauna can be both direct (i.e., excretion) and indirect (i.e., burrowing, pumping, and stimulation of microbial communities). For example, Banta *et al.* (1995), Flint and Kamykowski (1984), Hammond *et al.* (1985), Kanneworff and Christensen (1986), and Webb and Eyre (2004) reported a variety of macrofaunal influences on sediment-water exchange rates and other processes. Others have reported on the influence of redox and water quality conditions on sediment processes (e.g., Sundby *et al.*, 1992). The challenge of quantitative modeling of sediment-water processes and associated interactions was captured in a recent book by DiToro (2001).

Previous studies have concluded that, ultimately, organic matter supply rate to sediments was the overarching factor regulating sediment biogeochemistry and solute flux across the sediment-water interface. For example, comparative analysis among diverse estuarine systems indicates that benthic respiration rates are highly correlated with organic matter production rates (Nixon, 1981). The relationship appeared to be linear across a very large range of primary production rates ($\sim$75–1400 g C m^{-2} year^{-1}), including data from Chesapeake Bay (Kemp and Boynton, 1992). In northern European waters, rates of sediment respiration and ammonium and phosphorus fluxes tend to respond rapidly to deposition of spring and autumn algal blooms (Graf *et al.*, 1982; Jensen *et al.*, 1990). Although temperature appears to affect response time, similar relationships have been reported for sediment anaerobic respiration in North American systems (Marvin-DiPasquale *et al.*, 2003; Sampou and Oviatt, 1991).

Interacting effects of organic matter supply and temperature are illustrated with two examples from Chesapeake Bay aphotic sediments. In the first case (Cowan and Boynton, 1996), sediment chlorophyll *a* concentration (as an index of recent organic deposition) was related to sediment-water NH$_4$ fluxes measured during three years at three stations along the estuarine salinity gradient (Fig. 18.17). These stations varied substantially in terms of mean depth, O$_2$ conditions, sediment type, and macrofaunal characteristics; the strength of the observed relationship, therefore, emphasizes the overall importance of organic matter supply. A second point of interest is the lag time used in this analysis. Specifically, sediment chlorophyll *a* concentrations were averaged from just prior to spring bloom deposition through the summer period, while NH$_4$ fluxes were averaged from mid-spring through summer. Biogeochemical processes in this system, which has a large annual temperature range (0–33°C), are apparently not adapted to cold water (Sampou and Kemp, 1994). It is argued that sediment respiration and nutrient remineralization respond to spring bloom deposition and labile organic matter accumulation primarily after temperature increases beyond 10°C (Cowan and Boynton, 1996). Thus, there is a period of organic matter
Figure 18.17 A scatter plot of sediment NH_4 fluxes versus surface sediment chlorophyll *a* concentration collected for several years at three sites along the salinity gradient of Chesapeake Bay. Note that sediment chlorophyll *a* data were averaged from late winter through summer while sediment fluxes were averaged from late spring through summer. Figure was redrawn from Cowan and Boynton (1996). NB–Northern Bay (oligohaline); MB–Mid Bay (mesohaline); SB–South Bay (polyhaline).

loading to sediments followed by a period of NH_4 release. Other investigators have found a more immediate response to temperature (e.g., Banta *et al.*, 1995). However, the importance of organic matter supply rate is clearly evident in these results. The second example is from the Patuxent River, where multiple NH_4 flux measurements were made during three summer periods, all within the mesohaline region of the estuary (Stankelis *et al.*, 1999). Water column and sediment characteristics were also measured at flux site locations and a reasonably simple regression model was developed in which sediment chlorophyll *a*, as an index of labile organic matter supply, again played an important part (Fig. 18.18). An additional twist in this analysis was the apparent role played by sediment redox conditions. The model indicated that as sediment redox conditions became more positive, less NH_4 was released. This is consistent with the idea that sediment N is more likely to be nitrified when sediments are oxidized (Kemp *et al.*, 1990; Rysgaard-Petersen *et al.*, 1994).

We also examined flux data with respect to water temperature at the time of measurement using the sediment-water flux data set developed by Bailey (2005; Fig. 18.16D). In all cases there were sharp increases in rates with increased temperature. Estimated Q_{10} (0–30°C) values for NH_4, PO_4 and SOC fluxes were 2.9, 3.0, and 1.8, respectively. It is also useful to note there is considerable bias in the temperature range in which these measurements are made. Less than 10% of the reported rates were from temperatures <5°C, and only a slightly higher percentage were from temperatures of 5–10°C. About 50% of all measurements
Figure 18.18 A scatter plot of predicted versus measured NH$_4$ fluxes for the mesohaline region of the Patuxent River estuary. Data and figure are from Stankelis *et al.* (1999).

were made at temperatures between 10°C and 20°C, a fact that suggests a *Goldilocks and the Three Bears* approach to ecology wherein measurements were made when it was neither too hot nor too cold, but just right (Brett, 1987). To examine the influence of temperature on sediment fluxes in more detail, we organized a rare 9 year time-series of sediment NH$_4$ fluxes collected from two Chesapeake Bay tributaries- the Potomac and Patuxent River estuaries (Boynton and Rohland, 1998). For comparison, monthly NH$_4$ fluxes were expressed as percent of maximum flux observed during each year, averaged by month for the 9 year record, and then plotted as a function of average temperature at the time of measurement (Fig. 18.19). Results from the heavily nutrient enriched Potomac and moderately enriched Patuxent indicated increasing fluxes with increasing temperature through mid-summer but then sharply reduced fluxes at comparable or slightly higher temperatures through late summer and fall. A similar pattern was reported from a site in Chesapeake Bay (Cowan and Boynton, 1996). The substantial differences in flux magnitude before and after July indicate that other factors, such as supply of labile organic matter, limit remineralization in late summer and autumn. However, there appear to be a variety of seasonal patterns of sediment fluxes among estuaries. For example, Banta *et al.* (1995) and Nixon *et al.* (1976) found strong relationships between temperature and sediment ammonium fluxes in Buzzards Bay and Narragansett Bay. The seasonal pattern of sediment denitrification may also strongly influence the pattern of sediment ammonium fluxes (Hopkinson *et al.*, 1999).
Figure 18.19 A scatter plot of sediment NH_4 fluxes as a function of temperature from two tributary rivers of Chesapeake Bay. NH_4 fluxes were based on 9 years of monthly samples. Fluxes were expressed as a percent of the maximum flux observed in each year and then averaged, again by month, for all years. Temperature was the average temperature during each month of the 9 year record at each site. The Potomac site was very nutrient enriched and the Patuxent site was moderately enriched. Data were from Boynton and Rohland (1998).

5. Nitrogen and Primary Production

In many estuarine systems primary production by phytoplankton and other autotrophs is affected by N inputs and concentrations (e.g., Cloern, 2001; Howarth, 1988; Kelly, 2001; Nixon, 1992; Smith, 2003). For this review, we have compiled estimates of annual primary production and simple models used to relate production to nutrient conditions. We also discuss the evolution of thinking concerning nutrient limitation of pelagic primary production in estuaries. Finally, we review the conceptual models concerning benthic and pelagic primary production and consider the influence of N on these different autotrophic components.

5.1. Phytoplankton primary production

Annual rates of phytoplankton primary production from 120 different estuarine and coastal marine systems were organized in a frequency plot (Fig. 18.20). The most frequently encountered rates were those between 100 and 300 g C m^{-2} year^{-1}, corresponding to mesotrophic status in the classification suggested by Nixon (1995). Despite very real concern about increasing eutrophication of coastal systems, only 32%
Figure 18.20 Frequency distribution of annual phytoplankton primary production rates for a selection of estuarine and coastal marine systems. Data were from Borum and Sand-Jensen (1996), Boynton *et al.* (1982), Chen *et al.* (2000), Cloern (2001), Conley *et al.* (2000), deJonge *et al.* (1994), Harding *et al.* (2002), Kelly (2001), Nixon (1997), and Pennock and Sharp (1986). Inset diagram shows frequency distribution for total primary production (pelagic plus benthic) for a limited number of estuaries. Inset data were from Borum and Sand-Jensen (1996).

of these systems were in the eutrophic or hypertrophic categories. It is unclear, however, how representative this sample is of estuarine systems worldwide. It is almost certain that vast amounts of data remain to be mined from unpublished sources and that incorporation of this material might substantially change the observed pattern. In addition, most estimates of primary production are estimates of pelagic primary production; few included benthic primary production, which is especially important in shallow systems. We used the summary of total system (pelagic plus benthic) primary production compiled by Borum and Sand-Jensen (1996) and examined categories of production relative to trophic state (Fig. 18.20 inset). In this smaller sample, rates were generally higher, as expected, with 68% of the sites having annual productivity rates greater than 300 g C m^{-2} year^{-1}. Most of these sites were shallow, even by estuarine standards, and exhibited very high production rates, clearly indicating the importance of benthic primary producers. Borum and Sand-Jensen (1996) also pointed out that it was rare for both benthic and planktonic rates to be high in the same system, and indicated that conditions which enhance one group of primary producers tend to inhibit the other.

5.2. Statistical models of nitrogen and production

We also compiled reports of statistical models developed to relate primary production or algal biomass to N (Table 18.5). All but one of these were generated during the last two decades, and the models take a variety of forms, for example, using N

Table 18.5 A summary, by date of publication, of statistical models relating phytoplankton primary productivity or biomass to nitrogen (concentration or loading rates) or other variables

Location	Independent variable, X (units)	Dependent variable, Y (units)	Predictive equation	r^2/n	Reference
Multiple estuaries	TN loading (g N m^{-2} year^{-1})	Phytoplk Prod (g C m^{-2} year^{-1})	$Y = 25 + 13X$	0.60/14	Boynton $et\ al.$, 1982
San Francisco Bay other estuaries	Composite parameter $X = f(B, Z_p, I_0)$	(mg C m^{-2} year^{-1})	$Y = 15 + 0.73X$	0.82/211	Cole and Cloern, 1987
Narragansett Bay and Univ RI MERL	Composite parameter $X = f(B, Z_p, I_0)$	(g C m^{-2} year^{-1})	$Y = 220 + 0.70X$	0.82/1010	Keller, 1988
Multiple estuaries and Univ RI MERL	DIN-loading (mol N m^{-2} year^{-1})	(g C m^{-2} year^{-1})	$\log Y = 0.44\log(X) + 2.33$	0.93/19	Nixon $et\ al.$, 1996
Multiple estuaries	TN loading (g N m^{-2} year^{-1})	(g C m^{-2} year^{-1})	$Y = 244 + 175\log(X)$	0.36/51	Borum and Sand–Jensen, 1996
Boston Harbor	Composite parameter $X = f(B, Z_p, I_0)$	(mg C m^{-2} year^{-1})	$Y = 285 + 0.79X$	0.66/12	Kelly and Doering, 1997
Waquoit Bay system	Annual average DIN conc (μM)	(g C m^{-2} year^{-1})	$Y = 60.9 + 13.96X$	0.61/12	Valiela $et\ al.$, 2001
Chesapeake Bay	TN(x_1), TP(x_2) load (kg mol^{-1})	(g m^{-2} year^{-1})	$Y = 335 + 18.9X_1 - 164X_2$	0.67/11	Harding $et\ al.$, 2002

Multiple estuaries	DIN (m M m^{-3}); tidal range (m)	Phytoplk Biomass (µg I^{-1})	na; positive slope	na/163	Monbet, 1992
Multiple systems/ MERL	DIN input (mmol m^{-3} year^{-1})	(µg I^{-1})	na; positive slope	na/34	Nixon, 1992
Chesapeake Bay mesohaline region	River flow (m^3 day^{-1}) (proxy for N-load)	(kg estuary^{-1})	na; positive slope	0.70/34	Harding *et al.*, 1992
Maryland lagoons	TN load (g N m^{-2} year^{-1})	(µg I^{-1})	$Y = 16.9 + 0.70X$	0.96/9	Boynton *et al.*, 1996
Danish coastal waters	TN concentration (µg I^{-1})	(µg I^{-1})	na; positive slope	0.64/168	Borum, 1996
Canadian estuaries	TN concentration (µg I^{-1})	(µg I^{-1})	$\log Y = -4.06 + 1.78 \log X$	0.72/15	Meeuwig, 1999
Chesapeake Bay and Tributaries	Scaled TN load (mg N m^{-2} year^{-1}) (R_{time}, years)$^{-1}$	(mg m^{-2})	$Y = 18.9 + 0.078X$	0.82/17	Boynton and Kemp, 2000
Danish estuaries	TN concentration (µg N I^{-1})	(µg I^{-1})	$\ln(Y) = 0.96 \ln(X) - 4.19$	0.30/1347	Nielsen *et al.*, 2002

concentration or loading rate as an independent variable. Most models were computed on annual time scales, and for several it was unclear how temporal and spatial variability was taken into account. Sample size used to develop these models varied widely, and some were based on multi-system comparisons while others were based on multi-year data collected for one system. Given the myriad factors known to influence production and algal biomass accumulation, it is impressive that N alone was able to account for a large portion of the variability of phytoplankton production or algal biomass.

There are, of course, some serious limitations with these analyses. These are basically correlations and thus do not demonstrate causation; results may be related to some other co-variate. More importantly, other possible explanations for production or biomass variability were not always thoroughly examined (Peters, 1991). For example, in some of these papers it appeared that N was assumed, *a priori*, to be the key explanatory variable, while other factors, such as P or light availability, were not examined with equal rigor. One could make the case that sufficient data are now available to initiate a more comprehensive, comparative synthesis of estuarine primary production (both pelagic and benthic) that considers a wider selection of independent variables and uses dimensional scaling to the extent needed to ensure adequate comparability among different estuarine locations. In short, estuarine ecologists need to take a lesson from the limnologists who began doing just that some 30 years ago (e.g., Vollenweider, 1976) and developed tools useful for both scientific understanding and for lake management.

5.3. Nutrient limitation

The question of nutrient limitation is fundamentally important for understanding controls on estuarine production and practically important for understanding how to mitigate eutrophication. In recent decades, nutrient limitation concepts have been better defined, explanations for differences in nutrient limitation among systems have been clarified, and experimental approaches have been organized in a heiarchial suite, from short-term small-scale bioassays, to intermediate-scale mesocosm studies, to whole-system biogeochemical analyses. The history of development of nutrient limitation studies has been reviewed (Howarth, 1988) and more recent studies have discussed the use of data from these studies for nutrient management in such areas as Chesapeake Bay and the Baltic Sea (Elmgren and Larsson, 2001; Malone *et al.*, 1993). The basic story is summarized below.

In the 1970s limnologists produced convincing evidence that for many lakes P was the important limiting nutrient (e.g., Schindler, 1977). With the growing sense that estuaries and coastal waters were showing signs of serious nutrient-based eutrophication, the lake model was assumed to apply. However, contemporaneous studies in coastal areas (e.g., Ryther and Dunstan, 1971) suggested that N was more important than P in estuarine and coastal systems, and studies conducted during the 1980s generally supported that view (e.g., Caraco *et al.*, 1987; D'Elia *et al.*, 1986; Graneli, 1987). P limitation in lakes had been demonstrated at various scales of complexity/realism (i.e., bioassays, mesocosms and whole-lake experiments), but the same degree of testing had not been completed in estuaries and hence the N conclusion

needed to be viewed with caution (Hecky and Kilham, 1988). For many estuaries, however, long-term field studies (e.g., Jordan *et al.*, 1991), multi-year, system-wide bioassay studies (e.g., Fisher *et al.*, 1992, 1999), whole-year mesocosm experiments (D'Elia *et al.*, 1986; Harrison *et al.*, 1990; Oviatt *et al.*, 1995) and some whole–system experiments (Conley *et al.*, 2000; Elmgren and Larsson, 2001; Paerl *et al.*, 2004) have been completed, and the emerging story is more complete and complex.

In general, pelagic estuarine productivity tends to be limited by N; however, light, P, Si and other factors also play into the story. Nitrogen limitation appears to be more often the case in higher salinity than in tidal fresh waters and more intense in summer/fall than in winter/spring. These temporal/spatial patterns tend to parallel trends in dissolved inorganic nutrient ratios (DIN:DIP) in the water column which, in turn, are often reflective of the nutrient composition of inputs. Many authors indicate P limitation associated with high N: P ratios (>90, Caraco *et al.*, 1987; >90, D'Elia *et al.*, 1986; >80, Harrison *et al.*, 1990; >60, Kemp *et al.*, 2005; >30, Pennock and Sharp, 1994), a condition that often occurs during winter/spring in estuaries with significant freshwater inflows not dominated by sewage. Dodds (2003) reviewed use of DIN: DIP ratios as an indicator of nutrient limitation and argued for the use of TN:TP ratios rather than the inorganic ratios more commonly used in estuarine analyses. When N supply is extremely high (e.g., south China coast), P may be more generally limiting, but again, it seems probable that outside the plume of low salinity, N–rich water, limitation switches back to N (Harrison *et al.*, 1990). There is also some empirical evidence that P limitation is a more general feature of warm temperate embayments, such as those along the Gulf of Mexico (e.g., Murrell *et al.*, 2002).

In overview, the emerging picture is one of a mosaic of general N limitation, but with substantial time-space regions where productivity is limited by P and other factors. This description is certainly consistent with a view of estuaries as gradient-rich, dynamic ecosystems that lie between the land and the sea and are influenced by both. Given the diversity of responses reported for estuaries, a uniform nutrient management directive does not seem possible. In large temperate coastal systems that include a full salinity gradient from tidal fresh to polyhaline, it may be prudent to consider a "duel-nutrient reduction strategy" wherein both N and P loads are reduced. This approach ensures that eutrophic conditions will be reduced both in tidal freshwater areas where P tends to be limiting, and in meso- and polyhaline areas where N is more important (Conley, 1999; Elmgren and Larsson, 2001; Fisher *et al.*, 1999; Paerl *et al.*, 2004).

5.4. Benthic autotrophs and nitrogen

Although the majority of the discussion regarding N-productivity interactions has focused on phytoplankton, N is also an important control on benthic primary production in estuarine ecosystems. During the past two decades, there has been much research examining how nutrient additions have contributed to global seagrass decline (e.g., Duarte, 1995; Kemp *et al.*, 1983). The cause-effect linkage of seagrass decline and nutrient additions typically involves increased phytoplankton standing stocks and associated reduced water transparency (e.g., Nielsen *et al.*, 2002).

In addition, in some areas, enhanced epiphytic growth on seagrass leaves further reduces light availability, eventually leading to loss of this community (e.g., Taylor *et al.*, 1995; Twilley *et al.*, 1985).

In other shallow ecosystems, macroalgae play a prominent role in the response to N addition: as nutrient inputs are increased, macroalgae first replaces seagrasses and then with further nutrient increases, macroalgae are themselves replaced by dense phytoplankton stocks (Valiela *et al.*, 1992). This sequence is modified by the influence of water residence time and the nutrient buffering influence of adjacent fringing ecosystems (e.g., Valiela *et al.*, 2001). Bowen and Valiela (2001) traced historical changes in N loads to a cluster of coastal embayments and reported a doubling of loads between 1938 and 1990, progressive increases in phytoplankton and macroalgae stocks and a decline in seagrass coverage. It is somewhat dispiriting to learn that seagrass declines, at least in these coastal systems, were associated with N loads as low as 3 g N m^{-2} year^{-1}, rates far lower than for many estuaries (Fig. 18.9). A series of papers concerning nitrogen effects on autotroph assembledges in Danish estuaries were especially comprehensive considering water residence times, nutrient demands, growth rates, C:N:P ratios and light requirements. (Borum, 1996; Borum and Sand–Jensen, 1996; Pedersen and Borum, 1996; Sand-Jensen and Borum, 1991). These studies found that nutrient enrichment changed plant community composition such that slow growing macro-algae were replaced by fast growing algal species, both of which rely primarily on water column rather than sediment nutrient sources.

In overview, several things seem clear. Very high primary production rates can be maintained in benthic dominated systems (Fig. 18.20, inset) with sufficient light reaching the bottom. Benthic autotrophs (microalgae, macroalgae and seagrass) are capable of obtaining N needed for growth either from sediment porewaters or from overlying water column pools depending on concentration gradients. There appears to be a generally predictable sequence relating predominant autotrophic groups to nutrient enrichment level. This sequence is likely related to competition for nutrients and light, where seagrasses dominate at one end of the gradient (low nutrients) because of their ability to tap deep sediment porewater nutrients, and phytoplankton dominate the other end (high nutrients) because of their ability, at high densities, to shade out benthic autotrophs.

6. Nitrogen and Secondary Production

Inputs and transformations of N and other nutrients directly influence production of all populations of consumer organisms, be they small or large. On one hand, nutrient additions generally result in increased primary production, which propagates forward to support increased growth of consumer populations, including fish. The amplitude of nutrient enrichment effects, however, tends to be damped as it is passed from one consumer population to the next, with responses being relatively large for primary producers, modest for herbivores, and small for top-carnivores (e.g., Micheli, 1999). On the other hand, spatial or temporal shifts in the abundance of fish and other consumers can result in marked effects on nutrient transport and recycling

processes (e.g., Kitchell *et al.*, 1979). Primary production is passed on to diverse consumer organisms through feeding interactions and food-webs (e.g., Clarke, 1946; Lindeman, 1942). These webs can often be described with equivalent straight food-chains, where plants are consumed by herbivores, which are consumed by first-level carnivores, and so on (Ulanowicz and Kemp, 1979). Food-webs and food-chains are considered to be controlled by "bottom–up" or "top-down processes," depending on the relative responses to changes in nutrient inputs at the bottom or changes in carnivorous predation at the top, respectively (e.g., Carpenter *et al.*, 1985). Here, we address the double-edged question of how secondary production and nutrient cycling processes are related. We focus on N because it tends to be the limiting nutrient for primary production on annual time scales in most estuaries.

6.1. Effects of nitrogen enrichment on secondary production

It has been suggested by Caddy (1993, 2000) that nutrient enrichment affects secondary producers through a range of mechanisms that follow a sequence of three stages. At relatively low nutrient loading rates, the first stage involves enhanced production of demersal and pelagic species as a result of increased food availability. In the second stage, at moderate nutrient loading rates, benthic invertebrates and demersal fish tend to decline but planktonic consumers and pelagic fish species continue to increase with more nutrient additions. In the hypothesized third stage of this model, there is a general decline in total production of invertebrates and fish as water quality and habitat conditions become severely degraded. There is substantial direct evidence for the first two stages of this proposed sequence, while evidence for the third stage is more limited and indirect.

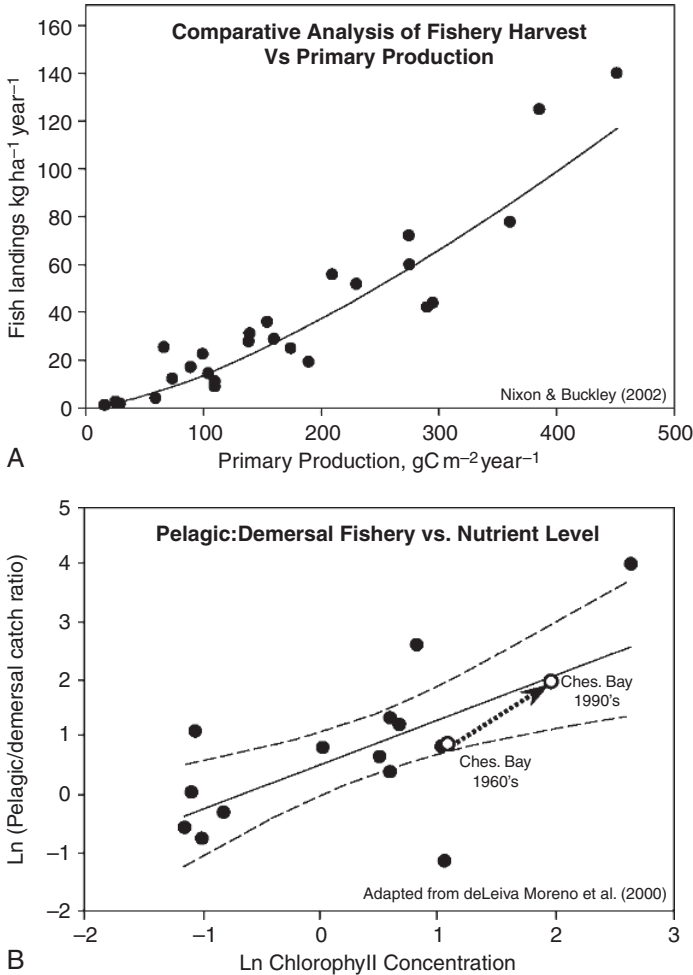
Comparative analysis of fisheries landings and primary production among diverse coastal systems (Nixon and Buckley, 2002) reveals a significant positive relationship (Fig. 18.21A). This may illustrate Caddy's first stage, where increasing inputs of nutrients support higher rates of primary production that in turn support higher rates of fish production and harvest. At least for herbivorous fish such as Atlantic menhaden, this relationship is supported by controlled experiments (Keller *et al.*, 1990) and bioenergetic models (Luo *et al.*, 2001) which indicate that production of estuarine fish tends to increase with nutrient enrichment. Although this relationship is impressive, there are key underlying assumptions which need to be considered. Perhaps the most obvious of these is the assumption that fisheries harvest provides a dependable index of fish production. The relationship (Fig. 18.21A) also suggests that exploited fish populations are generally food-limited and relatively unaffected by fishing mortality, conclusions that are difficult to reconcile with fundamental principles of fisheries science (e.g., Chesney *et al.*, 2000). Alternative explanations include the possibility that human population density (and associated nutrient loads) and fishing pressure are highly correlated when comparing different estuaries or regions. Consequently, densely populated coastal regions, which tend to have eutrophic estuarine waters and high rates of primary production, also support heavily exploited fisheries, often dominated by species feeding at lower trophic levels (e.g., Pauly *et al.*, 1998). Nevertheless, the strength of this relationship and the fact that similar patterns have been reported previously for lakes are undeniable (e.g., Nixon, 1988).


Figure 18.21 Comparative analyses of fisheries characteristics in relation to trophic status of estuarine and coastal ecosystems around the world: (A) fisheries harvest versus primary production (re-drawn from Nixon and Buckley, 2002); (B) ratio of pelagic-to-demersal fish caught in fishery plotted versus phytoplankton chlorophyll concentration (natural logarithm of both x and y variables). Figure 18.21 (B) was re-drawn from de Leiva Moreno *et al.* (2000) with Chesapeake Bay data added for two time periods.

Consistent with Caddy's second stage, recent data indicate that continued nutrient enrichment causes estuarine benthic habitats to become degraded, thereby contributing to marked shifts in food-web structure (e.g., Kemp *et al.*, 2005). For example, increased nutrient loading leads to decreased water clarity, which tends to cause loss of seagrass habitat in shallow areas (e.g., Duarte, 1995; Kemp *et al.*, 1983) and related reductions in fish and invertebrate production (e.g., Lubbers *et al.*, 1990). In some coastal lagoons, the loss of seagrass may be followed by outbreaks of dense benthic macroalgae stands with episodic hypoxic events that further degrade these

habitats for fish and benthos (e.g., Deegan, 2002). Enhanced phytoplankton production from N enrichment can also degrade deeper estuarine habitats by inducing prolonged seasonal hypoxia and anoxia in stratified water columns (e.g., Hagy *et al.*, 2004). As a result of this deep-water hypoxia, the behavior of bottom-dwelling animal populations is altered (e.g., Brandt, 1993; Phil *et al.*, 1991) and their abundance, diversity and production tend to decline (Howell and Simpson, 1994; Kemp *et al.*, 2005). A major consequence of benthic habitat degradation is a general switch from food-webs dominated by demersal pathways under low N-loading to ones dominated by pelagic pathways in more eutrophic estuaries (e.g., de Leiva Moreno *et al.*, 2000). It appears that this trend is often reflected in fisheries harvests with the ratio of pelagic-to-demersal (P/D) catch being directly related to indices of nutrient loading such as phytoplankton abundance (Fig. 18.21B). Time-series fisheries data in Chesapeake Bay from 1960 to 2000 reveal a trend of generally increasing P/D ratio that parallels increases in nutrient loading (Fig. 18.21B; Kemp *et al.*, 2005).

There is also evidence that N and P enrichment can significantly alter coastal ecosystems through changes in trophic structure that are not related to degradation of benthic habitat. With coastal eutrophication N and P loading tends to increase more rapidly than Si inputs, thereby resulting in decreasing Si:DIN ratios, limiting diatom growth and allowing smaller algal cells to dominate (e.g., Turner, 2001). The preponderance of smaller food particles reduces the efficiency by which primary production is transferred to herbivorous zooplankton and tends to increase the relative fraction of phytoplankton production that sinks to the benthos or enters the pelagic microbial loop (Kitchell and Carpenter, 1993). In addition to declining Si:DIN ratios, another mechanism causing a larger fraction of phytoplankton production to shift from zooplankton grazing to microbial degradation with nutrient enrichment involves predation-limitation on the growth of herbivore populations (e.g., Kemp *et al.*, 2001). Modeling studies suggest that this shift from metazoan grazers to microbial decomposers may be a general feature of all pelagic food-webs where exploited fisheries cause strong top-down control (Brooks *et al.*, 2005). Indeed, many investigators provide evidence to suggest that eutrophication tends to cause this shift from herbivorous grazing food-chains to microbial pathways (e.g., Baird *et al.*, 2004). Although detailed mechanistic understanding of these trophic responses to nutrient enrichment are generally lacking, recent evidence suggests that some systems may be currently experiencing Caddy's third stage (e.g., Yamamoto, 2003).

6.2. Effects of estuarine animals on nitrogen-budgets and cycles

In addition to being affected by N-loading to coastal waters, many animal populations in estuaries and other environments markedly influence the balance and cycling of N and other nutrients (Kitchell *et al.*, 1979). For example, respiration and excretion by Atlantic menhaden traveling in large schools can significantly deplete oxygen and increase ammonium concentrations in estuarine waters (Oviatt *et al.*, 1972). In pelagic estuarine mesocosm experiments, fish have been shown to enhance phytoplankton growth both through top-down effects on zooplankton grazing and through bottom-up effects of nutrient excretion (e.g., Micheli, 1999). In most cases, however, such large direct effects of fish on estuarine N

dynamics are confined to dense schools of herbivores or planktivores. In some estuaries with productive fisheries, harvest can account for a modest loss ($\approx$2–8%) of N inputs to the system, and an additional N sink of similar, or even larger magnitude, may be associated with emigration of fish using the estuary as a seasonal feeding ground (e.g., Boynton *et al.*, 1995; Deegan, 1993).

Benthic invertebrate populations can also influence N cycling in estuarine environments. As discussed earlier in this chapter, benthic invertebrates living as deposit-feeding infauna can influence nutrient cycling both through ventillation and bioturbation of sediments and through direct excretion and related metabolic processes. Reefs and other dense populations of benthic filter-feeders can, however, exert substantial influence on estuarine N cycling and transformation processes via a range of mechanisms. It is well established that filtration by clams, mussels and oysters can substantially reduce phytoplankton populations in overlying waters (e.g., Cloern, 1982). In many estuaries, native benthic filter-feeding populations have been depleted to levels that currently have little impact on plankton dynamics (e.g., Newell, 1988). In other estuaries, however, non-native species of benthic bivalves have grown to sufficient densities to readily control phytoplankton abundance in overlying waters (Cohen *et al.*, 1984). In a few coastal systems, healthy bivalve populations can still control plankton communities under certain hydrologic conditions (e.g., Møhlenberg, 1995). Similar densities of benthic bivalves, such as hard clams, have been shown to cause significant increases in rates of sediment N cycling through both direct excretion and increased turn-over of organic matter (e.g., Doering *et al.*, 1987). Under extreme conditions of intense benthic filtration associated with commercial culture, rates of N and P recycling can be greatly enhanced (e.g., Souchu *et al.*, 2001) stimulating growth of benthic macro-algae (e.g., Rafaelli *et al.*, 1998). In contrast, the eastern oyster, which maintains high clearance rates that are relatively independent of food concentration, produces large amounts of particulate N and P as psuedofeces (Newell *et al.*, 2004). Much of this pseudofecal material is deposited initially in shallow areas, where it supports enhanced production of deposit-feeding animals and increased nutrient burial (Newell *et al.*, 2004). In addition, recent experiments indicate that such oyster bio-deposits may stimulate N_2 loss via coupled nitrification-denitrification (Newell *et al.*, 2002). Although many questions remain, we are beginning to understand how heterotrophic organisms from bacteria to fish are linked together through diverse pathways and relationships in estuarine N cycles.

7. Summary and Future Directions

We indicated at the beginning of this paper that the last two decades have seen significant advances in understanding many aspects of N in estuaries. Scientific progress is, perhaps, difficult to comprehend on times-scales less than decades because the slow, incremental adaptation to new or refined ideas tends to mute our sense of progress. Our review of the estuarine N literature from the twenty years since the publication of Carpenter and Capone (1983) has revealed important new

developments in this field. A vastly expanded pool of measurements, ranging from simple N concentrations to far more sophisticated rate measurements, supports this conclusion. Improved measurement techniques and wider access to new instrumentation have also contributed to this progress. Twenty years ago, there were simply too few observations reported to develop robust generalizations about spatial and temporal patterns and controls on N cycling processes. In addition, a matured understanding of nutrient-limitation of primary production in estuarine systems during this time has contributed to development of science-based nutrient and eutrophication abatement programs in many estuarine systems.

Synthesis of these diverse observations into useful estuarine models of N transport, transformation, assimilation, and storage has, however, made less progress during this time period (e.g., Cloern, 2001; Nixon *et al.*, 1996). Using the broad, ecosystem scale perspective adopted in this paper, we emphasize the continued need for more rate measurements, data syntheses and predictive models of estuarine N cycling. Most estuarine research and monitoring programs have focused on measuring N concentrations, with much less emphasis on rate measurements that are needed to assess system dynamics. For example, N loss terms due to burial, denitrification and export are rarely measured at annual time-scales for whole systems, while other key rate processes such as primary production rates of benthic autotrophs have been virtually ignored until very recently (Chapter 23 by McGlathery, this volume). An important goal is to find ways to incorporate rate measurements into long-term, system–wide monitoring programs rather than relegate such measurements to research programs focused at smaller and shorter scales. For many coastal systems worldwide, vast and expanding water quality data sets call for integrated synthesis focused on N cycling and related issues. Nutrient budgets represent one type of synthesis that requires a variety of processes to be linked for computing the sources and fates of N in estuaries. The challenge is to develop multi-year N–budgets for diverse estuarine systems using consistent protocols (e.g., Gordon *et al.*, 1996). Future comparative analyses of these budgets will contribute to a deeper understanding of physical, geological and climatological controls on estuarine N dynamics.

Finally, we suggest that innovative conceptual, analytical and forecasting models need to be developed and tested against field and experimental observations. Recent conceptual schemes proposed to describe and explain ecological interactions associated with estuarine eutrophication (Cloern, 2001; Kemp *et al.*, 2005) need to be quantified toward the goal of developing reliable numerical models for testing our scientific understanding and for providing useful forecasts for estuarine nutrient management. It is particularly important that conceptual models relating N-loading to fish production and harvest (e.g., Caddy, 1993; Nixon and Buckley, 2002) be quantified, tested and improved to support ecosystem based management of water quality and fisheries. It is clear that current estuarine science is rich with empirical observations but relatively poor on integrated understanding. Nowhere is the need to apply such integrated, predictive scientific knowledge more severe than in the world's estuarine regions, where disturbance associated with densely populated human societies threatens the quality of these productive ecosystems.

Contents

1. Introduction

Nitrogen (N) availability is frequently cited as the factor limiting primary production in marine systems over annual time scales (Capone and Kiene, 1988; Ryther and Dunstan, 1971; Vitousek and Howarth, 1991) though phosphorus (P), silica (Si) limitation or co-limitation by N, P, and/or Si sometimes occur on seasonal time scales (Conley *et al.*, 1993; Malone *et al.*, 1996; Officer and Ryther, 1980). In offshore waters, the presence of bioavailable iron can also regulate primary productivity, particularly that by diatoms (Coale *et al.*, 1996; Hutchins and Bruland, 1998; Martin *et al.*, 1994). Sediment N pools reflect a balance between inputs (external or internal) and outputs (sedimentation, denitrification (DNF), long-term burial, or export), and this balance is affected by a variety of environmental and physiological factors (Joye, 2002). Within the sediment, N is cycled primarily by microbially-mediated redox reactions between more highly oxidized forms (nitrate, NO_3^-, or nitrite, NO_2^-) and more reduced forms (ammonium, NH_4^+, amino acids, or organic nitrogen compounds). Gaseous products of these redox reactions may include dinitrogen, N_2, nitric oxide, NO, and nitrous oxide, N_2O. One characteristic of the sediment N cycle is the coupling between aerobic and anaerobic processes. Another characteristic is that for a given species, e.g., NO_3^-, several competing pathways and potential fates may exist. In this chapter, we review the factors regulating sediment N cycling, both in the bulk sediment environment and on a process level.

2. The Sediment Nitrogen Cycle: Overview

Sediment processes are integral components of the N cycle, particularly in shallow waters that often have higher sedimentation rates than deeper waters. In shallow coastal ecosystems, sediments contribute to ecosystem metabolism and provide habitat for a variety of microorganisms, invertebrates, and plants. Because sediments are porous media comprised of water, inorganic particulates, and living and nonliving organic materials, they are characterized by interactions between physical, biological, and chemical processes (Van Cappellen and Gaillard, 1996), including advective and diffusive transport, resuspension, bioturbation, and bioirrigation. Because of the relative magnitudes of these physical–biological interactions, sediments often exhibit steep gradients of electron donors and acceptors and process rates. The organic nitrogen in sediments may derive from water column or benthic primary production, nitrogen fixation (NFIX), or allochthonous sources (e.g., river or terrestrial-derived particulate organic matter). Allochthonous N inputs may also include particulate inorganic components (e.g., ammonium sorbed onto particles). The rate at which organic nitrogen is mineralized to inorganic forms depends on its source and characteristics such as its C/N ratio (Burdige, 2006). Nitrogen content of

sediments in estuarine and coastal systems varies by over an order of magnitude, primarily depending on the sediment type. For example, in shallow sites located in Chesapeake Bay, sediment nitrogen varied from 0.0075% to 0.577% (Anderson, in preparation) and at sites on the continental shelf of Eastern Massachusetts ranged from 0.03% to 0.52% (Hopkinson *et al.*, 2001).

The presence of a solid matrix in sediments slows rates of diffusive and advective transport of chemicals, creating steep redox gradients that microbes may exploit for energy generation. These redox gradients also facilitate coupling between aerobic and anaerobic processes, such as nitrification (NTR)–DNF, that drive sediment–water column fluxes of NH_4^+, NO_x^-, N_2, and N_2O. The sulfur cycle, which plays an important role in mediating organic matter decomposition and whose intermediates regulate N-cycling processes, also requires close coupling between aerobic and anaerobic processes. Transport through sediments is related to porosity, which decreases exponentially with depth due to compaction (dewatering) of sediments (Rabouille and Gaillard, 1991). Transport is mediated by diffusion (Glud *et al.*, 2003), advection (horizontal or vertical; Huettel *et al.*, 2003; Ziebis *et al.*, 1996), and biological processes such as nonlocal mixing via bioturbation and bioirrigation (Aller, 1982, 1994; Aller and Aller, 1998; Meile *et al.*, 2001) or plant root release of materials (Frederiksen and Glud, 2006). The physical and chemical processes influencing sediment nitrogen processing are discussed further in Section 3.

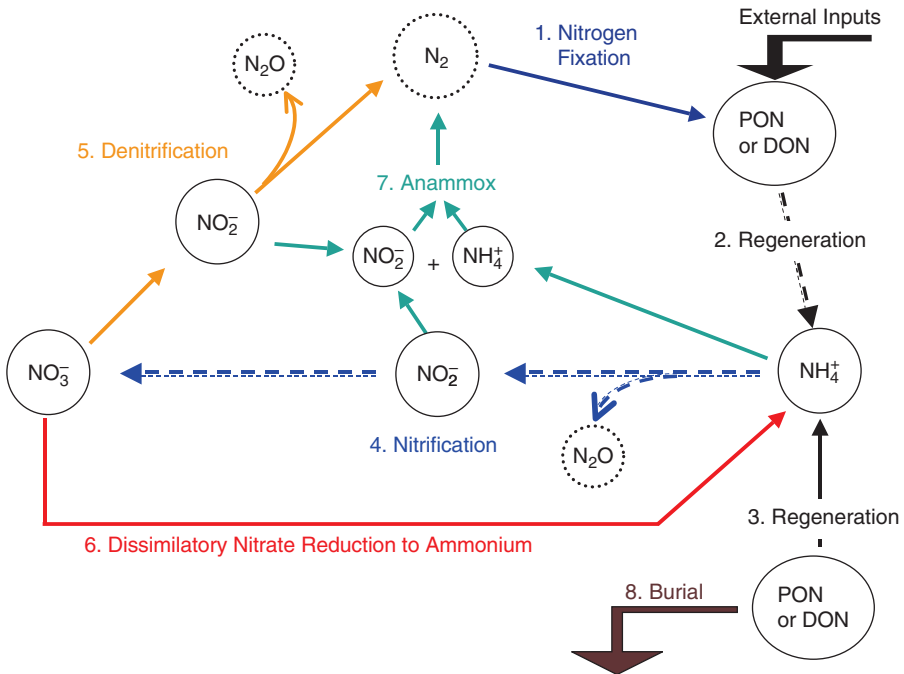
The sediment N cycle consists of oxidative and reductive processes that are frequently coupled in space and/or time (Herbert, 1999) and are strongly influenced by chemical, physical, and biological factors (Figs. 19.1 and 19.2). We present


Figure 19.1 Processes in the sediment nitrogen cycle. Hashed lines reflect aerobic processes while solid lines reflect anaerobic processes. Species in hashed circles are gaseous.
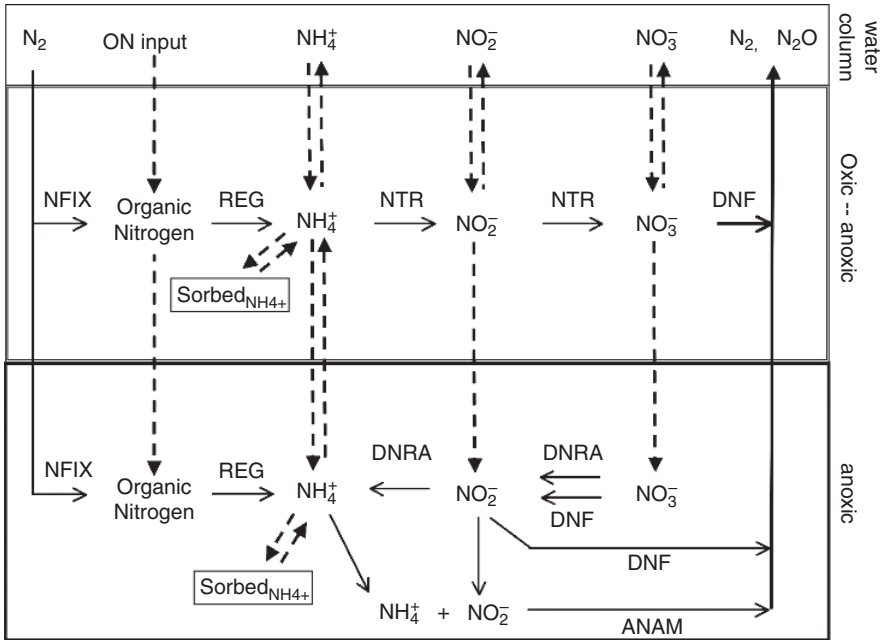

Figure 19.2 Spatial segregation of N cycle processes in sediments. Solid lines represent biological processes (NFIX = dinitrogen fixation; REG = regeneration; NTR = nitrification; DNF = denitrification; ANAM = anammox) and dashed lines represent exchange between boxes by diffusive, advective, or surface exchange (in the case of exchangeable ammonium) processes.

available ranges of rates of key processes; however, we note that a major problem with comparing rates available in the literature is the inconsistency of units for which rates are presented. We have limited our summary of activities to those that were either presented in, or easily converted to, units of mmol N m^{-2} d $^{-1}$. In addition, the ability to accurately determine most N-cycling process rates has suffered from methodological limitations; as a result the technology used to measure processes such as DNF has changed rapidly over the last 10 years, making it difficult to compare rates. The methodologies used to assess N-cycling process rates are discussed in Section 5. Throughout this chapter, we refer to rates >1.5 mmol m^{-2} d^{-1} as "high" and rates <0.25 mmol m^{-2} d^{-1} as "low."

2.1. Regulation of nitrogen fixation

NFIX is the biologically mediated conversion of molecular nitrogen (N_2) to cellular N (e.g., amino acids). NFIX rates in sediments are often lower than rates of the other N cycle processes because NFIX is inhibited by the high concentrations of bioavailable dissolved inorganic nitrogen (DIN) that are often present in sediments (Fig. 19.1, arrow 1; Capone, 1988; Seitzinger and Gardner, 1987). However, NFIX can occur at high rates, exceeding 2.5 mmol m^{-2} d^{-1}, in some sediments (Table 19.1). NFIX is mediated by a variety of organisms, including primary

producers (e.g., cyanobacteria), chemolithotrophs (e.g., photosynthetic bacteria and methanogens), and heterotrophs (e.g., sulfate reducers). NFIX requires a substantial input of energy; thus N_2 fixing microbes are often reductant limited. Rates of light–driven NFIX often exceed rates of chemolithotrophic (Van Gemerden, 1993) or heterotrophic NFIX (Bebout et al., 1987; Steppe and Paerl, 2002; Welsh et al., 1995), but elevated rates of heterotrophic NFIX have been observed in some wetland and seagrass habitats (Gotto and Taylor, 1976; Sundareshwar et al., 2003; Welsh et al., 1995).

In sediments with active communities of micro- (Paerl et al., 1993) or macro- (An et al., 2001; McGlathery et al., 1998) primary producers or with substantial rates of labile organic matter input (e.g., dissolved organic matter (DOM) leakage from roots; Howarth et al., 1988), rates of NFIX can be substantial. In general, rates of NFIX in subtidal sediments are lower than rates in intertidal sediments (Joye and Paerl, 1993) because light energy is more limiting in subtidal sediments, making heterotrophic NFIX the dominant process. Many of the factors that influence water column NFIX are less of an issue for benthic N_2 fixers. For example, metals, e.g., bioactive Fe, can be abundant in sediments but may limit water column NFIX

activity (Mills *et al.*, 2004; Paerl *et al.*, 1994). Oxygen concentration is a regulator of NFIX in both water column and benthic habitats. Highest NFIX rates tend to occur in tropical habitats but only limited data are available for temperate sediments and "hotspots" of NFIX in these habitats may remain to be discovered. Regulation of benthic N_2 fixation is discussed further in Chapter 4 by Ed Carpenter and Doug Capone; Chapter 21 by Judy O'Neil and Doug Capone, this volume.

2.2. Ammonium regeneration by mineralization

Organic nitrogen is introduced to sediments via either external (allochthonous) or internal (autochthonous, NFIX) mechanisms. The breakdown of sediment organic nitrogen occurs in several phases. Particulate organic nitrogen (PON) can be mineralized directly to ammonium (NH_4^+) or it may be metabolized to dissolved organic nitrogen (DON), which is further mineralized to NH_4^+. Mineralization of PON or DON to NH_4^+ occurs under both oxic and anoxic conditions (Fig. 19.1, arrows 2 and 3; Fig. 19.2). Ammonium regeneration is inherently linked to organic carbon oxidation; the fate of mineralized NH_4^+ depends in part on the C:N ratio of the reacting organic matter (Blackburn, 1979). Some PON escapes mineralization and is buried and subsequently sequestered in sediments for the long term (>100 or more of years; Fig. 19.1, arrow 8). Ammonium regenerated in sediments may either (1) be sorbed onto particles, (2) flux from the sediment to the overlying water, (3) be consumed by biological processes within the sediment or at the sediment–water interface (see Fig. 19.3, Section 4), (4) be transformed to nitrite (NO_2^-) and then nitrate (NO_3^-) by nitrifying microorganisms (Fig. 19.1, arrow 4; Fig. 19.2), or (5) be transformed to molecular nitrogen (N_2) via the anammox (ANAM) process (Fig. 19.1, arrow 7; Fig. 19.2). Ammonium can reversibly adsorb onto sediment particles (Rosenfeld, 1979) and adsorption can be described using a linear adsorption coefficient (Mackin and Aller, 1984). Ammonium adsorption onto particles may vary according to redox conditions (Morse and Morin, 2005) and possibly as a function of the NH_4^+ concentration if the solid phase is almost saturated with NH_4^+. Finally, some organic nitrogen may be transformed to form geopolymers via abiotic chemical condensation reactions (Burdige, 2006; Tisset and Welte, 1978). Geopolymers are resistant to microbial degradation and, thus, their formation represents a long-term sink for organic nitrogen in sediments; such compounds would be represented by Fig. 19.1, arrow 8.

2.3. Coupling of nitrification, denitrification, dissimilatory nitrate reduction to ammonium, and anammox

Because NTR links the reduced and oxidized sides of the N cycle, it can be considered a central process that provides substrate to microbes that employ nitrate or nitrite as oxidant (see Chapter 5 by Ward, this volume; Fig. 19.1, arrow 4). Like NH_4^+, the products of NTR, NO_2^-, and NO_3^-, may experience one of several possible fates, including (1) flux from the sediment, (2) assimilation within the sediment or at the sediment–water interface, or (3) reduction by one of three possible dissimilatory pathways: DNF, dissimilatory nitrate reduction to ammonium (DNRA), or ANAM (Fig. 19.1, arrows 5, 6, and 7; Fig. 19.2). Uptake of NO_x^- by
Figure 19.3 Impact of benthic primary producers on N cycle processes.

dissimilatory anaerobic processes requires diffusion of NO_x^- into anoxic zones or temporal separation of oxic production and anoxic consumption (e.g., daytime NO_x^- production followed by nighttime dissimilation).

Coupling of NTR and DNF or ANAM results in a net loss of fixed N, as gaseous forms, from the sediment (Fig. 19.2). DNF is the microbially-mediated conversion of NO_3^- to NO_2^- and then gaseous products, first nitric oxide, then nitrous oxide, N_2O, and finally dinitrogen, N_2, that are not generally considered to be bioavailable (see Chapter 6 by Devol, this volume). DNF rates have been reported for an extremely large number of sediments across the globe using a variety of methods (see Table 19.2). DNF rates vary as a function of NO_3^- availability, temperature, DOC concentration, and salinity; activity is much higher in shallow coastal estuaries (up to 30 mmol m^{-2} d^{-1}) compared to continental shelf or slope sites (~2 mmol m^{-2} d^{-1}; Table 19.2). Sediment DNF rates are often coupled to NTR rates, so DNF rates may provide insight regarding NTR rates in systems with low water column NO_3^- concentrations.

Until recently, DNF was considered the dominant dissimilatory NO_3^- sink in sediments (Hulth *et al.*, 2005); however, recent work has illustrated the importance of DNRA (An and Gardner, 2002; Binnerup *et al.*, 1992) and ANAM (Dalsgaard and

Thamdrup, 2002; Thamdrup and Dalsgaard, 2002a) in the sediment nitrogen cycle. DNRA converts NO_3^- to NH_4^+, thereby retaining N in a readily bioavailable form (Binnerup *et al.*, 1992; Jørgensen, 1989; Porubsky *et al.*, 2008a). ANAM microorganisms use NO_2^- as the oxidant for anaerobic NH_4^+ oxidation, and the metabolic end product is N_2 (Strous *et al.*, 1999). In fact, NO_2^- reduction coupled to NH_4^+ oxidation leading to N_2 generation was first documented in a *Nitrosomonas*-type nitrifying bacterium (Bock *et al.*, 1995; Poth, 1986). While DNF and ANAM lead to N_2 production and, thus, fixed N loss from the sediment, DNRA maintains fixed N in a biologically available form that can fuel subsequent microbial production. Compared to DNF, far fewer estimates of ANAM and DNRA rates are available in the literature (Table 19.3). For ANAM few studies report rates in units of mmol m^{-2} d^{-1}. For DNRA, rates are often comparable to DNF rates, though the maximum reported rates of DNRA are lower than those of DNF; this could result from the paucity of studies on published reporting DNRA rates.

A final component of the sediment N cycle that warrants mention is manganese-mediated conversion of NH_4^+ to NO_x^- or N_2. The reduction of Mn-oxides can be

coupled to the oxidation of NH_4^+ producing NO_x^-, and the oxidation of Mn^{2+} can be coupled to NO_3^- reduction and N_2 production. These processes are thermodynamically favorable at circumneutral pH (Luther et al., 1997). Interactions between manganese reduction and ammonium oxidation have been inferred from pore water data collected at a variety of sedimentary locations (e.g., Hulth et al., 1999, 2005; Luther et al., 1997, 1998; Mortimer et al., 2002; and references therein). However, attempts to quantify rates of this process directly using ^{15}N tracers have been unsuccessful thus far (Thamdrup and Dalsgaard, 2000), making the role of this process

in the N cycle under naturally occurring substrate concentrations and environmental conditions questionable (Hulth *et al.*, 2005).

3. Chemical and Physical Factors Influencing Sediment Nitrogen Transformations

3.1. Interactions between the nitrogen and sulfur cycles

A variety of chemical species and physical factors influence the fate of N in sediments, including salinity, pH, oxygen concentration, substrate concentrations, temperature, and residence time. The impacts of some of the common factors known to influence N cycle processes are shown in Table 19.4. The concentrations of many chemical species are regulated by biological activity. For example, hydrogen sulfide (H_2S) concentration is influenced by rates of microbial sulfate reduction and also by the sediment iron (Fe) oxide content because Fe oxides can titrate H_2S, thereby reducing the amount of H_2S in solution (Canfield, 1989). Sulfide inhibits both steps of NTR (Joye and Hollibaugh, 1995) and short-circuits DNF (Sørensen *et al.*, 1980), resulting in elevated production rates of N_2O relative to N_2 and reduced rates of overall DNF activity (Joye, 2002; Senga *et al.*, 2006). However, H_2S may stimulate DNRA (An and Gardner, 2002) and NFIX (Bebout *et al.*, 1993; Tam *et al.*, 1982). The effect of H_2S on ANAM is unknown.

In systems with high water column NO_3^- concentrations, high concentrations of H_2S in sediments may promote coupling of NO_3^- reduction and H_2S oxidation by vacuolate sulfur oxidizing bacteria (Otte *et al.*, 1999; Sayama, 2001; Zopfi *et al.*, 2001). These microorganisms appear to couple H_2S oxidation to DNRA, thus promoting N retention at the expense of N loss via DNF or ANAM. H_2S may also stimulate DNRA by additional fermentative microorganisms (An and Gardner, 2002). Thus, the overall effect of H_2S on the sediment N cycle is to promote sediment N retention or gain and reduce N loss through coupling of NTR and DNF (or ANAM). The presence of

Table 19.4 Impact of Various Physical Parameters and Chemical Species on Rates of Nitrogen Cycle Processes

Process	Factor						
	Oxygen	T(°C)	Labile DOC	H_2S	NH_4^+	NO_2^-	NO_3^-
Nitrogen fixation	−	+	+	+	−	−	−
Nitrification	+	+	−	−	+	−/?	N
Denitrification	−	−	+	−	N	+	+
Anammox	−	−	?	?	+	+	+
Dissimilatory NO_3^- rdn	−	+	+	+	N	+	+

(+) denotes stimulation while (−) denotes inhibition of activity. For temperature, the effect of temperature (>16°C) is noted. The impact of low temperature can be considered the opposite. N, no direct effect known; ?, unknown.

H_2S thus acts as a positive feedback on the N cycle, promoting N recycling and retaining N in the system so that it can fuel additional biological production, the regeneration of which further stimulates sulfate reduction and H_2S production.

3.2. Regulation of nitrogen cycle processes by oxygen

Oxygen is a potent regulator of most processes in the N cycle (Fig. 19.2; Table 19.4). The only process in the N cycle that is not strongly regulated by O_2 concentration is organic N mineralization (NMIN) ($\sim NH_4^+$ regeneration). Ammonium mineralization occurs consistently throughout the sediment column under both oxic and anoxic conditions, although rates may be slightly higher under oxic conditions. Decreases in rates of NMIN over depth are probably more strongly influenced by reductions in organic matter reactivity than by the transition from oxic to anoxic conditions (Blackburn, 1979). While surficial (recent) sediment organic nitrogen is dominated by amino acids and proteins, these labile components are lost during early diagenesis and more recalcitrant organic N forms (e.g., heterocyclic N) dominate at depth (Burdige, 2006; Dereene et al., 1998; Gelinas et al., 2001).

Of the other processes in the N cycle, NFIX, ANAM, and DNRA are obligate anaerobic processes while NTR is an obligate aerobic process (though anaerobic ammonium oxidation by Nitrosomonas has been reported; Poth, 1986). DNF is a facultative process meaning that most denitrifiers prefer to respire O_2 instead of NO_3^- when O_2 concentrations exceed $\sim 20\ \mu M$ (Tiedje, 1982). Though many N_2 fixing microbes survive exposure to oxic conditions, the process of NFIX is tightly regulated by O_2 because O_2 exposure deactivates key enzymes (i.e., nitrogenase; Postgate, 1998). Most of the microbes responsible for ANAM and DNRA are obligate anaerobes and while they are able to tolerate oxic conditions, their activity is limited largely to anoxic conditions (Dalsgaard et al., 2005; Kelly-Gerreyn et al., 2001; Risgaard-Petersen et al., 2004a,b, 2005). An exception to this is the vacuolate sulfur bacteria (e.g., Beggiatoa or Thioploca) that mediate DNRA. These facultative anaerobes are chemoautotrophs (Nelson and Jannasch, 1983) that concentrate NO_3^- in a central vacuole (McHatton et al., 1996) and use it as the electron acceptor for anaerobic H_2S oxidation (Otte et al., 1999; Sayama, 2001). The role of vacuolate sulfur bacteria in the sediment N cycle is increased when both NO_3^- and H_2S are present (Sayama et al., 2005). Species such as Thioploca can link the N and S cycles when surface NO_3^-–rich and deep H_2S-rich zones are separate by vertical migration of filaments within sheaths (Zopfi et al., 2001).

Variations in the concentration and distribution of oxygen (O_2) in sediments can result from benthic primary production, release of O_2 from plant roots, advective mixing of overlying water into the sediment (bioturbation), or diffusive exchange of O_2 between the overlying water and sediments. The activity of benthic primary producers drives microscale (μm to cm) variation in O_2 concentrations and distributions in sediments (Revsbech et al., 1989; Wiltshire et al., 1996) while macrobiological activity, including bioturbation, bioirrigation, or plant-mediated root dynamics, can alter O_2 distributions at spatial scales from centimeter to tens of centimeter. The presence of benthic primary producers at the sediment–water interface also drives dramatic day–night variations in both the O_2 concentration and the vertical extent of the oxygenated zone (Revsbech et al., 1983). Rooted

macrophytes or the presence of tube-dwelling animals further intensifies horizontal and vertical O_2 distributions (Aller, 1982, 1994; Aller and Aller, 1998; Frederiksen and Glud, 2006; Kemp and Murray, 1986). Variations in rates of benthic production, root O_2 release and/or animal activity generate spatial and temporal complexity in sediment O_2 distributions and thus in the cycling of N in sediments. These topics are discussed further in the "biotic controls" section (Section 4).

The concentrations of different oxidized N species, such as NO_2^- and NO_3^-, hereafter referred to as NO_x^-, are largely regulated by biological processes. However, elevated water column concentrations of NO_x^- can result from septic or agricultural and groundwater inputs as well as from *in situ* biological processes (water column NTR) occurring in rivers (Berounsky and Nixon, 1990; Pakulski *et al.*, 1995). In some cases, high water column NO_x^- concentrations support NO_x^- diffusion into sediments, which fuels dissimilatory processes. However, in most cases sediment NTR of NH_4^+ generated by mineralization of PON or DON provides the majority of NO_x^- consumed by dissimilatory processes or by benthic primary production, suggesting that NTR limits most other nitrogen requiring processes, such as, ANAM, DNRA, DNF, and GPP (gross primary production) (An and Joye, 2001; Anderson *et al.*, 2003; Dollhopf *et al.*, 2005).

Fluctuating oxic–anoxic conditions may facilitate coupling between NMIN, NTR, and the dissimilatory processes of DNF, DNRA, or ANAM (An and Joye, 2001; Risgaard-Petersen *et al.*, 2005; Rysgaard *et al.*, 1994). Strictly oxic or anoxic conditions may lead to efflux of NO_3^- or NH_4^+, respectively, from the sediment (Kemp *et al.*, 1990; Fig. 19.2; Table 19.4). Shallow, well-lit sediments exhibit high rates of benthic production and strong diurnal variability in O_2 dynamics. Such habitats may favor metabolically versatile microorganisms that can quickly adapt to changing environmental conditions. For example, the metabolic flexibility of denitrifying microbes may provide them a competitive advantage over microbes conducting ANAM or DNRA. In the absence of NO_x^-, denitrifiers may either conduct aerobic respiration or utilize alternate electron acceptors (e.g., Fe oxyhydroxides). Denitrifiers can also survive extended periods of low or zero NO_x^- concentration (Risgaard-Petersen *et al.*, 2005). While ANAM microorganisms are not immediately killed by oxygen exposure and appear to recover ANAM activity fairly quickly after oxygen exposure (Strous *et al.*, 1997), the ability of denitrifiers to respire O_2 may offer them a competitive advantage.

Hypoxia, which refers to low oxygen conditions ($\sim$3 mg L^{-1} or 90 μM dissolved O_2; Diaz and Rosenberg, 1995), occurs when rates of oxygen consumption exceed rates of oxygen supply to a water body. Hypoxia is one of the most common symptoms of eutrophication (Boesch, 2002). Hypoxic waters provide poor habitat for pelagic and benthic fauna and persistent or intermittent water column hypoxia can exert profound effects on the sediment N cycle. For example, hypoxia can impact the N cycle by reducing the density and activity of benthic infauna responsible for bioturbation and bioirrigation; by increasing the organic deposition rate to sediments as a result of asphyxiation and subsequent demise of water column fauna; by stimulating benthic anaerobic respiration and associated nutrient recycling such as sulfate reduction to H_2S, with associated inhibitory effects on N-cycling processes and on benthic primary producers which assimilate N; or, by thinning the sediment oxic zone, which reduces or eliminates the activity of O_2-dependent N cycle processes, like NTR (Diaz and Rosenberg, 1995; Kemp *et al.*, 1990, 1992; Ritter and Montagna, 1999).

Water column hypoxia results from a variety of interrelated factors including water column stratification, elevated rates of nutrient or organic matter loading and increased fluxes of H_2S (which reacts rapidly with and hence consumes O_2) from the sediments to the overlying water (Ritter and Montagna, 1999). Hypoxia decreases rates of coupled NTR–DNF (Kemp and Boynton, 1990; Kemp et al., 1990) while enhancing rates of DNRA. As NH_4^+ accumulates and fluxes to the water column, primary production and organic matter sedimentation to the benthos will increase, resulting in a positive feedback whereby benthic respiration and O_2 consumption increase further exacerbating hypoxia.

3.3. Advective and diffusive transport through sediments

Physical factors such as transport clearly influence N cycling in sediments at a variety of spatial and temporal scales. Diffusive and advective processes generate flow through sediments. Sediment texture plays a major role in regulating transport through the sediments, and transport influences the rates and pathways of N processing. In low permeability muddy sediments molecular diffusion and infaunal irrigation control pore fluid transport through the sediments (Aller, 1982). In high permeability sandy sediments waves (Riedl et al., 1972) and/or bottom topography and currents (Huettel and Gust, 1992; Huettel et al., 2003) enhance fluid exchange between the sediments and overlying water column (Huettel and Webster, 2001).

Generally speaking, when sediment permeabilities exceed 10^{-12} m^2, advection of fluids through sediments can increase exchange by up to two orders of magnitude relative to that expected from molecular diffusion alone (Huettel et al., 2003). Variable density gradients in sediment pore waters relative to the overlying water (e.g., lower pore water salinity relative to the salinity in the overlying water) may also enhance fluid flow. Such density gradients can result in pore water convection and enhanced mixing (Webster et al., 1996).

Advective fluid flow has been shown to influence the rates and pathways of N processing in sediments. Bottom topography and currents result in local changes in NH_4^+ and NO_2^-/NO_3^- concentrations and likely stimulate rates of NTR and possibly DNF (Huettel et al., 1998). Advection can enhance the sediment oxygen uptake by ~25% in medium-grained and coarse-grained sands while NH_4^+ fluxes decrease and NO_3^- fluxes increase as grain size increases (Janssen et al., 2005). Increased permeability and advection-enhanced fluid flow through sediments appear to favor conversion of NH_4^+ to NO_3^- may stimulate sequestration of bioavailable N into microbial biomass in sediments (Huettel et al., 1998; Janssen et al., 2005) and may increase exchange of reduced metabolites (e.g., NH_4^+, Fe_2^+) from the sediments to the overlying water (Huettel et al., 1998; Precht et al., 2004). This occurs because elevated rates of fluid flow through sediments not only increase the oxidant supply but may also increase the supply of organic material to the sediments because of trapping (e.g., filtering out) of suspended particulate organic matter from the overlying water, thus increasing sediment respiration rates. Increased rates of organic matter mineralization can increase NH_4^+ fluxes but may reduce NTR rates due to O_2 limitation (Caffrey et al., 1993).

3.4. Porewater exchange—Resuspension

Physical processes that mix sediment pore fluids with the overlying water column can also affect the N cycle because the concentrations of N species in sediments are much higher than concentrations in the overlying water column. For example, NH_4^+ can reach millimolar concentrations in pore fluids while surface water concentrations are typically micromolar or less. These concentration differences lead to substantial rates of diffusive- and advective-driven effluxes of nutrients from sediments to the water column (Rowe *et al.*, 1975), which may support high rates of water column production. Resuspension of sediment (Fanning *et al.*, 1982), which results from wind or wave disturbance of bottom sediments (Chang *et al.*, 2001), barge traffic, trawling or dredging (Morin and Morse, 1999; NRC, 2002; Pilskaln *et al.*, 1998), also transfers nutrients into the overlying water. While some previous studies concluded that resuspension is of minor consequence for overlying water nutrient budgets (Blackburn, 1997; Sloth *et al.*, 1996), others have shown that resuspension can significantly increase DIN exchange between sediments and overlying waters (Fanning *et al.*, 1982; Morin and Morse, 1999). For example, release of NH_4^+ from sediments related to a single dredging of the main channel in Laguna Madre (TX, USA) introduced as much NH_4^+ into the water column as the diffusive NH_4^+ efflux from the sediments to the water column over the summer. Other studies have postulated that trawling activities play an important role in transferring mineralized nutrients from the sediments to the overlying water (Pilskaln *et al.*, 1998). The impact of dredging and trawling activities on the transfer of nitrogen from the sediments to the water column and on sediment N processing deserves further study (NRC, 2002).

3.5. Relationship between water residence time and nitrogen fate in coastal systems

Understanding the relationship between water residence time and nitrogen dynamics is complicated by the difficulty in quantifying residence time and by the fact that many of the data used to develop residence time–N cycle relationships were obtained in dark (rather than light) incubations. Thus, more work is required in this area but the available data will be summarized here. The residence time of a water body, which denotes the average length of time a parcel of water remains in the system, influences the fate of N and other nutrients within a system and also impacts nutrient export. Nielsen *et al.* (1995) and Nixon *et al.* (1996) first suggested that on a system-wide basis DNF in estuaries was proportional to the residence time within the system as a whole: A longer water residence time provided more opportunity for DNF to consume N, thus reducing N export from a system. A logarithmic relationship between N cycle processes and residence time in estuaries was later observed (Dettmann, 2001): Increases in residence time led to increased rates of DNF, which corresponded to reduced N export from the system. DNF was assumed to account for a constant fraction of N removal (69–75%) and total N removal increased substantially as residence time increased (Dettmann, 2001). Though DNF accounts for a large fraction of the total N removed, less than 40%

of the N load to a system is removed via DNF if the residence time is about 3 months; this fraction levels out to around 80% in systems with residence times greater than 100 months (Dettmann, 2001).

However shallow systems may behave differently than deeper estuarine systems. For example, residence time in shallow coastal bays has been shown to be highly variable across systems. Thus, the influence of N-cycling processes in both the pelagic and benthic zones on whole system export may depend upon position within the system (Fugate et al., 2006). Most coastal estuaries have residence times less than 100 days, making DNF an inefficient mechanism for reducing total N loading under most circumstances. For example, only 8% of the N load to Boston Harbor was denitrified and Nowicki et al. (1997) attributed this to the short residence time (2–10 days) of the system. Similarly, in Norsminde Fjord (Denmark), a rapidly flushed system with a 2–13 day residence time, DNF removed only 2–3% of the N load (Nielsen et al., 1995). Sporadic increases in freshwater delivery to coastal systems via storm-derived runoff can result in "contact limitation" of DNF, in that sediment denitrifiers do not have the opportunity to remove N before it is exported from the system (Joye and Paerl, 1993). As such, N export is generally much higher during high flow events (Nixon et al., 1996).

In some shallow coastal ecosystems with short residence times, benthic primary production can regulate coupled NTR–DNF. When N loads are high, benthic primary production can significantly stimulate coupled NTR–DNF resulting in substantially higher rates of N loss via DNF than would be predicted from the system residence time. For example, Joye and An (1999) studied DNF in Galveston Bay, TX, a shallow estuary with a seasonally varying residence time. The residence time of Galveston Bay is short (30 days) during the wet winter and spring periods and long (100 days) during the dry summer period. DNF rates determined in two separate studies were lowest in winter and spring and highest during summer as predicted by residence times (Joye and An, 1999, in preparation; Zimmerman and Benner, 1994). However, DNF rates determined in dark chamber incubations yielded system-wide rates of DNF that amounted to about 7% of the N load to the system (Zimmerman and Benner, 1994). This value agrees well with the DNF rate that would be predicted from the residence time–DNF relationship reported by Nixon et al. (1996) and Dettmann (2001). However, DNF rates determined in light chamber incubations yielded system-wide DNF rates that amounted to about 50% of the N load to the system, a value that falls significantly off the regression line of the published residence time–DNF relationship (Joye and An, 1999). Joye and An (1999) attributed the observed stimulation of DNF in the light to oxygenation of the sediments by benthic microalgae, thereby increasing rates of NTR and subsequent DNF. Thus, high rates of benthic primary production can offset short residence times and enhance DNF-based N removal in systems that one might assume to be quite inefficient at removing N based solely on measurements of residence time. On the other hand, in the shallow coastal bays of Virginia's Delmarva Peninsula, with residence times varying from 10 to 23 days for most of the system and with limiting water column DIN, McGlathery et al. (2004) attributed the observed low rates of DNF to competition between denitrifiers and benthic microalgae.

Whole estuary ^{15}N-cycling studies in which $^{15}NO_3^-$ is dripped into a tributary over multiple weeks allow determination of N uptake, processing, transformation, and export under natural conditions. This approach provides a powerful way to evaluate N cycling at the ecosystem scale. For example, the NISOTREX I experiment, conducted in the Parker River estuary of northern New England, demonstrated that when flushing rates were low and water column primary production was high, the planktonic centric diatom, *Actinocyclus normanii*, effectively removed all of the water column NO_3^- with little export of DIN downstream. Planktonic diatoms and their phytodetritus played the most important role in fueling production of numerous estuarine consumers including planktonic copepods, benthic amphipods, grass shrimp, mud crabs, and both planktivorous and benthivorous fishes (Holmes *et al.*, 2000; Hughes *et al.*, 2000). Since nitrogen demand of phytoplankton in the Parker River greatly exceeded riverine supply, production was supported mainly by benthic regeneration of N taken up by planktonic diatoms and subsequently sedimented to the benthos. On the other hand, during NISOTREX II, conducted in the Rowley River estuary, also in northern New England, but with a residence time shorter than the doubling time of phytoplankton, benthic microalgae rather than phytoplankton were responsible for most of the system's primary production and N demand (Tobias *et al.*, 2003b), and regenerated N was mainly exported from the system.

3.6. The influence of salinity on nitrogen cycle processes

The salinity of coastal estuaries varies on daily, seasonal, and annual time scales as a function of freshwater inputs and tidal fluctuations. Salinity influences many processes in estuarine ecosystems, including sediment N-cycling processes ranging from ammonium sorption and regeneration to NTR and DNF. The impact of salinity on sediment NH_4^+ pools, DNF, and NTR has received considerable study but the impacts of salinity on other sediment N cycle processes (NFIX, ANAM) are not well known. Furthermore, the physical or physiological consequences of varying salt content versus impacts resulting from other constituents associated with seawater, e.g., sulfate and associated increases in sulfate reduction rates, are unclear.

The pool of exchangeable NH_4^+ in sediments decreases with increasing salinity; this pattern has been documented in a variety of aquatic sediments (Seitzinger, 1988; Seitzinger *et al.*, 1991; Simon and Kennedy, 1987). In low salinity sediments, a primary consequence of the higher exchangeable NH_4^+ concentrations is elevated NTR, and coupled DNF rates. For example, Boynton and Kemp (1985) showed that benthic NH_4^+ fluxes increased with increasing salinity while benthic NO_3^- fluxes decreased. Gardner *et al.* (1991) and Seitzinger *et al.* (1991) expanded on this work, showing that changes in sediment NH_4^+ fluxes and N cycle processes were driven largely by variations in ionic strength (i.e., salinity), which altered the exchangeable NH_4^+ pool size.

Salinity effects may be both indirect, by controlling substrate pool sizes, or direct, by regulating physiological processes. Kana *et al.* (1998) showed that sediment DNF rates were independent of salinity at low salinities (<13 ppt) but were dependent on the NO_3^- concentration in the overlying water. Rysgaard *et al.* (1999) were the first to illustrate a salinity-linked physiological inhibition of both NTR and DNF in

estuarine sediments. The capacity of sediments to bind NH_4^+ decreased with increasing salinity, as noted previously. Results of assays for NTR and DNF in substrate amended incubations over a salinity range between 0 and 30‰ demonstrated that both NTR and DNF decreased with increasing salinity, suggesting that increasing ionic strength inhibited both processes (Rysgaard et al., 1999). In subsequent studies, evidence for a physiological inhibition of NTR or DNF with increasing salinity has been less clear. Fear et al. (2005) found no relationship between increased salinity and DNF in the Neuse River (NC, USA). And, Magalhaes et al. (2005) found that DNF rates in the Douro Estuary (Portugal) were strongly correlated with NO_3^- concentrations and that NO_3^- concentrations co-varied with salinity. They suggested that the pattern of decreasing DNF rates with increasing salinity reflected the limited NO_3^- supplies at higher salinities. NTR showed no consistent pattern with respect to salinity or NH_4^+ concentrations (Magalhaes et al., 2005). Thus, while salinity appears to physiologically inhibit the processes of NTR and DNF to some extent, substrate availability or the presence of inhibitory compounds (e.g., H_2S concentrations increase with salinity and H_2S inhibits NTR and DNF rates; Joye, 2002; Joye and Hollibaugh, 1995) may be a more important factor in determining absolute rates of these processes and other N cycle transformations.

4. Biotic Factors Influencing Sediment Nitrogen Transformations

Numerous biotic factors influence N processing within sediments, including the composition of the microbial, macrofaunal, and macrophyte communities, behaviors of the various infaunal communities, and trophic transfer of carbon and nitrogen between communities. Interactions between benthic communities may be physical, chemical, or biological in nature and, in turn, are influenced by the physical nature of the environment, sediment composition, and autotrophic dominance (Fig. 19.3).

4.1. Benthic–pelagic coupling: Impact of benthic primary production

Prior to the 1980s most studies of water column primary production ignored the role of the benthos in regenerating, transforming, or retaining nutrients. It was assumed that phytoplankton production was supported by a combination of allochthonous inputs of nutrients and by recycling of particulate organic matter in the water column (Johannes, 1969; Ryther and Dunstan, 1971). There was little to no consideration of benthic–pelagic coupling (Nixon, 1981). Measurements of benthic fluxes were generally performed in the dark; thus, the influence of benthic autotrophs on benthic fluxes was generally not realized (McGlathery et al., 2004), although Henriksen et al. (1980) noted the importance of benthic microalgae in taking up water column nutrients. More recent studies have demonstrated that in many coastal systems benthic remineralization of particulate organic matter, derived from a variety of sources, is responsible for supporting a large portion of both pelagic

and benthic primary production (Anderson *et al.*, 2003; Nixon, 1981). Whereas in the dark or in deep water benthic and pelagic processes are closely coupled, in the light benthic autotrophs, including seagrasses, macroalgae, and benthic microalgae, may decouple the benthic and pelagic zones by retaining, and transforming nutrients in sediments (McGlathery *et al.*, 2004).

The impact of benthic primary production on sediment–water fluxes of NH_4^+ is clearly demonstrated when cores collected from shallow water sites are incubated in the light and dark. Cores collected from a wide variety of shallow sites located along the axis of Chesapeake Bay in Maryland and Virginia demonstrated that regardless of salinity or degree of anthropogenic disturbance, NH_4^+ release from sediment to the water column was either less in the light or there was uptake (instead of release) by sediments (Anderson *et al.*, in preparation; Fig. 19.4). Similar results are evident when sediment–water NH_4^+ fluxes from shallow littoral zone sites (<2 m mean low water (MLW)) are compared to fluxes from deeper water sites (>2 m MLW). Fluxes from shallow water sediments are less than those from deeper water sediments (Fig. 19.5), suggesting autotrophic uptake at shallower depths. In addition to light temperature, by regulating the rates of benthic microbial processes, is also expected to influence the magnitude and direction of NH_4^+ fluxes. In studies conducted at numerous latitudes, average annual NH_4^+ fluxes were low or directed into sediment at low and high latitudes and were directed out of sediments in mid-latitudes (Fig. 19.6).

4.2. The influence of benthic macrophytes on nitrogen cycle processes

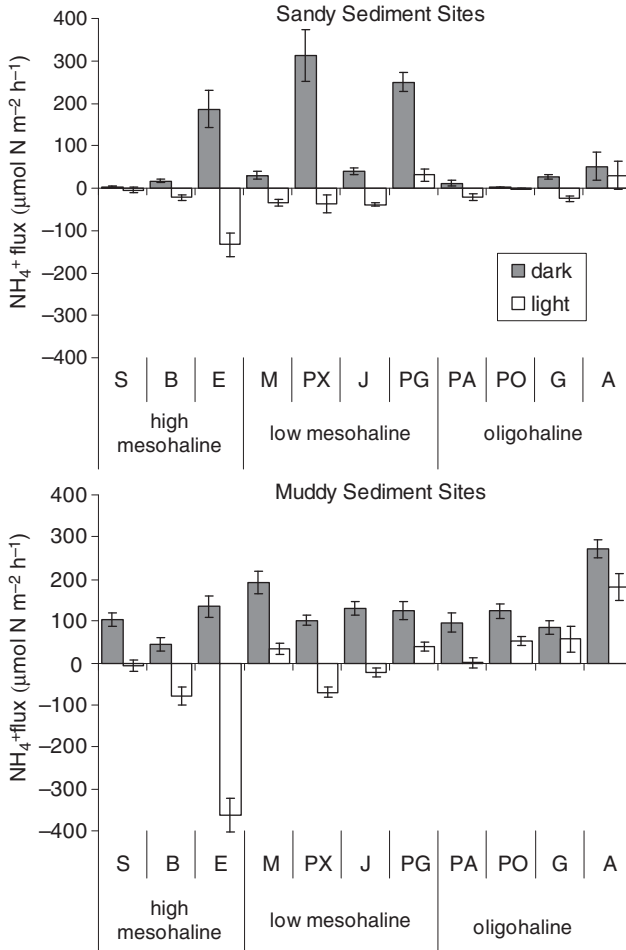
Benthic macrophytes, including rooted seagrasses and marsh grasses, and ephemeral and longer-lived macroalgae have been estimated to account for 40% of the primary production in shallow coastal ecosystems (Duarte, 1995). They play an important role in influencing microbial N transformations in sediments (Tobias *et al.*, 2001) and are described extensively in Chapter 23 by McGlathery (this volume) and in Chapter 22 by Hopkinson and Giblin (this volume). Detrital material derived from rooted macrophytes or their epiphytes is a source of both particulate and DOM fueling sediment metabolic processes, N transformations, benthic fluxes, microbial N immobilization, burial, and transfer of N to higher trophic levels. However, macrophyte-derived detrital material may not be quantitatively as important a source of N or C as the particulate organic matter sedimenting from the water column or resuspended from the benthos and physically trapped by either seagrasses or marsh grasses (Boschker *et al.*, 1999; Canuel, 1997; Currin *et al.*, 1995; Dahllöf and Karle, 2005; Duarte and Cebrian, 1996; Gacia *et al.*, 2002). Burial of both C and N has been observed in sediments of seagrass meadows such as *Posidonia oceanica*, due to low mineralization rates of particulate organic matter, derived from deposited seston and seagrass detritus (Gacia *et al.*, 2002). On the other hand, Evrard *et al.* (2005) observed rapid root uptake of N mineralized from ^{15}N-labeled phytodetritus (diatoms) injected into the sediment surface of an Indonesian sea grass bed dominated by *Thalassia hemprichii*, *Cymodocea rotundifolia*, *Halodule unineris*, *H. pinifolia*, *Halophila ovalis*, and *Syringodium isoetifolium*. *Zostera marina* has also been shown capable of taking up both urea and dissolved free amino acids (DFAAs) through their leaves (Hansen *et al.*, 2000). The rate of mineralization and burial of particulate organic


Figure 19.4 Light versus dark. Mean NH_4^+ sediment–water fluxes (mmol N m^{-2} h^{-1}; ±SE bars) in sandy and muddy littoral zone sites of the Chesapeake Bay (Anderson, Stanhope, and Schaffner, in preparation). S = Severn River, Virginia; B = Back River at Langley Air Force Base, Virginia; E = Elizabeth River, Virginia; M = Monie Bay, Maryland; PX = Patuxent River at Patuxent Naval Air Station, Maryland; J = James River at Fort Eustis, Virginia; PG = Pagan River, Virginia; PA = Pamunkey River, Virginia; PO = Potomac River at Quantico Marine Corp Base, Virginia; G = Gunpowder River at Aberdeen Proving Grounds, Maryland; A = Anacostia River, Virginia.

matter has been shown to be strongly influenced by sediment resuspension, which may mix porewater DOM into the water column and oxygenate the sediments (Arzayus and Canuel, 2004) or mix small particulates such as algae or bacteria into porous sandy sediments (Ehrenhauss *et al.*, 2004). In addition to serving as a source of detrital particulate organic matter or as a sink for mineralized dissolved nitrogen, macrophytes also release dissolved organic carbon, which may support processes such as NFIX (McGlathery *et al.*, 1998; Whiting *et al.*, 1986), DNF, (Eyre and Ferguson, 2002), and DNRA (An and Gardner, 2002). Indeed the partitioning of nitrate reduction between DNF and DNRA appears to be heavily influenced by the quality and quantity of available dissolved organic carbon (Christensen *et al.*, 2000).
Figure 19.5 Annual mean NH_4^+ sediment–water fluxes (mmol m^{-2} d^{-1}) for shallow ($\leq$2 m) and deep ($>$2 m) sites. Shallow sites ($n = 18$) were included only if fluxes were measured in both light and dark using either *in situ* chambers or incubated sediment cores (Ferguson *et al.*, 2004; Fisher *et al.*, 1982; Nowicki and Nixon, 1985; Reay *et al.*, 1995; Rizzo, 1990; Sundback and Miles, 2000). Flux measurements from deep sites ($n = 12$) were measured at *in situ* light levels or only in the dark (Christensen *et al.*, 2000; Cowan and Boynton, 1996; Dollar *et al.*, 1991; Fisher *et al.*, 1982; Hopkinson *et al.*, 2001; Ibarra–Obando *et al.*, 2005; Pomroy *et al.*, 1983; Rizzo and Christian, 1996). Boxes and error bars represent 10th, 25th, 50th, 75th, and 90th percentiles and circles are outliers.
Figure 19.6 Latitudinal variation in annual mean NH_4^+ sediment–water fluxes (mmol m^{-2} d^{-1}) for shallow ($\leq$2 m) sites. Shallow sites ($n = 18$) were included only if fluxes were measured in both light and dark using either *in situ* chambers or incubated sediment cores (Ferguson *et al.*, 2004; Fisher *et al.*, 1982; Nowicki and Nixon, 1985; Reay *et al.*, 1995; Rizzo, 1990; Sundback and Miles, 2000).

4.3. The influence of macroalgae on sediment nitrogen cycle processes

In shallow, coastal littoral zone systems, macroalgae have been shown to alter benthic–pelagic coupling (Sundback and McGlathery, 2005; Valiela *et al.*, 1997). While alive, macroalgae intercept DIN, DFAA, and urea fluxing from sediments and release N as dissolved combined amino acids (DCAAs) (Tyler *et al.*, 2001, 2003). However, the ephemeral macroalgae (*Ulva lactuca* and *Gracilaria tikvahiae*) often found in eutrophied systems tend to undergo "boom and bust" cycles, dying off as summer temperatures peak in temperate zones. Following senescence macroalgae may decompose releasing much of the N stored in their biomass as dissolved inorganic and organic nitrogen (Tyler *et al.*, 2001). The fate of macroalgae depends on numerous factors, including its chemical composition, elemental stoichiometry, grazing, and physical parameters including temperature and energy of the surrounding environment. Since ephemeral macroalgae tend to have lower C:N and less structural material than rooted macrophytes, they are more rapidly and completely degraded by bacteria (Duarte, 1995).

In moderately eutrophied coastal ecosystems, bloom-forming "nuisance" macroalgae may become the dominant autotrophs. These nuisance macroalgae occur mainly as filamentous (e.g., the green algae: *Cladophora*, *Enteromorpha*, and *Chaetomorpha* species and the red algae: *Gracilaria*, *Spyridea*, and *Laurencia*) or sheet-like (e.g., *Ulva* species) forms and may accumulate as thick mats over the sediment surface (McGlathery *et al.*, 2004; Sundback and McGlathery, 2005; Valiela *et al.*, 1997) where they out compete the slower–growing seagrasses for N and reduce light availability for both seagrasses and benthic microalgae due to shading. Macroalgae can temporarily store a significant portion of the N load to a coastal embayment. For example, in Waquoit Bay, MA, macroalgal N was of the same magnitude (greater than 5 g N m^{-2} d^{-1}) as the annual N load from the watershed (Peckol, 1994; Valiela *et al.*, 1997). Much of the DIN assimilated by macroalgae is rereleased as DON, with release rates ranging from 17% to 99% of gross N uptake (Tyler, 2002).

Self-shading within the macroalgal mat, light attenuation by phytoplankton, and high temperatures eventually result in decay of macroalgal blooms with concomitant release of stored N. In Hog Island Bay, Virginia, Tyler *et al.* (2001) reported dissolved inorganic and organic N release rates following the collapse of a bloom composed primarily of *Gracilaria vermiculophylla* and *U. lactuca* that were sufficient to completely mineralize the macroalgal biomass (up to 650 gdw m^{-2}) within ~13 days. Release of plant-bound nutrients following these "dystrophic" events may stimulate phytoplankton and bacterial metabolism in the water column (Lunsford, 2002; McGlathery *et al.*, 2001; Valiela *et al.*, 1997).

During periods when decomposition rates are high, sediments underlying macroalgal mats are typically heterotrophic with high rates of N turnover (Trimmer *et al.*, 2000). Sediments may become anoxic, have high concentrations of dissolved inorganic and organic nitrogen, and H$_2$S in their pore water, and may be a source of NH$_4^+$ and DON to the overlying water column depending upon the abundance and productivity of rooted macrophytes and/or benthic microalgae on the sediment surface (Anderson *et al.*, 2003; Bartoli *et al.*, 1996). Regeneration of DIN by mineralization of particulate organic matter under these mats may provide a

high percentage of the N demand of macroalgae (Anderson *et al.*, 2003; Sundbäck *et al.*, 2003) or benthic microalgae (Anderson *et al.*, 2003). With decreased N demand by seagrasses and benthic microalgae due to shading, a positive feedback will occur in which N retention in sediments will decrease; fluxes of N to the water column will increase and may result in a shift of dominance to phytoplankton (Duarte, 1995; Sundback *et al.*, 1996; Sundbäck *et al.*, 2003). Sulfide accumulation in anoxic sediment with high rates of organic matter decomposition has been shown to interfere with coupled NTR–DNF and shift NO_3^- reduction toward higher rates of DNRA, further increasing fluxes of NH_4^+ out of sediments (Joye and Hollibaugh, 1995; Viaroli *et al.*, 1996). Eyre and Ferguson (2002) observed a negative relationship between DNF efficiency, calculated as N_2-N/(N_2-N + DIN), and rates of C decomposition. On the other hand, Krause-Jensen *et al.* (1999) demonstrated in a laboratory experiment that dense macroalgal mats did not significantly influence rates of DNF but instead moved the zone of DNF from the sediments up into the mat with peak rates at the oxic–anoxic interface.

4.4. The relationship between production/respiration and nitrogen cycle processes

Rooted macrophytes, macroalgae, and benthic microalgae all influence O_2 availability and, thereby, sediment biogeochemistry both in the light, during photosynthesis, and in the dark, due to the respiration of photosynthate. As discussed above, most N-cycling processes are regulated by the availability of O_2, as are other biogeochemical processes, e.g., sulfur, iron, and manganese transformations, which indirectly regulate N cycling. The sediment gross primary production to respiration ratio (P/R) has been shown to be a useful indicator of various N-cycling process rates and fluxes. For example, in Australian estuaries, NH_4^+ fluxes out of sediments were inversely related and DON fluxes positively related to P/R (based on either O_2 or CO_2; Eyre and Ferguson, 2002, 2005). The relationship between P/R and DNF was more complex, with DNF decreasing with increased CO_2-based P/R up to 0.4 and then increasing as net autotrophy increased; the presence of high macrofaunal biomass confounded these relationships (Eyre and Ferguson, 2005). Anderson *et al.* (in preparation) performed studies in shallow sites along the axis of Chesapeake Bay and observed a similar inverse relationship between P/R and NH_4^+ fluxes, which may have resulted in part from the increased macrofaunal abundance also observed with decreasing P/R. Other variables, such as salinity, nutrient standing stocks, and anthropogenic disturbance, also tend to co-vary with P/R in Chesapeake Bay and may confound relationships between P/R and N-cycling process rates.

4.5. Effects of shifting autotrophic dominance on nitrogen cycle processes

As eutrophication proceeds in response to nutrient enrichment and depending upon water residence time in coastal ecosystems there may be a shift in autotrophic dominance from rooted macrophytes to perennial macroalgae to ephemeral macroalgae and finally to phytoplankton (McGlathery *et al.*, 2004; Valiela *et al.*, 1997) and

references herein (see Chapter 23 by McGlathery, this volume, for more detail). The composition of the autotrophic community can influence nitrogen retention in sediments as well as microbial community structure. Degradation of macrophytes or macroalgae, such as *U. lactuca*, with low C/N and little cellulose and lignin in their biomass, occurs readily and may result in hypoxia–anoxia with efflux of NH_4^+ due to NMIN and influx of NO_3^- due to DNF. On the other hand, decomposition of *Z. marina* with higher C:N ratio and whose biomass contains greater quantities of both cellulose and lignin may result in net microbial immobilization of NH_4^+ to support microbial decomposition, as described by Dahllöf and Karle (2005).

4.6. Influence of benthic microalgae of sediment nitrogen cycle processes

Benthic microalgal (BMA) mats, containing primarily diatoms, but also including cyanobacteria, benthic dinoflagellates, and euglenoids, are important primary producers in shallow subtidal and intertidal systems. Because shallow sediments are frequently resuspended into the overlying water and phytoplankton are deposited into sediments, the distinction between pelagic and benthic species of microalgae is often blurred. The biomass of BMA normalized per square meter of surface often exceeds that of phytoplankton in the overlying water (MacIntyre *et al.*, 1996). In temperate and tropical systems, BMA are active throughout the year, and in polar regions they demonstrate changes in photophysiology and community composition in response to sea ice breakout (Glud *et al.*, 2002; McMinn *et al.*, 2004; Sundback and McGlathery, 2005). Although BMA primary production is generally confined to the top 1–3 mm of sediments, viable microalgal cells may be found at depths as great as tens of centimeters depending on sediment grain size, physical energy of the system, and abundance of bioturbating macrofauna (MacIntyre *et al.*, 1996). In intertidal sediments BMA migration as well as changes in species distribution and photophysiology occur during tidal cycles (down during flood tides and up again during ebb) as well as on diurnal cycles (Pinckney *et al.*, 1994; Underwood *et al.*, 2005). BMA biomass is usually in the range of 1–5 g C m^{-2} with a C/N ratio of $\sim$9 (Sundback *et al.*, 2000).

Benthic microalgae occupy a unique position both at the boundary between benthic and pelagic zones but also in many cases at the sediment oxic–anoxic interface. Thus, the environment to which BMA are exposed is dynamic both with respect to physical and biogeochemical factors. Benthic microalgae potentially impact the benthos in numerous ways, regulating sediment nitrogen cycling, sediment–water nutrient fluxes, sediment redox state, growth of macroalgae, supporting benthic food webs, and contributing to sediment stability. In shallow coastal estuaries and lagoons BMA compete for light and nutrients with phytoplankton, macroalgae, seagrasses, and bacteria. The outcome of this competition is dependent upon residence time and physical energy of the system, source of N (water column nutrient loading vs sediment DIN regeneration), and light availability (Fong *et al.*, 1993; Sundback and McGlathery, 2005; Sundback *et al.*, 2000; Valiela *et al.*, 1997). BMA production is not usually N limited in sediments because of high rates of sediment NMIN (Anderson *et al.*, 2003; MacIntyre *et al.*, 1996). However, recent studies in coastal Georgia have illustrated primary N and subsequently Si limitation of benthic diatom production (Porubsky *et al.*, 2008b), so in some cases, benthic microalgae may be nutrient limited. In mid-summer when macroalgal populations

decline because of self-shading or increased respiratory demand, BMA may become the dominant primary producers in subtidal systems (McGlathery *et al.*, 2001). In intertidal salt marsh dominated systems BMA production may represent 30–40% of macrophyte production even though the sediment surface is shaded to some extent by the macrophytes (Anderson *et al.*, 1997; Pinckney and Zingmark, 1993).

Numerous studies have shown that when sediments are net autotrophic BMA and the associated benthic bacterial community play a role in reducing the flux of remineralized nutrients from sediments to the overlying water column (Anderson *et al.*, 2003; Bartoli *et al.*, 2003; Cerco and Seitzinger, 1997; Eyre and Ferguson, 2002, 2005; Sundback *et al.*, 2000; Veuger *et al.*, 2007a). Thus, the benthic microbial community effectively decouples N remineralization within the sediments from primary production by both phytoplankton and macroalgae. If sediment nutrient sources are insufficient to meet growth demands, there also may be an influx of nutrients from the water column to the benthic community. Whether or not BMA effectively ''cap'' the sediment efflux of nitrogen over long time scales depends upon the fate of BMA biomass, which turns over on the scale of days or less (Cebrian, 2002; Tobias *et al.*, 2003a,b). Consequently, BMA only serve to ''cap'' the sediment nutrient flux if their own biomass is converted into forms of N and C that are either not released to the water column, or are released in a less biologically reactive form. Working in Rehobeth Bay, Delaware, Cerco and Seitzinger (1997) suggested that on annual time scales BMA may actually enhance and extend the duration of phytoplankton blooms by sequestering mineralized nutrients in the winter and spring and releasing them again in summer when BMA become light-limited due to increased phytoplankton shading. More work is needed to track the fate of macroalgal carbon and N through the benthic community over various time scales.

The influence of BMA on sediment biogeochemistry is both direct, due to competition for limiting nutrients with nitrifying and denitrifying bacteria, and indirect due to oxygenation of sediments by photosynthetic processes and also due to production and excretion of DOC, which serves as an energy source for bacterial processes (Veuger *et al.*, 2007a; Cook *et al.*, 2007). The effect of BMA on sediment–water fluxes of NH_4^+ is demonstrated in Figs. 19.4 and 19.5. In the light fluxes from sediments to the water column are either reduced relative to dark fluxes or fluxes are reversed and NH_4^+ is taken up by sediments. On the other hand, NO_3^- fluxes did not appear to vary in a predicable way in light versus dark incubations (Anderson *et al.*, in preparation).

Benthic microalgae cope with their high energy physical environment by releasing extracellular polymeric substances (EPS), which stabilize sediment structure and reduce resuspension. The release of extracellular DOC (Otero and Vincenzini, 2004; Underwood and Smith, 1998; Underwood *et al.*, 2005; Wolfstein *et al.*, 2002), which may account for more than 50% of the C fixed by BMA, also plays a role in BMA motility and influences N-cycling processes. Uptake of DIN by shallow euphotic sediments from both the water column and sediment pore water may be in response to the release of EPS by BMA. In order to use this carbon rich DOM, bacteria may depend on uptake of DIN to meet their N requirements (Cook *et al.*, 2007). The partitioning of NO_3^- reduction between DNF and DNRA may be regulated by the relative abundance of electron donors, such as labile DOC, to electron acceptors, such as NO_3^- (Tiedje, 1988). Although generally autotrophic, the BMA community has also been shown to take up DFAA under both enriched

and depleted inorganic N conditions (Admiraal *et al.*, 1984, 1987; Nilsson and Sundback, 1996, Veuger and Middelburg, 2007b).

Regulation of coupled NTR–DNF by benthic microalgae depends to a large extent on the availability of limiting N either in the water column or sediment. When N is limiting, DNF in benthic communities with actively photosynthesizing BMA is usually reduced both due to competition for substrate as well as by the O_2 produced (Eyre and Ferguson, 2005; Risgaard-Petersen, 2003; Sundback and Miles, 2000). BMA can similarly out-compete nitrifying bacteria for limiting NH_4^+ in the photic zone both because of their higher uptake rates and faster growth rates (Risgaard-Petersen *et al.*, 2004a,b). Because most of the BMA are motile and capable of vertical migration, they may also effectively compete for N with denitrifiers even below the photic zone (Risgaard-Petersen *et al.*, 2004a,b). On the other hand, oxygen production by BMA photosynthesis may enhance coupled NTR–DNF under conditions when N is not limiting and when surface sediment is anoxic, as is often the case in organic-rich sediment (An and Joye, 2001; Sundback *et al.*, 2000).

Ammonium fluxes out of sediments have often been calculated based on measured rates of net ecosystem metabolism (NEM based on dissolved O_2 uptake or DIC release) (Burdige and Zheng, 1998; Hopkinson *et al.*, 2001). In oxic sediments where NTR is likely to play an important role in transformation of NH_4^+, total DIN rather than the NH_4^+ flux should be more closely related to the stoichiometry of NEM, whereas in anoxic sediments where DNF is important the estimated DIN flux will not equal that predicted by NEM stoichiometry. Calculation of DNF has often been based upon this "missing" DIN.

However, in net autotrophic systems where immobilization of DIN by either BMA or microorganisms occurs, N-cycling rates or sediment–water fluxes calculated based on NEM stoichiometry will often result in overestimation of those rates (Anderson *et al.*, 2003). In general, BMA uptake represents a major fate of mineralized N compared to coupled NTR–DNF in net autotrophic sediments (Risgaard-Petersen, 2003). This was documented during a review of data derived from the EU-funded Nitrogen Cycling In Estuaries project performed in 18 European estuaries (Risgaard-Petersen, 2003); in a study of Hog Island Bay, Virginia, sediments (Anderson *et al.*, in preparation); in southern England sediments dominated by macroalgae (Trimmer *et al.*, 2000); in the Tagus Estuary, Portugal (Cabrita and Brotas, 2000), and at sites along the west coast of Sweden (Sundback and Miles, 2000). The DIN fluxes observed in these littoral zone systems differ markedly from those observed in sublittoral zone systems, which typically exhibit release of NH_4^+ or DIN, closer to values predicted by NEM (Burdige and Zheng, 1998; Giblin *et al.*, 1997; Hopkinson *et al.*, 1999) (Fig. 19.5).

4.7. The influence of benthic infauna on nitrogen cycle processes and fate

Meio- and macrofauna impact benthic nutrient cycling through grazing and by physically mixing sediment during the processes of feeding, burrow construction, and irrigation (Aller, 1982, 1994; Aller and Aller, 1998). The process of bioturbation, which depends on the feeding mode of the macrofaunal species, increases exposure of sediment to oxygen, vertically distributes both dissolved and particulate nutrients and thereby influences a variety of microbial activities, including organic

matter mineralization and respiration and nitrogen–cycling process rates, including NTR, DNF, and DNRA (Kristensen and Mikkelsen, 2003; Welsh, 2003). For example, subsurface deposit feeders contribute to mechanical breakdown and mixing of fresh particulate organic matter into deeper sediment strata with deposit of fecal castings and pore waters at the sediment surface. Surface deposit feeders, many of which occupy U-shaped burrows, increase diffusive exchanges between sediments and the water column and reoxygenate sediment pore water. Like deposit feeders, suspension feeders similarly influence organic matter processing by bioturbation and ventilation; however, they also increase organic matter inputs to the sediments, with rates estimated to range from 1 to 70 g C m^{-2} d^{-1} (Graf and Rosenberg, 1997). Introduction of labile organic matter and electron acceptors to deeper sediment strata stimulates decomposition of ''refractory'' organic matter by surface deposit feeders, perhaps due to introduction of electron acceptors or by increasing bacterial co–metabolism (Graf, 1992). Depending upon the relative importance of organic matter inputs versus mixing of electron acceptors to deeper sediment layers, benthic macrofauna influence the balance among dissolved inorganic and organic N species exchanged between sediments and the water column. For example, high organic matter inputs by suspension feeders and the resulting anoxia, may inhibit NTR, increasing fluxes of NH_4^+ out of the sediments (Caffrey *et al.*, 1993). When water column NO_3^- is available, high organic matter inputs may stimulate DNRA relative to DNF, again resulting in increased fluxes of NH_4^+ out of the sediments (Welsh, 2003).

Sediments underlying an oxic water column are dissected by a wide variety of tubes and burrows constructed by polychaetes, crustaceans, and bivalves. These macrofaunal structures are irrigated with oxic surface water and thereby influence the distribution of oxic–anoxic interfaces across 3-dimensional space and play an important role in regulating nitrogen and carbon mineralization rates. The volume of oxic burrow walls may be several-fold higher than that of oxic surface sediment (Kristensen, 2000). Linings of burrows and tubes are usually enriched in organic matter compared to surrounding sediments and have variable permeabilities, ranging from 10% to 40% of that in free solution. Kristensen (2000) modeled organic matter decomposition in sediments populated with the deposit feeding polychaete *Nereis diversicolor* and calculated an enhancement in mineralization of old and partially degraded organic matter of 47%. Others have measured increases in potential NTR rates related to duration of irrigation on burrow walls of an order or more in magnitude (Kristensen *et al.*, 1985; Mayer *et al.*, 1995). High rates of potential NTR have been associated directly with animal surfaces (Welsh, 2003), and increased rates of both coupled and uncoupled DNF have been observed in sediments bioturbated by the amphipod *Corophium volutator* (Pelegri *et al.*, 1994; Rysgaard *et al.*, 1995).

4.8. The role of benthic suspension feeders in reducing eutrophication potential

The increasing eutrophication observed in estuaries such as the Chesapeake Bay results not only from the bottom–up effect of increased nutrient loading, but also from the top–down effect of decreased abundance (100–fold decline over 150 years)

of the eastern oyster, *Crassostrea virginica* (Kemp *et al.*, 2005). Although oysters remove seston, thereby increasing light available to support benthic primary production, they also deposit feces and pseudofeces to the sediments, from which DIN may be regenerated. The effectiveness of *C. virginica* to impact water column primary production depends in part upon the fate of the DIN regenerated from their feces and pseudofeces. The fate of DIN regenerated from POM in the light and dark in aerobic and anaerobic sediments varies: in the dark DNF accounted for 17% (high POM loading) to 24% (low POM loading) of DIN removal; in the light benthic microalgae effectively intercepted and competed with denitrifiers for regenerated DIN and NFIX was an additional source of N to benthic microalgae (Newell *et al.*, 2002). The long-term fate of the N retained by the benthic microbial community, about which little is currently known, depends upon potential transformations to recalcitrant forms and burial in sediments and transfer to higher trophic levels.

Other benthic suspension feeders may have increased in abundance to occupy the niche formerly filled by *C. virginica*. For example, in certain areas of the lower Chesapeake Bay it has been reported that 35–100% of net plankton community production may be transferred from the pelagic to the benthic zone to support production of the polychaete, *Chaetopterus* cf. *variopedatus* and its tubes, given an ecological transfer efficiency of 10% (Thompson and Schaffner, 2001). Tube production by suspension feeders may be a mechanism by which nitrogen is transferred to and retained in sediments. Approximately 12% of the N flux to the benthos in central Long Island Sound, NY, reportedly is necessary to support tube production by the sea anemone *Ceriantheopsis americanus* (Kristensen *et al.*, 1991).

4.9. Transfer of benthic microalgal-derived carbon and nitrogen to higher trophic levels

Benthic microalgae serve as a base for the benthic infaunal food web where they provide particulate organic matter for sediment microfauna (<63 μm size class, mainly ciliate protozoans), meiofauna (63–500 μm size class, mainly nematodes, oligochaetes, and harpacticoid copepods), and macrofauna (>500 μm size class). Observations suggest that BMA, which are a rich source of proteins and lipids, are preferred by deposit feeders compared to macrophyte detritus (Miller *et al.*, 1996). Natural abundance multiple stable isotope studies similarly demonstrate the importance of BMA as a food resource to consumers in salt marsh sediments (Currin *et al.*, 1995). On the other hand Veuger *et al.* (2007a) noted that incorporation of ^{15}N-labeled microbial biomass into macrofauna in an intertidal sediment was negligible relative to the ^{15}N in total benthic biomass. In Korean coastal bay systems, Kang *et al.* (2003) observed that the natural abundance isotopic signatures of subtidal benthic deposit feeders reflected a diet almost exclusively of BMA, whereas the isotopic signature of suspension feeders suggested a diet made up approximately of an equal mixture of BMA and marine phytoplankton. BMA community production is regulated by the interactions between bottom–up (nutrients and light) and top–down controls (Hillebrand *et al.*, 2000; Worm *et al.*, 2000); for example, in intertidal sediments production is tightly linked to meiofaunal grazing. Grazing pressure and BMA community structure vary seasonally. In a study conducted at intertidal sites in

Terrebonne Bay estuary, Louisiana Pinckney *et al.*, (2003), observed high BMA biomass, dominated by diatoms, and low meiofaunal abundance and grazing (as a percentage of biomass) in January and low BMA biomass, dominated by cyanobacteria with high meiofaunal abundance and grazing in June. BMA production rates were not significantly different between seasons suggesting that grazing may increase BMA production by allowing increased light penetration and nutrient regeneration.

5. Methodologies Used for Measurements of Nitrogen Cycle Process Rates

It is widely recognized that measurements of most N-cycling process rates suffer from methodological limitations, as described below. Although techniques have been evolving rapidly during the last 10 years, difficulties remain. The ongoing development of molecular techniques capable of quantifying the abundance of specific genes involved in nitrogen transformations holds a great deal of promise (Dollhopf *et al.*, 2005; Wuchter *et al.*, 2006; Zehr *et al.*, 2001) yet more research is required to determine how gene copy number relates to process rates measured by more conventional techniques. What follows is a discussion of the more common biogeochemical techniques used to assess N-cycling process rates in sediments.

5.1. Nitrogen fixation

NFIX in surface sediments is most often measured using the acetylene (C_2H_2) reduction technique. Surface cores are incubated in sealed vials with a headspace containing 10–20% (v/v) C_2H_2 in both light and dark. Acetylene reduction activity (ARA) is determined by the rate of production of ethylene, which is measured on a gas chromatograph equipped with a flame ionization detector (Currin *et al.*, 1996). This technique can also be adapted for assessing ARA activity by heterotrophic N-fixers in the rhizosphere of marsh or seagrasses. McGlathery *et al.* (1998) removed pore water from intact seagrass-vegetated cores, equilibrated the pore water with C_2H_2, and reintroduced the pore water back into the core by vacuum. An advantage of the perfusion technique in intact vegetated cores is that it allows determination of the effects of photosynthate on NFIX. Whiting *et al.* (1986) estimated heterotrophic NFIX in saltmarsh sediments by perfusing C_2H_2 within *in situ* chambers. One caveat to consider when attempting to relate ARA to NFIX is that the conversion (moles of C_2H_2 reduced to ethylene vs N_2 fixed into NH_4^+ + DON) can vary across a wide range and often exceeds the theoretical 3:1 ratio used by many to estimate NFIX from ARA (Seitzinger and Garber, 1987). Thus, it is important to calibrate the ARA technique by measuring $^{15}N_2$ uptake into sediment extractable ammonium and labile organic N. More recently NFIX has been measured by using membrane inlet mass spectrometry (MIMS) in combination with the isotope pairing technique (An *et al.*, 2001), a modification of the method of Kana *et al.* (1994). This method allows simultaneous measurement of both DNF and NFIX by monitoring the relative fluxes of $^{28}N_2$, $^{29}N_2$, and $^{30}N_2$ from sediments enriched with $^{15}NO_3^-$. A problem noted with the MIMS method is its sensitivity to bubble formation, limiting its usefulness in net autotrophic systems in the light (Eyre *et al.*, 2002).

5.2. Sediment nitrogen mineralization

Measuring NMIN in sediments is complicated by the multiple processes that can produce or remove NH_4^+ and the sensitivity of these processes to environmental conditions such as availability of oxygen and sulfide. Net mineralization is often estimated as the net flux of DIN out of sediments in the dark. This does not account for loss of N due to DNF. The net N flux can be compared to that predicted based on inorganic carbon release or dissolved oxygen uptake during sediment respiration (Giblin *et al.*, 1997; Hopkinson *et al.*, 2001). In some cases the difference between the predicted and measured N fluxes is attributed to DNF (see Section 5.4). In net autotrophic sediments, net NMIN is usually low relative to gross NMIN, especially in the light. Gross NMIN represents turnover of the sediment NH_4^+ pool and can be measured by the $^{15}NH_4^+$ isotope pool dilution technique as described first by Blackburn (1979) and modified by Jochem *et al.* (2004) and Anderson *et al.* (1997). Sediment cores injected with $^{15}NH_4^+$ are incubated under ambient conditions, extracted with 2 M KCl, and the NH_4^+ isolated by diffusion as described by Brooks *et al.* (1989). Both the concentration and atom % enrichment of the extracted NH_4^+ are measured, and the mineralization rates determined using a model similar to that derived by Blackburn (1979) and described by Wessel and Tietema (1992), which takes into account both changes in enrichment of the ^{15}N-labeled pool and the total concentration of that pool ($^{15}N + {}^{14}N$).

5.3. Nitrification

Because of the steep redox gradients in many sediments and the often rapid removal of the products of NTR by DNF and other dissimilatory processes, measurements of NTR remain problematic. NTR has been estimated in the presence and absence of specific inhibitors by the accumulation of NH_4^+ (Henriksen *et al.*, 1980; Caffrey *et al.*, 2003) or by dark $H^{14}CO_3^-$ uptake into SOM (Dore and Karl, 1996). The inhibitors used include nitrapyrin (N-serve), methyl fluoride, dimethyl ether, acetylene, and allylthiourea. Problems involved with these methods include nonspecificity of inhibitors and difficulty in determining the correct conversion factor for ^{14}C uptake to NH_4^+ oxidized, which has been observed to range from 8.3 to 42 mol NH_4^+ oxidized per mol C fixed. Dore and Karl (1996) used an independent chemical assay of nitrite oxidation to verify the conversion factor used. NTR has also been estimated by the accumulation of nitrite in the presence versus absence of chlorate, an inhibitor of nitrite oxidation (Belser and Mays, 1980). $^{15}NO_3^-$ isotope dilution techniques, similar to those used to measure NMIN (see Section 5.2) have been used to measure NTR (Anderson *et al.*, 1997; Risgaard-Petersen *et al.*, 1994); however, when DNRA rates are high, the added $^{15}NO_3^-$ may disappear faster than it is sufficiently diluted to accurately estimate NTR.

5.4. Denitrification

The product of DNF, dinitrogen (N_2), is a major component of the atmosphere, meaning that natural waters contain high concentrations of N_2 (≥ 300 μM) when in equilibrium with the atmosphere. This high background makes measuring the

production of N_2 via DNF (or ANAM) difficult because one must quantify a small change against a large background; this is particularly problematic when DNF rates are low (Cornwell *et al.*, 1999; Joye, 2002). There are several different ways to estimate DNF rates in coastal sediments. Here, direct methods will be used to refer to techniques that measure the production of N_2 under approximate *in situ* conditions. Indirect methods measure the production of an intermediate, usually nitrous oxide, or a metabolite (O_2) than can be used as a stoichiometric proxy for total N_2 production rates. Direct and indirect rates can reflect *in situ* or potential activity; potential activity reflects rates in the presence of additional NO_3^- or organic carbon substrate.

The most common direct approaches to measure DNF include gas chromatography (thermal conductivity detection, TCD; Seitzinger *et al.*, 1980; Nowicki, 1994) and MIMS (Kana *et al.*, 1994, 1998). Techniques based on GC-TCD often require degassing to reduce background N_2 concentrations (Seitzinger *et al.*, 1980) but use of novel separatory columns such as calcium chabazite can alleviate this problem and permit quantification of small amounts of N_2 against a high background (An and Joye, 2001). The MIMS approach is more advantageous than the GC-TCD approach because of its quickness, ease, and small sample requirement.

Indirect methods used to estimate DNF include the acetylene block method (Sørensen, 1978), metabolite stoichiometry (Dollar *et al.*, 1991), or stable isotope tracers (Nielsen, 1992). Acetylene (C_2H_2) blocks the terminal step of DNF, the conversion of N_2O to N_2, and the DNF rate is estimated by quantifying the production of N_2O on a gas chromatograph with an electron capture detector. Problems with the acetylene block technique include blockage of NTR (which means that rates of coupled NTR–DNF cannot be obtained), inefficacy at low NO_3^- concentration, and interference by H_2S. Sulfide appears to alleviate the acetylene block of nitrous oxide reductase and permit full reduction of N_2O to N_2.

Metabolite stoichiometry provides a relatively straight-forward approach for estimating DNF rates without quantifying concentrations of N_2 gas. Typically, whole sediment cores are incubated under *in situ* conditions and fluxes of oxygen, dissolved inorganic carbon, or dissolved inorganic phosphorus are used to predict fluxes of dissolved inorganic N based on elemental stoichiometry. The predicted N flux is compared to the observed inorganic nitrogen flux and the difference is a proxy for the net DNF rate (Joye *et al.*, 1996, Giblin *et al.*, 1997). The errors associated with this method are typically large because of the heterogeneity associated with benthic fluxes between replicate cores. Abiotic and biotic oxygen consumption can lead to overestimates of O_2–based DNF rates. Finally, fluxes of DON are not accounted for in benthic flux mass balances and can lead to errors in DNF estimates.

Stable nitrogen isotopic tracers provide another way to estimate DNF rates and are often used in concert with the direct approaches (described above) to better constrain rates of coupled NTR–DNF. Heavy (^{15}N-labeled) NH_4^+ or NO_3^- is added to samples in tracer quantities and the subsequent production of ^{15}N-labeled gases ([15]N:[14]N or [15]N:[15]N) is quantified (Nielsen, 1992). The main drawback of this approach is that pore water N pools may not reach isotopic equilibrium during the incubation, which complicates calculation of DNF rates.

5.5. Dissimilatory nitrate reduction to ammonium

Measuring rates of DNRA requires a ^{15}N tracer approach (Binnerup *et al.*, 1992; Koike and Hattori, 1978); otherwise it is impossible to distinguish NH_4^+ generated from organic matter mineralization from that derived from NO_3^-. Relative to DNF, DNRA rates are poorly constrained but DNRA activity can be comparable to DNF activity in coastal sediments (An and Gardner, 2002; Binnerup *et al.*, 1992; Jørgensen, 1989). The general approach for estimating DNRA is to add ^{15}N-NO_3^- and track the production of ^{15}N-NH_4^+ over time. Because ^{15}N-NH_4^+ can rapidly adsorb onto particles, it is important to quantify both dissolved and solid phase ^{15}N-NH_4^+ pools. Often, only the pore water or overlying water ^{15}N-NH_4^+ pool is quantified, which can lead to significant underestimates of DNRA rates. The isotopic signature of ^{15}N-NH_4^+ can be estimated by high performance liquid chromatography (Gardner *et al.*, 1995) or by isotope ratio mass spectrometry (Holmes *et al.*, 1998).

5.6. Anammox

As no specific inhibitor is currently available to block ANAM without blocking DNF (Jensen *et al.*, in press), quantifying rates of ANAM remains an analytical challenge. The generally accepted procedure is to use a combination of ^{15}N-based tracers to tease apart the relative importance of DNF and ANAM (Dalsgaard and Thamdrup, 2002; Risgaard-Petersen *et al.*, 2004a,b; Trimmer *et al.*, 2003). Typically ^{15}N-NO_2^-, ^{15}N-NH_4^+, and ^{15}N-NO_3^- are added to separate samples, which are subsequently incubated anaerobically. ANAM activity is evidenced by the production of mass $^{29}N_2$ (^{14}N:^{15}N) from any of the three substrates (^{15}N-NO_2^-, ^{15}N-NH_4^+, or ^{15}N-NO_3^- while DNF is evidenced by the production of $^{30}N_2$ (^{15}N:^{15}N) from either ^{15}N-NO_2^- or ^{15}N-NO_3^- (note that no DNF should result from ^{15}N-NH_4^+ (via coupled dentrification) if sediments are incubated anaerobically). A major complication related to quantifying ANAM rates is the contemporaneous occurrence of DNRA. DNRA converts ^{15}N-labeled N oxides to $^{15}NH_4^+$; if that $^{15}NH_4^+$ were consumed by ANAM, it would generate $^{30}N_2$ (^{15}N:^{15}N), which would be interpreted as resulting from DNF using standard methods (Porubsky *et al.*, 2008a). More methods development is required to quantify ANAM rates in the presence of DNF and DNRA.

6. FUTURE RESEARCH

Nitrogen cycling in sediments influences the global N cycle and hence global patterns of primary production in aquatic sediments. In this chapter, we have summarized the factors regulating sediment N cycling from chemical, physical, and biological perspectives, showing that in most cases, several processes control the concentrations and fate of N in sediments. While some aspects of the sediment N cycle have become more clear with each passing year, e.g., we know that sediments exposed to fluctuating oxic–anoxic conditions, such as those with active benthic primary producer communities, are characterized by dynamic diel variability in the rates and patterns of N processing; other issues require additional, more detailed study.

Given the increasing nutrient, particularly N, loads characteristic of most coastal watersheds, much research has focused on understanding the factors that regulate N removal from the system. However, the complexity of the sediment N cycle has resulted in many studies that focus on one process in isolation, such as DNF, rather than on linkages between competing processes. As noted earlier, the number of studies focusing on DNRA and ANAM pale in comparison to the number of studies focusing on DNF. Part of the reason for this bias toward DNF is that DNRA rates are more difficult to quantify than DNF and ANAM was only recently discovered. Now that it is clear that DNF, DNRA, and ANAM may co-occur in sediments, we need to understand the environmental triggers that select for one pathway at the expense of another. Thus, documenting and understanding the biotic, chemical, and physical factors that regulate the fate of NO_3^- by dissimilatory processes in sediments is deserving of more detailed study.

Furthermore, the role of factors, such as salinity, metabolic status, grazing, trophic transfer, and residence time on controlling the fate of N in coastal systems warrants additional study. While some studies have suggested that salinity influences rates of NTR and DNF, others have suggested that the availability of substrates, NH_4^+ or NO_3^-, is more important. Clearly, sediments with productive benthic autotrophic communities exhibit different patterns of N processing than do sediments that are net heterotrophic. The role that meiofauna and macrofauna play in determining the fate of nitrogen taken up by benthic microalgae and sediment microbes remains unclear. A better understanding of the effect of ephemeral changes in metabolic status on N processing is needed. Finally, most of the data used to develop residence time–DNF relationships utilized methods that ignored the impact of benthic primary producers on DNF. More work is needed to quantify DNF rates in the presence of active benthic primary producers to determine how primary production alters N removal via DNA (or ANAM) at the system level.

An ideal way to understand the detailed controls on N processing within ecosystems is to employ *in situ* ^{15}N tracer experiments, such as those conducted by Tobias *et al.* (2003a,b) in two Massachusetts estuaries and by Veuger *et al.* in intertidal sediments (2007a). Such studies provide insight into the biotic, chemical, and physical factors regulating N flow and also permit tracking of the tracer into the benthic and pelagic food webs. For example, pulse–chase experiments performed by Veuger *et al.* (2007a, b) in intertidal sediments followed by determinations of incorporation of ^{13}C and ^{15}N into bacterial specific biomarkers such as D-alanine have greatly clarified the role of the benthic microbial community in sequestering and transforming nitrogen and hold great promise for elucidating the fate of nitrogen in sediments (Veuger *et al.*, 2005). These integrative studies require collaboration of a number of investigators with diverse backgrounds and can be expensive but the scientific payoff justifies the effort.

MACROALGAL-DOMINATED ECOSYSTEMS

Peggy Fong

Contents

1. INTRODUCTION AND OBJECTIVES

The objective of this chapter is to summarize and synthesize what is known about the role of nitrogen (N) in forming the structure and defining the function of macroalgal–dominated marine ecosystems. Specifically, marine macroalgae will first be broadly defined and a perspective given on its global importance relative to other primary producers in the ocean. Second, I will describe community characteristics of the four major habitat types that may be dominated by macroalgae: (1) soft–sediment areas such as bays, estuaries, and lagoons; (2) coral reefs; (3) rocky subtidal zones; and (4) the rocky intertidal. For each, what is known about the role of changing supplies of N—both natural and anthropogenic—and the increasing frequency of phase shifts will be summarized. Third, evidence for and current approaches to determining the importance of N limitation across these systems will be reviewed and areas for methodological improvement identified. Fourth, what is known about the role of macroalgae in the N cycle will be discussed, including the relative importance of

various sources of N across macroalgal-dominated habitats, and the role macroalgae play in retention, cycling, turnover, and export of N at the local scale. Fifth, exciting new approaches to using macroalgae as indicators of N sources and supply rates will be reviewed; this is especially timely as N supplies to coastal marine systems will continue to increase in the future. Finally, I hope to identify knowledge gaps and suggest directions for future research.

2. Diversity and Productivity of Marine Macroalgae

Marine macroalgae form productive and highly diverse ecosystems along continental shelves worldwide. Members of this functional rather than phylogenetic group are from two Kingdoms and span at least four major divisions (Rhodophyta, Phaeophyta, Chlorophyta, and Cyanophyta) with worldwide distribution. Structurally, macroalgae include such diverse forms as simple chains of prokaryotic cells, single-celled yet multinucleate thalli over a meter in length, and giant kelps over 45 m in length with complex internal structures analogous to vascular plants. The overall percentage of total oceanic net primary productivity attributed to macroalgae ranges from 4.8% to 5.9% (calculated from Duarte and Cebrian, 1996). Although relatively low compared to oceanic (81.1%) and coastal (8.5%) phytoplankton productivity, on a global basis macroalgae ranks third most productive. However, local macroalgal productivity is comparable to some of the most productive terrestrial ecosystems such as tropical forests and varies greatly across the macroalgal-dominated systems discussed below (Mann, 1982).

Mechanisms that control net production of marine macroalgae are the same as for other primary producers: Geographic limits for growth are set by temperature and light and for removal by grazing and physical disturbance. Within these geographical limits, biomass accumulation is controlled by many interacting biotic and abiotic factors including light quantity and quality, water motion, intra- and interspecific competition, herbivory, and physical disturbance. However, in most places where macroalgae proliferate and dominate coastal communities, this dominance is a function of nutrient, usually nitrogen (N), availability (for reviews see Downing *et al.*, 1999; Howarth and Marino, 2006; Valiela *et al.*, 1997; Vitousek *et al.*, 1997). Despite this importance, our knowledge about the role of N limitation in determining community structure and dynamics and the role of macroalgae in N cycling varies dramatically among macroalgal-dominated ecosystems.

3. Macroalgal-Dominated Communities: Nitrogen Supply Controls Community Characteristics

3.1. Bays, estuaries, and lagoons

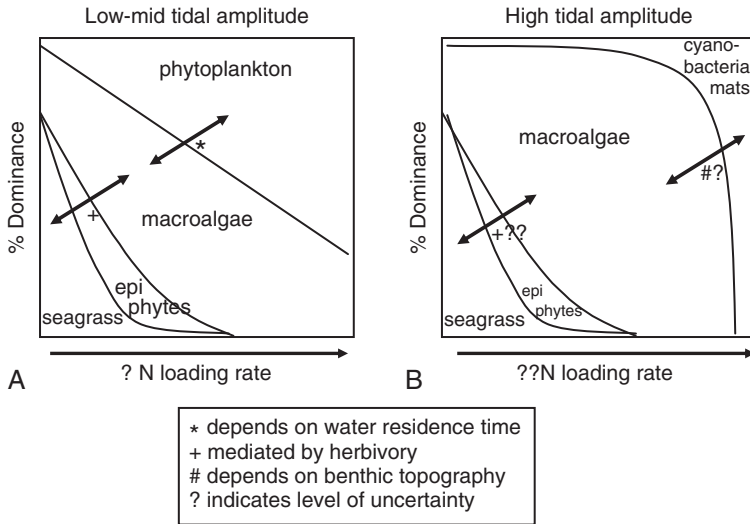
Macroalgae are important members of the primary producer community in shallow soft-sediment systems worldwide where light penetrates to large areas of the benthos. In soft-sediment systems subject to low N-loading rates, macroalgae are


Figure 20.1 Conceptual model of the relationships among N-loading rate and the community composition of primary producers in bays, estuaries and lagoons. Adapted from Vaiiela *et al.* 1997.

an integral component of the seagrass community (Fig. 20.1), where they occur in relatively low abundance attached to the benthos, epiphytic on seagrass blades, or forming drifting mats. Within pristine tropical seagrass beds, calcareous green macroalgae are commonly attached to the benthos; calcification provides protection from most herbivores and ultimately contributes to the accumulation and stabilization of tropical sands (MacIntyre *et al.*, 2004). In both tropical and temperate seagrass beds, macro- and microalgae attach epiphytically to seagrass blades. Although even low abundances of epiphytes can have negative effects on seagrasses due to shading and interference with gas and nutrient exchange, in seagrass systems with low-nutrient loading and intact herbivore populations epiphyte biomass accumulation is modest. In low N systems, drift macroalgae are also present in low abundance, but are ecologically important as they may provide protection from predation and aid in dispersal of invertebrates and fishes (Holmquist, 1994; Salovius *et al.*, 2005). However, as biomass of drift macroalgae increases with N-loading rate (Fig. 20.1), effects on diversity and abundance of fauna associated with the benthos become negative (Norkko *et al.*, 2004).

There is empirical, experimental, and theoretical evidence that as N loading to shallow semi-enclosed coastal systems from developing watersheds increases, sea-grasses are replaced by blooms of opportunistic macroalgae (Fig. 20.1A; for reviews see Duarte, 1995; Valiela *et al.*, 1997). It is well documented that blooms of green or red macroalgae dominate many shallow estuaries and lagoons worldwide that are subject to N enrichment (e.g., Geertz-Hansen *et al.*, 1993; Hauxwell *et al.*, 1998; Hernández *et al.*, 1997; Kamer *et al.*, 2001; Marcomini *et al.*, 1995; Page *et al.*, 1995; Peckol *et al.*, 1994; Raffaelli *et al.*, 1989; Sfriso *et al.*, 1987, 1992; Valiela *et al.*, 1992, 1997). One mechanism driving this phase shift is increased growth and biomass accumulation of drift macroalgae with N enrichment (e.g., Hauxwell *et al.*, 2000;

McGlathery, 2001). These large floating or stationary mats smother seagrasses and lead to local declines in the diversity and abundance of benthic infauna (e.g., Cummins *et al.*, 2004). As the frequency, magnitude, and duration of nuisance blooms of macroalgae increase with rising N supplies, macroalgal blooms eventually replace seagrasses entirely. While this seagrass-to-macroalgal phase shift is well documented elsewhere, there is only anecdotal evidence of former seagrass dominance along the West Coast of the United States (Fig. 20.1B). Any losses that may have occurred predate scientific documentation in the southern California region and only a few estuaries now support remnant seagrass populations (Stewart, 1991); all have either continuous or episodic blooms of macroalgae (Kennison *et al.*, 2003). Thus, these systems deserve further study as potential models representing future stages in the estuarine degradation process.

There is mounting evidence that another phase shift may occur if N loading continues to rise in systems presently dominated by macroalgal blooms (Fig. 20.1). The driving mechanism is self-shading of macroalgal mats once they reach a critical density (Krause-Jensen *et al.*, 1999; Peckol *et al.*, 1994); decomposition of these mats leads to release of N to the water for use by other producers. In estuaries with low to moderate tidal amplitude, macroalgae are replaced by blooms of phytoplankon (Duarte, 1995; Valiela *et al.*, 1997), and this transition is thought to be dependent on water residence time (Valiela *et al.*, 2000). Results of the only *in situ* enrichment experiment on the West Coast of the United States suggest that this final ecosystem transition along a eutrophication gradient will be to benthic cyanobacterial mats (Armitage and Fong, 2004) rather than to phytoplankton. We hypothesize that this transition may be attributed to the higher tidal amplitudes and existence of broad areas of intertidal mudflats in these systems. These mats of cyanobacteria are unpalatable or may even be toxic to the dominant herbivores (Armitage and Fong, 2004).

Because coastal bays, estuaries, and lagoons are of immense economic and social importance, the effects of increased anthropogenic N loading are perhaps the best understood of all macroalgal-dominated ecosystems. These systems have been subjected to increased frequencies and magnitudes of harmful macroalgal blooms, resulting in phase shifts from seagrasses to macroalgae and changing food webs, energy flow, and N cycling. Ecosystem-process level impacts of blooms include decreases in biodiversity and disruption of biogeochemical cycling (Valiela *et al.*, 1997). Algal blooms reduce diversity in estuaries by depleting the water column and sediments of oxygen (Sfriso *et al.*, 1987; Valiela *et al.*, 1992; Young *et al.*, 1998). Low dissolved oxygen content in estuarine water results in fish (Coon, 1998) and invertebrate mortality and subsequent changes in both trophic and community structure (Bolam *et al.*, 2000; Raffaelli *et al.*, 1989, 1991). Effects on biogeochemical cycling include reduction in N retention, more rapid N regeneration, and uncoupling of benthic and water column N cycling in these systems (e.g., Valiela *et al.*, 1997, and see section 5).

3.2. Coral reefs

Coral reefs are productive, diverse, and economically important ecosystems that dominate hard-bottomed habitats in low-nutrient tropical and subtropical waters. On pristine coral reefs, it is widely accepted that fleshy macroalgae are rarely spatially
Figure 20.2 Relationships between N-loading rates and phase shifts among primary producers in coral reef communities.

dominant (Littler and Littler, 1984); rather, tropical reefs in low-nutrient waters are dominated by encrusting and turf-forming algae and dominance is maintained by high levels of herbivory (Fig. 20.2). These algae form the base of benthic food chains, contribute to biodiversity, and stabilize reef framework. Crustose coralline algae play an important role in reef accretion, cementation, and stabilization (Littler et al., 1995). Algal turfs, comprised of filamentous algae and cropped bases of larger forms, are ubiquitous throughout tropical reef ecosystems with high rates of primary productivity. Fleshy macroalgae have been documented to proliferate on reefs, especially those with chemical defenses, or in areas where there is overfishing of herbivorous fishes (Hughes et al., 2003; Jackson et al., 2001), in other spatial or temporal refuges from herbivory (Hay, 1984; Smith, 2005), and in areas subject to increased N loading.

Coral reefs are undergoing phase shifts to macroalgal domination on a global scale. The mechanisms causing these transitions are hotly debated, with the relative importance of nutrients and herbivory at the center (reviewed in McCook, 1999; Szmant, 2002). Some question whether algae in tropical systems are usually, or ever, limited by nutrients. One rationale advanced is that if tropical algal turfs are extremely productive even in areas characterized by low water column nutrients (Hatcher, 1988; McCook, 1999), then they cannot be nutrient limited. To support this, Williams and Carpenter (1998) provided evidence that supply of solutes to algal turfs may be more limited by boundary layers than concentration. A second rationale focuses on field studies where water nutrient concentrations do not correlate with algal growth or abundance in the field (e.g., McCook, 1999).

Microcosm and in situ field experimental studies of nutrient limitation of tropical algae have had conflicting results, adding fuel to this controversy. Across many systems and scales, effects of nutrient additions have varied from no effects (Delgado et al., 1996; Koop et al., 2001; Larkum and Koop, 1997) to orders of magnitude differences in effects on photosynthesis, growth, and biomass accumulation

(Lapointe, 1987, 1989; Lapointe et al., 1987; Schaffelke and Klumpp, 1997, 1998). Interpretation of experimental results is limited, in part, by the difficulty of relating results of laboratory or microcosm studies of the effects of nutrient addition to natural growth in high-energy, high-flow environments with variable nutrient supply typical of coral reefs (Fong et al., 2006), and the related methodological challenge of effectively conducting in situ experiments in these same environments (reviewed in McCook, 1999). Factors potentially confounding experimental microcosm approaches include, among others, the lack of recognition of the role of nutrient history and status of the experimental macroalgae (Fong et al., 2003a). Many experiments are conducted without setting them in the context of the natural spatial and temporal variability inherent in the environment. On the other hand, several processes that are difficult to control in the field may confound in situ enrichment experiments. On the local scale, preferential selection for enriched, fast-growing algae by herbivores may effectively mask the effects of enrichment in small-scale in situ experiments (Boyer et al., 2004; Fong et al., 2006). In addition, sources of nutrients in tropical systems may not be solely from the water column but may flux from sediments (e.g., Stimpson and Larned, 2000) and therefore not be included in traditional supply estimates. Because of these complex processes and many possible confounding factors, the importance of nutrient limitation for tropical algae is not well understood.

There is some indication that phase shifts may be attributed to strong interactions between the forces of nutrients and herbivory (Fig. 20.2). Increasing supplies of N and possibly P (see section 4) may stimulate productivity; however, at low to intermediate nutrient supplies this may not translate into increased algal biomass in the presence of intact herbivore populations (e.g., Hughes et al., 2003; Jackson et al., 2001; Pandolfi et al., 2003). Rather herbivores strongly mediate the position of the phase shift along the nutrient supply gradient, virtually acting as lawnmowers, limiting algal biomass accumulation and negating the impact of nutrients. This maintains the competitive dominance of slower growing corals. Once herbivores are removed, algae become competitively dominant and a phase shift from coral to algal dominance occurs. Others argue that reduced herbivory is not always needed to initiate a phase shift attributable to altered outcomes of competition. One alternative mechanism is for increased nutrient supplies to stimulate rapid growth and allow algae to escape control by herbivores, biomass to accumulate, a change in competitive dominance from coral to algae, and ultimately a phase shift from coral to algae (e.g., Lapointe, 1997). The only resolution to this controversy is to focus more research on the interactive effects of consumers and nutrients on relative abundance of coral and macroalgae in this important ecosystem.

3.3. Rock reefs

Rocky subtidal reefs support dense, diverse, and highly productive kelp forests that are constrained by light at high latitudes and by nutrients, warm temperature, and other macrophytes at low latitudes (for a review see Steneck et al., 2002). Within ~40–60° latitude, kelp forests dominate rocky substratum; dominance extends

toward the equator where gyres bring cold–water currents along coasts and where upwelling occurs. Kelp are foundation species or "eco-engineers," creating one of the largest biogenic structures found in any benthic marine community (Dayton, 1985). In southern California alone, kelp forests support over 200 species of algae, invertebrates, fishes, and marine mammals, many of which are commercially impor- tant (Graham, 2004). Kelp forest inhabitants are linked tightly to kelp forests via both trophic and habitat associations. Kelp forests are characterized by extremely high rates of primary productivity, comprise the base of a complex food web, form a three-dimensional structure that provides physical shelter for many inhabitants, have large algal standing stocks within forests, and export substantial biomass as drift algae that support other coastal ecosystems (Graham *et al.*, 2003; Steneck *et al.*, 2002). Kelp have high N requirements to support rapid growth. A long life span (max = 25 years (Steneck *et al.*, 2002)) coupled with tremendous biomass accumulation results in relatively slow turnover and recycling of N. Thus, kelp forests contain a very large and relatively stable reservoir of N compared to other algal dominated coastal systems.

N availability controls the large–scale biogeography of kelp (for a review, see Witman and Dayton, 2001), limiting distribution to cold regions and upwelling zones with high concentrations and supplies of inorganic N (Fig. 20.3). When temperatures remain high, as during an El Niño Southern Oscillation event when upwelling is suppressed in southern California, the combination of high respiration and N limitation causes the distribution, abundance, and size of kelp to decline (Dayton *et al.*, 1999). Large reserves of N in kelp tissues provide a mechanism of tolerance for high temperature, and may aid in surviving warm summers and cold winters in geographic margins (Gerard, 1997; Hernandez–Carmona *et al.*, 2001; Pueschel and Korb, 2001).

Outside of major climactic events and away from geographic boundaries, how- ever, N supply in kelp forests may be relatively less important in shaping community
Figure 20.3 Relationships between N–loading rates and phase shifts in rocky subtidal habitats.

structure than other ecosystem processes. Witman and Dayton (2001) suggested that in N-rich areas, such as areas with predictable upwelling, N limitation may be relieved and the importance of biotic interactions may increase. Steneck *et al.* (2002) stated that within biogeographic boundaries, kelp distribution and abundance is most often limited by herbivory by abundant sea urchins (Fig. 20.3), and that the relative importance of urchin herbivory is increasing globally due to overfishing of apex predators. Even low abundances of herbivores may be important in marginal habitats (Russell and Connell, 2005) as these habitats demonstrate strong interaction between top–down and bottom–up factors. Overall, however, these studies suggest that within the geographic boundaries of kelp, N limitation is less important than herbivory in controlling kelp abundance. It is likely that internal stores of N within kelp forests are so large that they provide a buffer against short-term fluctuation in N supply.

The relative importance of N loading in kelp forests may change with anthropogenic disturbance. Although difficult to predict, global warming may have severe impacts on kelp forests by dramatically decreasing N supplies via suppressed upwelling and increased stratification (for a review see Steneck *et al.*, 2002). Decreases in N loading may result in phase shifts as in other macroalgal-dominated communities (Fig. 20.3); in this case, decreases in N may cause transitions to turf and crustose coralline algae, and, as in coral reef systems, may be strongly mediated by herbivores. At present, there is little evidence that increased anthropogenic sources of N have had any impact on kelp forests on open coasts (Steneck *et al.*, 2002). However, we do not know if there are threshold effects of varying N supplies as there are for herbivore abundance, so future increases in bottom–up control should not be ruled out (Fig. 20.3).

3.4. Rocky intertidal

Rocky intertidal zones worldwide are dominated by macroalgae and sessile invertebrates. Considering their relatively small area, virtually a one-dimensional ring bordering the world's coasts, the amount of research conducted in these habitats is extremely disproportionate (Witman and Dayton, 2001), and therefore our knowledge of many aspects of their structure and functioning is more complete than for other systems (Menge and Branch, 2001). The rocky intertidal zone is characterized by environmental extremes (temperature, salinity, desiccation, nutrient supply), yet there are also strong biotic interactions determining community structure. Macroalgae play important roles as the dominant *in situ* producers, forming the base of local food webs. Macroalgae in rocky intertidal habitats are highly diverse and abundant, especially in temperate regions. There is some evidence to suggest that rocky intertidal zones in tropical regions such as the Pacific coast of Panama are controlled by the same processes as temperate systems (Lubchenko *et al.*, 1984); however, rocky intertidal systems in tropical regions are far less studied.

Compared to the plethora of research on biotic and abiotic interactions in rocky intertidal habitats, comparatively few studies examine the role of nutrients in controlling macroalgal productivity (Menge and Branch, 2001). Some recent work

is focused on the importance of nutrient supply, especially N, at both the local and regional scales (for a review see Menge and Branch, 2001). These studies stress the importance of ''subsidies'' of organic and inorganic N from adjacent ecosystems such as coastal upwelling, detritus from kelp forests, or guano from sea bird colonies, rather than terrestrial sources or *in situ* regeneration and recycling (but see Bracken, 2004). Although rarely studied, it is likely that nutrient subsidies are also important in some tropical intertidal zones such as on the windward side of Oahu, Hawaii, where dense aggregations of *Sargassum* and *Turbinaria* occur (personal observation). This productivity may be supported by high water flow rates creating a high nutrient supply despite low water column concentrations. A few investigators have begun to quantify the effects of N subsidies on some well-known biotic interactions, finding that species interactions were much stronger with subsidies, with resultant differences in community structure (e.g., Menge *et al.*, 2003).

Recent experimental evidence may be pointing toward an emerging paradigm common to other macroalgal-dominated systems, one of a series of phase shifts along a N–supply gradient mediated by herbivores (Fig. 20.4). Enrichment experiments on rocky shores have provided mixed results; in Oregon alone results ranged from no effect at the population level (Pfister and Van Alstyne, 2003) to dramatic changes in community measures of algal diversity, evenness and complexity of thallus form (Nielsen, 2003). One possible explanation may be that these experiments started at different points along the N–loading gradient, and that different initial states resulted in differing outcomes (Fig. 20.4). Worm *et al.* (2002) and Worm and Lotze (2006) provided support for this explanation through a series of experiments and meta–analyses replicated across nutrient supply gradients. They determined that nutrients always increased macroalgal abundance and consumers moderated that response. However, areas with low ambient nutrients responded to enrichment by increased algal thallus
Figure 20.4 Relationships between N–loading rates and phase shifts in rocky intertidal habitats.

complexity and diversity (Fig. 20.4, phase shift 1), while more enriched areas already supporting more productive macroalgal assemblages responded with decreases in diversity due to a shift in dominance to opportunists (Fig. 20.4, phase shift 2). In addition, they found that, although grazing was important in controlling blooms of opportunistic macroalgae, it could not overcome the effects of increases in N loading across the whole supply gradient.

Overall, it is too soon to make generalizations on the relative importance of N-loading rate in controlling phase shifts among macroalgal communities in rocky intertidal zones compared to other biotic and abiotic processes that have been so well established. More work is needed to set the role of N in these systems into perspective.

4. Nitrogen Limitation of Marine Macroalgae: Evidence and Approaches

The importance of nutrients, especially N, in supporting coastal primary production has been firmly established (e.g., Downing et al., 1999; Howarth, 1988; Howarth and Marino, 2006; Nixon, 1995; Nixon et al., 1995; Vitousek et al., 1997). Overwhelming evidence has also accumulated that N is the most limiting nutrient to macroalgae in temperate regions (e.g., Lyngby et al., 1999; Taylor et al., 1995; Valiela et al., 1997). N limitation is also widespread in estuaries and lagoons with Mediterranean climates such as in Italy (Marcomini et al., 1995; Sfriso and Marcomini, 1997; Sfriso et al., 1987) and southern California (Kamer et al., 2004a,b). However, in Mediterranean climates there is some indication that the importance of N limitation may be seasonally variable and may relate to watershed development and algal type (Fong et al., 1993, 1994b; Lavery and McComb, 1991; Lavery et al., 1991).

For tropical marine macroalgae, quantifying the relative roles of N and phosphorus (P) limitation has been an important focus of research in recent years. In contrast to temperate systems (Fujita et al., 1989; Gallegos and Jordan, 1997; Rivers and Peckol, 1995; Sfriso and Marcomini, 1997; Taylor et al., 1995; Thybo-Christesen et al., 1993), some tropical studies found P to limit productivity and growth more frequently than N (Lapointe, 1987, 1989; Lapointe et al., 1992); however, even these studies found seasonal N limitation. Others found stimulation by both N and P (Lapointe, 1987; Schaffelke and Klumpp, 1998), or dual limitation (Fong et al., 2003a). There are several possible explanations why there is high spatial and temporal variability in the relative importance of N and P limitation in tropical systems. The strength of P limitation has been related to the amount of P-adsorbing carbonate in sediments (Delgado and Lapointe, 1994; Lapointe et al., 1992; McGlathery et al., 1994) and the habitat or substrate type the alga occupied (Lapointe, 1989; Littler et al., 1988). Others hypothesized that the relative importance of N and P limitation varied across a nutrient supply gradient, with N increasing in importance in more eutrophic systems due to saturation of the P adsorption capacity of sediments (Delgado and Lapointe, 1994; Downing et al.,

1999). Studies in Kaneohe Bay, Hawaii, an area with a history of nutrient enrichment, supported this hypothesis as N limited 9 of 10 species tested from a broad range of functional forms (Larned, 1998; Larned and Stimson, 1997). However, Fong et al. (2003a) found that several species of macroalgae in Puerto Rico differed in their response to N and P additions depending on their nutrient status; nutrient-replete algae did not respond strongly to either nutrient. Thus, more research is needed to further our understanding of the relative importance of N and P limitation in tropical marine ecosystems.

Two indirect approaches have been used extensively to determine if N and/or P limits productivity of marine macroalgae. In the first approach, N:P ratios of dissolved inorganic nutrients in the water column have been used as a measure of nutrient availability; water column N:P ratios are compared to nutrient requirements of algae to determine limitation (e.g., Duarte, 1992; Lapointe, 1989; Redfield et al., 1963; Wheeler and Björnsäter, 1992). However, different species or functional forms of algae may require nutrients in differing proportions; one study found that one alga was limited by N and another by P when grown together in seawater of the same N:P ratio (Fong et al., 1993). In addition, water column measures provide only a snapshot in time and may not adequately characterize availability in areas where nutrients are supplied in pulses as in the tropics (McCook, 1999) or in estuaries (Boyle et al., 2004; Fry et al., 2003). In the second approach, N:P ratios in algal tissue have been used to predict nutrient limitation (e.g., Lapointe et al., 1992; Wheeler and Björnsäter, 1992). However, this method also has limitations, because differing uptake and storage capacities of algae may confound the relationship. For example, if both N and P are abundant in the water, and an alga has a greater uptake ability and storage capacity for N than P, then the resultant high tissue N:P ratio would indicate P limitation when limitation by nutrients was not occurring. Sfriso (1995) suggested that either N or P could be considered limiting to a single algal species in Venice Lagoon, Italy, depending on what measure of limitation was used (tissue N content vs water column nutrients).

A third approach used to determine N or P limitation is factorial enrichment experiments adding N and P alone and in combination, and quantifying response variables such as photosynthesis, growth, and changes in tissue N and P content (e.g., Fong et al., 1993; Lapointe, 1987, 1989; Larned, 1998). When addition of a nutrient increased any of these response variables, it was considered to be limiting. This approach has been used across a range of scales, from laboratory or field microcosm dose–response experiments (e.g., Fong et al., 2003a) to large-scale and longer-term in situ experiments (Koop et al., 2001). The limitations include choice of realistic experimental enrichment levels, effectively scaling up the relatively short-term and small-scale responses from microcosm experiments, and effectively enriching in situ experiments in high-energy environments. The advantages, however, are that the experimental approach provides direct rather than indirect evidence of limitation. Although at present the disadvantages of this approach require careful interpretation and application of experimental results, the strength provided by direct evidence warrants further research and development.

5. The Role of Marine Macroalgae in Nitrogen Retention, Cycling, Turnover, and Loss

5.1. Sources of nitrogen to macroalgae

The primary source of ''new'' N to macroalgal-dominated marine communities has long been identified as terrestrial inputs via rivers from coastal watersheds (e.g., Downing *et al.*, 1999; Howarth and Marino, 2006; Nixon *et al.*, 1995; Vitousek *et al.*, 1997), although upwelling has also been recognized to be important along portions of the west coasts of major continents (Duxbury, 1979; Menge and Branch, 2001; Smith *et al.*, 1996; Fong *et al.*, in preparation). While these sources are still considered of primary importance, there is an increasing focus on other sources, including nitrogen fixation (for a review see Howarth and Marino, 2006), groundwater, and aerial deposition (e.g., McClelland and Valiela, 1998; Page, 1995; Whitall and Paerl, 2001). With the exception of upwelling and N-fixation, all of these sources of new N to macroalgae are rapidly increasing as a result of anthropogenic alterations of the global N cycle (for a review see Vitousek *et al.*, 1997). The role of anthropogenic versus natural sources of N in stimulating macroalgal blooms has been well established in estuarine systems (Fig. 20.5); evidence of the same processes occurring in rocky intertidal zones is accumulating (Worm and Lotze, 2006). In coral reefs it is highly debated, and in kelp forests it has yet to be demonstrated (Steneck *et al.*, 2002). Overall, systems more closely associated with terrestrial watersheds and with restricted water exchange such as estuaries are thought to be subject to and affected the most by increasing anthropogenic N supplies compared to open oceanic systems such as kelp forests (Fig. 20.5).

In situ sources of N to macroalgae include recycling from other biota, and, in soft-bottomed systems, regeneration from the sediments (Fig. 20.5). Across all systems, biotic sources include regeneration of N from primary producers during decomposition. In estuaries, macroalgal blooms may be sustained by nutrient release of N from senescent or self-shaded portions of the blooms (Peckol *et al.*, 1994) or by recycling of N from nearby vascular plant communities such as seagrass beds (for a review see McGlathery *et al.*, 2004). Flocculent material, most likely at least partially of biotic origin, settling on the surfaces of algal thalli has been identified as a source of N to macroalgae in coral reefs (Schaffelke, 1999). Animals in coral reefs and kelp forests that live in close association with macroalgae may have positive effects by releasing nitrogenous waste products (Bracken, 2004; Hurd *et al.*, 1994; Williams and Carpenter, 1988).

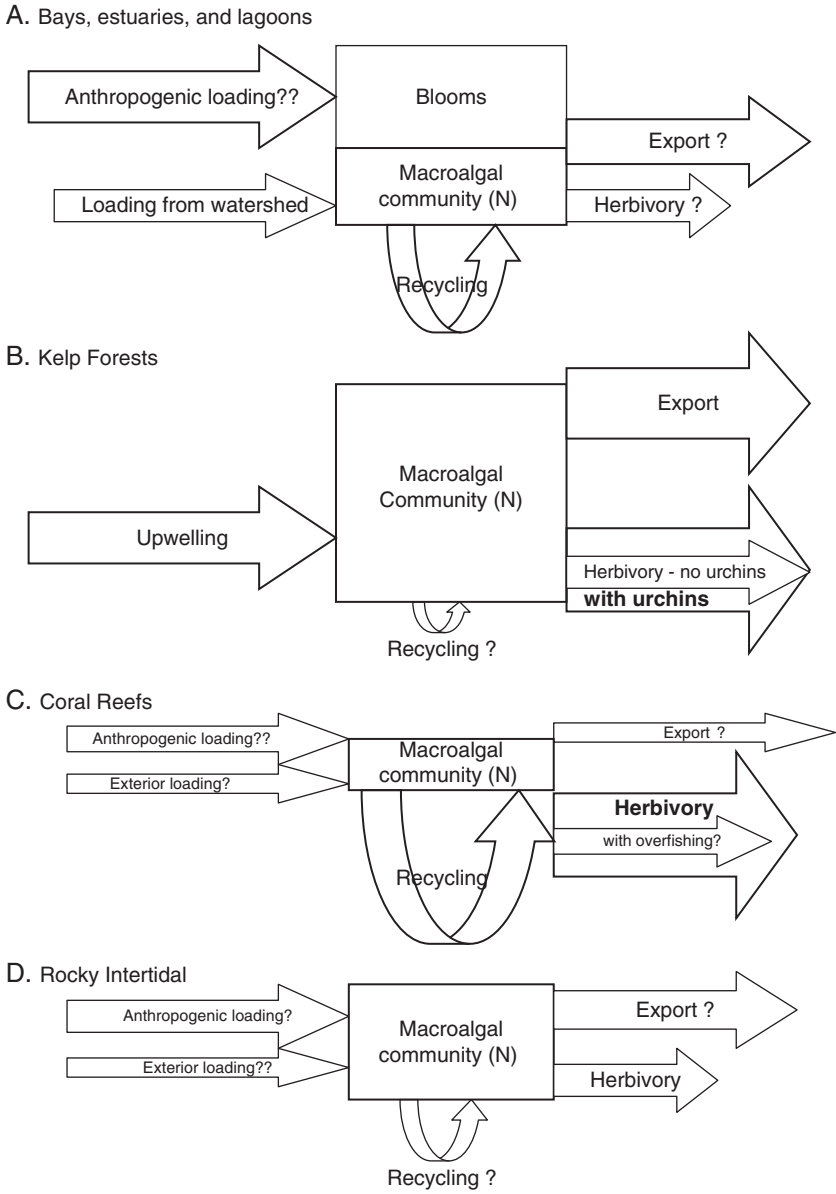
Across macroalgal-dominated systems, recycling of N from sediments and biota is most likely greatest in estuaries and coral reefs (Fig. 20.5). It is well known that macroalgae intercept fluxes of N regenerated from estuary and lagoon sediments in temperate and Mediterranean regions (e.g., Fong and Zedler, 2000; McGlathery *et al.*, 1997; Tyler *et al.*, 2001, 2003), in some seasons meeting up to 100% of macroalgae N demand (Sundbäck *et al.*, 2003). In tropical systems, recycling from sediments is most likely only a significant contribution in enriched systems (Stimpson and Larned, 2000). The relative importance of sediment regeneration


Figure 20.5 Sources, sinks and cycling of N in macroalgal dominated ecosystems. Width of arrows and size of boxes indicate relative magnitudes.

may vary along a N–resource gradient (Kamer *et al.*, 2004b) or may be a result of historical N enrichment (Stimpson and Larned, 2000). Macroalgal interception of N fluxes is ecologically important as macroalgae may uncouple sedimentary and water column N processes (Valiela *et al.*, 1992, 1997), reducing supplies to other producer groups (Fong and Zedler, 2000). Thus, preemptive competition for

recycled N by macroalgae may partially explain why some blooms dominate year-round (Kennison *et al.*, 2003).

5.2. Macroalgae as a sink of nutrients: nitrogen uptake

Predicting uptake rates of N by macroalgae from water column sources is complex. For years, N uptake was thought to be a simple function of water column inorganic N concentration that could be described by Michaelis–Menten uptake kinetics (e.g., Fong *et al.*, 1994b), an approach proven successful for phytoplankton (Droop, 1983; Sommer, 1991). More recently, the recognition that macroalgae are often both relatively stationary in a dynamic flow environment and have significant N storage capacities that reflect past nutrient supplies has focused current research into the physics of dissolved solute transport across boundary layers as well as the influence of the biological condition of algal thalli on uptake (for a review see Hurd, 2000). Both of these must be incorporated into our understanding of N availability to and uptake by macroalgae.

Uptake of N from the water column depends on many factors, including the nature and velocity of water flow, water nutrient concentrations of biologically useable substrates, and algal metabolic demand. The nature (turbulent vs laminar) and velocity of water flow affects the depth of the diffusion boundary layer surrounding an algal thallus while the nutrient flux across this boundary layer is controlled by the water nutrient concentration at the top and the metabolic demand which drives the rate of removal at the bottom (Hurd, 2000). If algal metabolic demand is low because storage is high or other factors are limiting, then mass transfer of nutrients across the diffusion boundary layer is not limiting. Theory predicts that mass transfer will be limiting most often when both flow and water column N concentrations are low. However, the importance of mass transfer limitation may be influenced by several factors, including other sources of nutrients such as the sediments or closely associated animals, the flexibility or flapping of algal thalli generated by water motion, and transient surge due to surface wave or tides (for a review see Hurd, 2000). In addition, for small filamentous or crustose algae completely within the benthic boundary layer, current speeds may be much reduced compared to those that extend into the overlying faster water flow (Carpenter and Williams, 1993; Nepf and Koch, 1999).

Algal morphology affects uptake of nutrients by controlling the accessibility to uptake sites on the algal thallus. As discussed above, morphology controls the algal height with respect to the benthic boundary layer and thallus structure may enhance uptake by flexibility in flowing water (Hurd, 2000). In addition some algal growth forms, such as densely packed mats, may reduce uptake (Fong *et al.*, 2001). Morphology also determines the physical surface area of an algal thallus containing uptake sites. Several studies have identified a positive relationship between an alga's surface area to volume ratio and uptake of nutrients (e.g., Hein *et al.*, 1995).

Once N crosses the boundary layer and contacts the macroalgal thallus surface, it must be transported across the cell membrane and then assimilated into organic compounds, followed by incorporation into proteins and macromolecules for

growth (Cohen and Fong, 2004b; McGlathery *et al.*, 1996). These processes vary among commonly co–occurring forms of N in coastal marine waters, including both inorganic forms (NH_4^+ and NO_3^-) considered most readily taken up by macro-algae. For example, some algae have strong preferences for NH_4 while others take up either inorganic N source (e.g., Hanisak, 1983; Lotze and Schramm, 2000; Naldi and Wheeler, 2002). Uptake of NH_4^+ is less energetically costly, as NO_3^- must first be reduced to NH_4^+ by nitrate reductase before assimilation (Hurd *et al.*, 1995); thus, energetics may explain preference for NH_4^+ by some macroalgae. However, NH_4^+ storage capacity may be limited due to toxicity (Haines and Wheeler, 1978; Lotze and Schramm, 2000; Waite and Mitchell, 1972), and therefore assimilation rate into inorganic molecules may limit maximum uptake rate of this form of N. Opportunistic macroalgae's ability to take up both forms of N simultaneously may be one mechanism that results in algal blooms (Cohen and Fong, 2004b; Thomas and Harrison, 1987).

Algal demand, a function of algal tissue nutrient status, also influences nutrient uptake rates of macroalgae. Tissue nutrient status reflects the history of nutrient supply to an alga as algae subject to excessive or pulses of nutrients may store nutrients for future growth (Fong *et al.*, 1994a,b; Lapointe and Duke, 1984; Wheeler and North, 1980). Several investigators (e.g., Fong *et al.*, 2003a; Fujita, 1985; McGlathery *et al.*, 1996) found that algae with nutrient enriched tissues always took up N more slowly than nutrient depleted algae. These studies demonstrate that algae with higher internal nutrient content will have lower metabolic demand and therefore slower N uptake rates.

Pedersen (1994) separated uptake of N into three phases. The first phase, surge uptake, is transiently enhanced nutrient uptake by nutrient-limited algae that may last only minutes to hours. Surge uptake has been documented in response to high-concentration pulses of N (500 µM N) for bloom species in southern California estuaries (Kennison *et al.*, in preparation) and tropical algae from nutrient-poor sites in Puerto Rico (Fong *et al.*, 2003a). Because water column nutrients in tropical systems are characteristically low, experimental nutrient pulses to macroalgae in these latter experiments were also relatively low ($\sim$20 µM N), yet the algal response was rapid and of equal magnitude to the bloom-forming species from temperate estuaries. This suggests that tropical macroalgae may be especially well adapted to take advantage of pulses of nutrients through surge uptake. During the second, internally controlled phase of uptake, the rate-limiting step is assimilation of N into organic compounds (Fujita *et al.*, 1988; Rees *et al.*, 1998). This occurs when external N is maintained at a relatively high concentration for enough time that storage pools within algal tissue begin to fill (Cohen and Fong, 2004b; Fujita *et al.*, 1988; Lotze and Schramm, 2000; McGlathery *et al.*, 1996). The third phase of uptake, externally controlled uptake, occurs at low substrate concentrations and is regulated by the rate of nutrient transport across the alga's surface (Pedersen, 1994). This is a function of mass transport to the thallus surface as well as diminishing water column nutrient concentration.

The complex and interacting factors and processes affecting N uptake rates of marine macroalgae result in a wide range of rates in the field, which may mask increasing N supplies to these systems. N uptake rates of estuarine macroalgae have

been well studied, as these systems have been long at risk from excessive N loading (Fig. 20.5A). In mesotrophic estuaries and lagoons still dominated by seagrasses, uptake by seagrass epiphytes may exceed that of seagrass despite low biomass levels (Dudley *et al.*, 2001). As algae have faster N uptake compared to seagrasses, phase shifts to algae may change N dynamics by increasing internal sequestering and by recycling pulses of nutrients to these systems (Valiela *et al.*, 1997). Overall, maximum values of N uptake have been found for bloom-forming green macroalgae in highly eutrophic estuaries and lagoons. The limited data available for kelp suggest uptake rates are also relatively high (Hurd *et al.*, 1996; Probyn and McQuaid, 1985), presumably to sustain the typically high levels of algal biomass (Fig. 20.5B). In coral reefs, algae respond quickly to even low levels of N enrichment by enhanced uptake rates (Fong *et al.*, 2001, 2003a), though rates most likely never approach those in systems characterized by high water column availability (Fig. 20.5C). Although little data are available, nutrient uptake rates of macroalgae from the rocky intertidal may rival those of kelp forests and estuaries, as many genera are shared among these habitats (Kim *et al.*, 2004). Thus, high N uptake in macroalgal-dominated systems may mask increasing supplies by maintaining low water column concentrations, the usual metric to assess increasing nutrient supplies. This has significant implications for managing water quality in coastal ecosystems.

5.3. Macroalgae as a sink of nutrients: nitrogen storage and retention

The capacity to store N, represented by standing stock or biomass, varies tremendously across macroalgal-dominated ecosystems. As an example consider the tremendous differences in biomass between one study of coral reef algae (e.g., 0.03–0.6 kg wet wt m^{-2} based on a wet:dry wt ratio of 10:1; Foster, 1987) and another in kelp forests (e.g., 3.5 kg wet wt m^{-2}; Manley and Dastoor, 1987). Although both are highly productive in terms of gross primary productivity, they clearly occupy different ends of a spectrum in terms of biomass accumulation and therefore N storage capacity. Although there are exceptions, in general opportunistic species with simple thallus forms such as those that dominate coral reef turfs often have low levels of biomass despite relatively rapid growth rates due to short life spans, susceptibility to removal by physical disturbance, and grazing by herbivores. In contrast, persisters such as kelp often have high standing stocks due to longevity of individual thalli, investment in structure to withstand physical disturbances, and chemical defenses as protection from herbivores. One exception to this generalization is blooms of opportunistic macroalgae in shallow estuaries and lagoons that can also reach very high biomass levels (Fig. 20.5). Estimates from these systems range from 1 to 10 kg wet wt m^{-2} (Kamer *et al.*, 2001; Maroli *et al.*, 1993). Blooms in these systems have been clearly linked to increased N loading (e.g., Boyle *et al.*, 2004; Valiela *et al.*, 1997).

Reservoirs of N stored in macroalgae often undergo cyclical and/or seasonal patterns. Kelp forests have lower standing stocks in stormy seasons, when there is ice, or in response to ENSO warming (Witman and Dayton, 2001). Intertidal macroalgae on rocky shores, especially in higher tidal zones, respond to interactions among monthly and seasonal changes in tidal amplitude, temperature, and light by changing

biomass (Menge and Branch, 2001). Even some coral reef algae demonstrate marked seasonal variation in biomass (e.g., Lirman and Biber, 2000). Macroalgae in lagoons and estuaries have dramatic seasonal cycles, usually in response to changes in nutrient supply, temperature, and light, especially in eutrophic systems where seasonal blooms occur (Kamer *et al.*, 2001). Valiela *et al.* (1997) found that the N stored in seasonal blooms of macroalgae in eutrophic estuarine systems can equal the total annual N-load.

Estimates of standing stocks or biomass alone may not be an adequate measure of N retention in macroalgal-dominated systems, as some macroalgae are able to store excess supplies of N that occur seasonally or episodically in pulses within tissues. This results in high spatial and temporal variability in tissue N content. For example, tissue N content of *Enteromorpha intestinalis* ranged from 1.6% to 4.2% N seasonally and 1.8% to 4.2% N spatially within a single season in Newport Bay, CA (Kamer *et al.*, 2001). The range of tissue N in *E. intestinalis* within estuaries increased with latitude along the California Coast (Fong *et al.*, in preparation) attributed to greater oceanic supplies from upwelling coupled with slower growth due to colder water temperatures. These patterns demonstrated that storage capacity for excess N in algal tissues and algal growth are interrelated. For example, opportunistic green macroalgae may store enough N to sustain high growth rates for about 10–14 days (Fong *et al.*, 1994a; McGlathery *et al.*, 1996) while kelp may be able to store enough N to support slower growth over a period of weeks to months. Arctic kelp stored considerable amounts of N (as NO_3, protein, and chlorophyll) that was used to maintain growth over 9 months of N starvation (Korb and Gerard, 2000; Pueschel and Korb, 2001). Thus, calculations of N storage across macroalgal-dominated systems must take into account standing stock, growth and removal processes, and tissue N content.

5.4. Macroalgae as a source of nitrogen: turnover rates

Turnover rates of N stored in algal biomass in macroalgal-dominated systems depend on rates of consumption by grazers, recycling due to death and decomposition, and export (Fig. 20.5). Macroalgal turnover rate can affect different processes and storage compartments of the N cycle, including rates of microbial transformations and sediment and water column pools. Overall, for systems dominated by opportunists that bloom, there is a more rapid turnover of N compared to systems dominated by persisters like kelp (e.g., Worm and Lotze, 2006).

On a global scale, direct consumption by grazers was estimated as 33.6% of total macroalgal net primary productivity, demonstrating the general importance of macroalgae as the base of gazing food webs in coastal ecosystems (Duarte and Cebrian, 1996). However, the importance of grazing varies greatly across ecosystems, depending, in part, on the abundance and nature of the resident herbivores and relative nutrient supply rates. While seagrass ecosystems with low N loading have historically been thought to support detritus-based food webs, recent evidence demonstrates macroalgae contribute significantly to a grazing-based web (e.g., Tomas *et al.*, 2005). In a shallow lagoon (Hog Island Bay, USA) where macroalgae proliferate, grazing snails may consume up to 88% of growth daily, functioning to

accelerate turnover of large amounts of N stored in tissue and enriching sediments (Fig. 20.5A; Giannotti and McGlathery, 2001). In contrast, in a highly eutrophic lagoon in California, snails release N bound in sediments, fueling macroalgal blooms (Fong et al., 1997). In sub-estuaries of Waquoit Bay, USA, subject to different N loading, the relative importance of top–down forces (grazing by herbivores) decreased as nutrient supplies increased (Hauxwell et al., 1998).

Evidence has begun to accumulate that this negative relationship between the relative strength of N supply and herbivory may be applicable across macroalgal-dominated systems (Valiela et al., 2000). For example, in rocky intertidal habitats, grazing is important in controlling algal blooms and maintaining diversity, but cannot overcome the effects of increased N loading across the whole nutrient gradient (Fig. 20.5D; Worm and Lotze, 2006). Also, on pristine, low-nutrient coral reefs, there are a multitude of large herbivorous fishes and sea urchins, and experimental and historical evidence abounds to show that herbivores consume a large proportion of macroalgal productivity (Fig. 20.5C; for a review see Jackson et al., 2001). The exception to this pattern is kelp forests, where nutrients are in high supply and grazing can also be so important that the abundance of herbivorous sea urchins determines whether an area supports a kelp forest or a ''barren'' dominated by grazer-resistant crustose calcareous algae (Fig. 20.5B; reviewed by Graham, 2004; Steneck et al., 2002). Clearly the generality of a negative top–down/bottom–up relationship warrants further research.

Death and subsequent decomposition of macroalgal detritus results in release and recycling of stored N (Fig. 20.5). Processing of N through detrital pathways comprises about a third of macroalgal net primary productivity globally (Duarte and Cebrian, 1996). However, like grazing, the relative importance of recycling varies across habitats. For example, high-energy zones like kelp forests recycle much less detritus within the system compared to lagoons, while the estimates for recycling within coral reef algae is very high (Duarte and Cebrian, 1996). When algae decompose, they release organic N to the water and, in soft-sediment systems, to the sediments (for a review see McGlathery et al., 2004). Recent studies demonstrated that substantial dissolved organic N also ''leaks'' from healthy thalli (Fong et al., 2003b; Tyler et al., 2003); healthy macroalgae in bloom phase may release 39% of gross primary productivity, including N, which is processed via detrital pathways. Some organic compounds in the water can be taken up directly or are quickly remineralized to inorganic forms that may fuel productivity of other primary producers. If burial in the sediment occurs, remineralization may be slower; thus, sediments may act as a slow release fertilizer and enhance algal productivity when external supplies are low (Boyle, 2002; Kamer et al., 2004b). N released from algae and stored in sediments may also be used by vascular plants (Boyer and Fong, 2005). Alternatively, sediment N may be denitrified, a net loss of N from marine ecosystems.

In shallow estuaries and lagoons subject to macroalgal blooms, the collapse of blooms and subsequent turnover of N can have major ecosystem level effects. Release of organic N may alter food webs toward heterotrophic bacteria pathways (Valiela et al., 1997), depleting water and sediments of oxygen. If severe, the result is die-off of resident fish and invertebrates. In addition, sediment anoxia may cause

direct release of N stored in sediments, a secondary or indirect effect on N cycling. Sediment anoxia may decrease denitrification in the sediment, or bring the denitrification zone (the anoxic–oxic interface) up into the decomposing mats on the surface (Krause-Jensen *et al.*, 1999; Trimmer *et al.*, 2000). Clearly blooms of macroalgae in shallow semi-enclosed systems cause dramatic changes in N processing in these systems.

N export from macroalgal-dominated habitats varies tremendously across eco-system types (Fig. 20.5). Duarte and Cebrian (1996) calculate a global average of 43.5% of macroalgal net primary production is exported; however, the range is perhaps the more important metric, varying from ∼0% to 85% across macroalgal–dominated habitats. Over all ecosystems, export is a function of standing stock, water motion, and algal morphology. Kelp forests export a far larger amount of N than coral reefs despite vigorous wave action in both systems due to their vastly larger standing stock. In contrast, pristine lagoonal systems export less N compared to kelp forests as there is both less physical disturbance and lower water exchange with other systems to detach and remove biomass. Thus, seagrasses in lagoons represent a large and relatively stable reservoir of N. In contrast, in eutrophic systems there is often accumulation of large floating algal rafts. In this case, phase shifts to macroalgae result in faster turnover and potentially more rapid net export of N to the ocean (Flindt *et al.*, 1997; Salomonsen *et al.*, 1999). Thus, phase shifts in lagoons and estuaries may have "downstream" effects on other nearshore macroalgal-dominated habitats such as coral reefs, kelp forests, and rocky intertidal zones.

6. MACROALGAE AS INDICATORS OF SOURCES AND MAGNITUDE OF NITROGEN SUPPLY

Because N loading to coastal macroalgal–dominated systems is rapidly accel-erating with resultant phase shifts, it is increasingly important to develop more accurate and affordable techniques to quantify the magnitude and sources of N available to primary producers (e.g., McClelland *et al.*, 1997). Water sampling can quantify N concentrations and species (NO_3^-, NH_4^+, DON), but can be costly as sampling must be spatially and temporally intensive in order to make representative conclusions (Fry *et al.*, 2003). This is especially true in macroalgal-dominated systems where nutrient concentrations have high temporal and spatial variability, such as estuaries and coral reefs (Fong *et al.*, 2001; Fry *et al.*, 2003; McGlathery *et al.*, 1996; Valiela *et al.*, 1992). In addition, changes in water quality parameters are often only measurable near points of discharge due to dilution, while effects may extend longer distances (Fong *et al.*, 2001; Jones *et al.*, 2001).

Macroalgae have been used successfully to identify changing N supplies to nearshore coastal areas (Costanzo *et al.*, 2000; Fong *et al.*, 1998, 2001; Horrocks *et al.*, 1995; Jones *et al.*, 2001; Lyngby, 1990). Macroalgal tissue N concentration reflects nutrient loading because N uptake and growth are often temporally decoupled, resulting in storage (Birch *et al.*, 1981; Hanisak, 1979; Martins *et al.*, 2001). Opportunistic green and red algae take up N very quickly (hours) in

proportion to changes in supply and retain the signal for up to 10 days (Fong *et al.*, 1998, 2001; Fujita, 1985; McGlathery *et al.*, 1996). Thus, tissue N content of macroalgae can be an effective bioindicator of the relative magnitude of N enrichment in coastal estuaries, lagoons, and nearshore open-coast ecosystems (Costanzo *et al.*, 2000; Fong *et al.*, 1998, 2001; Horrocks *et al.*, 1995; Lyngby *et al.*, 1999).

Stable isotopes of N (δ^{15}N) sequestered in algal tissue provide an integrative measure of relative supply of stable isotopes to a system and thus have been linked to ratios in nutrient sources (Costanzo *et al.*, 2000; Cohen and Fong, 2006). δ^{15}N values of algae, usually phytoplankton, have indicated not only whether N was from a terrestrial or a marine source (Page, 1995; Rogers, 1999; Van Dover *et al.*, 1992), but also whether the N came from fertilizer, processed sewage, soil, atmospheric sources, or groundwater (Heaton, 1986; Kendall, 1998; Page, 1995). However, these average δ^{15}N ratios can vary greatly depending on the type of N (NH_4^+ or NO_3^-), the origin of the material (e.g., inorganic vs animal waste fertilizer), and the amount of biogeochemical processing (denitrification, volatilization, mineralization, nitrification) (Kendall, 1998), making interpretation complex. Despite these limitations, sources of N have been identified based on numerical comparisons of isotopic ratios (Heaton, 1986; Kendall, 1998).

There are two important assumptions underlying the use of macroalgal tissue δ^{15}N as an indicator of nutrient sources that must be more fully investigated to validate the approach. The first is that δ^{15}N values of the water reflect δ^{15}N values that result from simple mixing of sources. However, there are complex interactions of source mixing and chemical and biological modification once the source N enters the system (Owens, 1985) that must be considered. One possible solution is the use of a suite of complementary indicators that may resolve multiple sources (Cohen and Fong, 2006). The second assumption is that macroalgae take up ^{15}N in proportion to availability in a predictable manner (Cifuentes *et al.*, 1989). Selection for ^{14}N versus ^{15}N atoms, or fractionation, has been documented for phytoplankton (Cifuentes *et al.*, 1989; Owens and Law, 1989). Theoretically, some level of fractionation will always occur in any alga since ^{15}N is heavier than ^{14}N and therefore kinetics predict differences in diffusion rates and processing of the two isotopes (Kendall, 1998). However, if fractionation over a range of natural conditions is predictable, macroalgal tissue δ^{15}N values may be used to indicate corresponding water column δ^{15}N values. Cohen and Fong (2005) found accumulation of ^{15}N in the macroalga *E. intestinalis* was predictable over a wide range of δ^{15}N values and N concentrations in microcosm experiments. In one experimental field study, *Ulva lactuca* converged on signature ratios adjusted for 3–4‰ fractionation within 2 days (Teichberg *et al.*, 2007). In addition, a limited number of field tests have used δ^{15}N in macroalgae to distinguish N sources to coastal areas (Cole *et al.*, 2005; Costanzo *et al.*, 2000; McClelland *et al.*, 1997; Cohen and Fong, 2006). While caution must be exercised when interpreting δ^{15}N data due to differential *in situ* processing of sources and fractionation effects, the relative importance of various N sources have been successfully identified in these studies using macroalgal tissue δ^{15}N ratios.

One recent study suggested that a suite of macroalgal indicators may be most effective in assessing N sources in coastal ecosystems subject to multiple sources

(Cohen and Fong, 2006). Tissue N concentration was used to quantify the magnitude of nutrient supply while $\delta^{15}N$ in conjunction with tissue potassium (K^+) concentration was used to differentiate N sources. K^+ functions as an osmolyte in some euryhaline macroalgae (Black and Weeks, 1972; Karsten *et al.*, 1991; Ritchie and Larkum, 1985a,b; Young *et al.*, 1987), and varies predictably with salinity across a wide range of natural salinity fluctuations (Cohen and Fong, 2004a). Thus, tissue $\delta^{15}N$ and K^+ concentration were used together as indicators to resolve complexity associated with multiple N sources that may be difficult to distinguish (Cohen and Fong, 2006). For example, within-estuary processes such as denitrification can lead to high $\delta^{15}N$ values in residual available N (Cifuentes *et al.*, 1989; Horrigan *et al.*, 1990) that may be similar to high $\delta^{15}N$ values usually associated with waste–derived N in groundwater (Fry *et al.*, 2003; Kendall, 1998). In this situation, high $\delta^{15}N$ values in association with low K^+ concentration could be used to distinguish between watershed sources and enrichment resulting from *in situ* processes (Cifuentes *et al.*, 1989). Further investigation into the use of a suite of macroalgal indicators to obtain simultaneous and integrated measures of nutrients and salinity for identifying N sources to estuaries is promising.

7. Knowledge Gaps and Future Directions

We have made tremendous progress over the last 20 years in advancing our understanding of the role of marine macroalgae in N processing and cycling in shallow seas and coastal ecosystems. Macroalgal-dominated ecosystems are the third most productive when considering global ocean productivity, and, when calculated on an areal basis, are the most productive habitats in the ocean. Macroalgae are important sinks, sources, and reservoirs of N within habitats, and often function as sources of N to other marine systems. The role of N in fueling productivity of macroalgae has been well established in some marine systems, especially semi-enclosed ecosystem such as lagoons, estuaries, and bays. In these systems, clear linkages have been established from these bottom–up processes through all levels of ecosystem functioning. Understanding is further advanced in these systems at least partially because their semi-enclosed nature makes experimental and modeling approaches more tractable. Most importantly, however, their proximity to and close relationship with terrestrial watersheds makes them most vulnerable to anthropogenic changes in N supply. Because these habitats are at risk from eutrophication due to excess N loading, with many already undergoing losses in diversity, changes in biogeochemical cycling, and even phase shifts, much effort has been expended in understanding N processes in these systems.

There are still many challenges to be met in the future. Clearly the progress made in semi-enclosed ecosystems must be continued, as these habitats are so gravely at risk from increasing anthropogenic sources of N. In addition, as lagoons and estuaries continue to degrade, their role in N retention and processing may also be compromised and effects may be translated "downstream" to open-coast habitats. Therefore, just as clearly, more study of nutrient supply and effects in other

macroalgal-dominated ecosystems such as coral reefs, rocky intertidal zones, and kelp forests is essential as N loading to the coastal ocean is most certainly going to increase. If the role of changes in N supply in controlling macroalgal productivity, abundance, and diversity remains understudied in some systems due to methodological complexity, or is overlooked due to possible threshold rather than continuous responses, these systems may be facing a very important threat in the future. We know that ''hysetersis'' or abrupt phase shifts occur in response to N enrichment in semi-enclosed systems such as estuaries and lagoons, where effects of N are predictably stronger due to greater retention times. Therefore it is very possible that increases in N loading may have to be larger or of longer duration in open–coast systems, but that the effects may ultimately take the same path. One approach to maximize future progress is more comparative work among the different macroalgal-dominated systems.

One important challenge to furthering our understanding of the role of N in open–coast macroalgal-dominated systems is to solve some very difficult methodological issues. As discussed earlier, it is difficult to scale up from microcosm experiments, yet equally challenging to effectively enrich *in situ* areas typified by high wave energy and water flow. Some promising approaches have emerged, including comparing similar areas with differing oceanography (e.g., upwelling vs downwelling, Menge *et al.*, 2003; Smith, 2005), enriching tidepools or tidally isolated coral micro atolls (Koop *et al.*, 2001; Nielsen, 2003), or taking advantage of ''natural'' experiments where N supply changes over space (Lapointe *et al.*, 2004) or time (Smith *et al.*, 1981). Others have successfully enriched experimental plots or transplanted macroalgae on coral reefs using slow release fertilizer (Fong *et al.*, 2006; Smith, 2005; and others).

Another challenge is to continue to investigate the relative importance of different N sources. Steps have been made toward understanding the importance of groundwater and aerial deposition. Sediment regeneration has been identified as important in soft-bottomed systems, and other recycled sources such as pulses of N from closely associated animal populations have begun to be investigated in other systems. This may be especially key in coral reef ecosystems that harbor a multitude of cryptic and/or territorial fauna. The traditional method of sampling the water column to identify these types of sources may not be an adequate tool as they may be extremely temporally and spatially patchy. Therefore, more research on macroalgal bioindicators of differing sources is essential.

Nitrogen Cycling in Coral Reef Environments

Judith M. O'Neil *and* Douglas G. Capone

Contents

1. Introduction

Nitrogen cycling on coral reefs is a multifaceted process operating from the micro-scale of prokaryotes to ocean biogeochemistry cycles. Coral reefs are known for their high productivity despite low concentrations of ambient nutrients in the clear, well lit tropical and sub-tropical waters where they exist. Most of the productivity associated with coral reefs is benthic (Crossland, 1983; D'Elia and Wiebe, 1990; Webb *et al.*, 1975) and water column nutrient dynamics over the reef largely reflect net benthic metabolism. Most of the organic matter produced on the reef is recycled and retained in living organisms, or sediments within the reef system (Ayukai, 1995; Suzuki *et al.*, 1995).

Studying the changes in nutrient concentrations in waters before and after they flow over reefs was an approach first utilized to study coral reef nitrogen dynamics

(Sargent and Austin, 1949). These studies were followed by the landmark work of Odum and Odum (1955) and subsequently the Symbios project in Eniwetok Atoll, Marshall Islands in the Pacific, (Webb and Wiebe, 1975; Webb et al., 1975; Wiebe et al., 1975) which enabled a "big picture" idea of the net fluxes of nutrients cycling on reefs.

The results of these early experiments framed our view of coral reefs as areas of very high gross productivity, but low net productivity, which was hypothesized to be due to the efficient recycling of nutrients (D'Elia and Wiebe, 1990; Odum and Odum, 1955; Smith and Marsh, 1973). Research in the 1970s showed that reefs could be a source of nitrogen, particularly dissolved organic nitrogen (DON). Sources of nutrients to coral reef environments vary based on factors including proximity to the coast, ocean topography and latitude, amongst others. Whereas open ocean reefs can exist in extremely oligotrophic regions, reefs in fact exist along a gradient of nutrient regimes in coastal and mid-ocean regions (Szmant, 2002). Nitrogen sources include upwelling, lateral advective transport, coastal runoff, groundwater seepage, nitrogen fixation and in situ regeneration (D'Elia, 1988), as well as atmospheric inputs (Barile and Lapointe, 2005; Szmant, 2002) and localized guano inputs (Albert et al., 2005; Smith and Johnson, 1995). Wet deposition of inorganic nitrogen in episodic rainfall events is estimated to provide up to 20% of the "new" nitrogen to meet the metabolic demands of macroalgae on coral reefs in the Bahamas (Barile and Lapointe, 2005). Of primary interest in the last few decades is elucidating the anthropogenic components of groundwater seepage, coastal runoff and atmospheric deposition.

Understanding nitrogen cycling on coral reefs is paramount to understanding the "paradox of the coral reef": the anomalously high productivity in such low ambient nutrient waters (Szmant, 2002; Webb et al., 1975). Coral reefs have been described as "oases" in an otherwise oceanic desert (Hoegh-Guldberg, 1999). Another appropriate metaphor is perhaps that corals act as "cacti," effectively conserving precious limiting resources. The two most important underlying mechanisms to explain the coral reef paradox are: (1) the recycling of nutrients between algal symbionts and invertebrate hosts and (2) new nitrogen (Dugdale and Goering, 1967) introduced through nitrogen fixation by cyanobacteria and heterotrophic bacteria. The closely coupled nutrient and community dynamics that creates the circumstances for "something from nothing" (Hoegh-Guldberg, 1999) reveals a very complex interrelationship between habitat, hosts and symbionts with a true dependency between species (obligate mutualism).

How the species assemblages, and the delicate interchanges and balance among species may react to environmental changes is currently being tested as anthropogenic influences increase across the world's coral reef environments (Bellwood et al., 2004; Brodie, 1995; Hoegh-Guldberg, 1999, 2004a,b; Hughes et al., 2003; Knowlton, 2001; Pandolfi et al., 2003; Gardner 2003; Mora 2008). Increased concern over the fate of the world's coral reefs due to pronounced declines in the areal extent of coral reefs, their health and biodiversity, has been a central theme and impetus of much of the coral reef research carried out in recent decades (Birkeland, 1997, 2004). In addition to studying nutrient inputs, research has focused on the effect of other anthropogenic influences including over-fishing, coastal development and global climate change (Pew Oceans Commission, 2003).

1.1. New developments

Recent research on nitrogen cycling on coral reefs ranges from the further elucidation of the structural and functional properties of the reef that increase regeneration of nutrients leading to enhanced retention of nutrients within the reef system (Szmant, 2002), to the finer details underlying cycling of nutrients and the emerging importance of microbes interacting with the entire coral ''holobiont.'' In addition to the coral itself, this includes the zooxanthelleae, fungi, endolithic algae, >30 species of bacteria as well as the recently discovered coral-associated Archaea (Wegley et al., 2004). Oceanic Archaea have recently been found to play an important role in nitrification in the marine N cycle (see Chapter 5 by Ward, this volume).

Other new developments reveal that heterotrophic bacteria in the coral mucus layer (and other areas of the coral colony) may be critical to the health, nutrient cycling and resilience of the coral holobiont (Knowlton and Rohwer, 2003; Rohwer et al., 2002). The importance of both coral mucus (Wild et al., 2004a, 2005, 2008) and products from mass spawning (Wild et al., 2004b; Patten et al., 2008) as nutritional sources back into the reef system has also been documented. The significance of bacteria and viruses to sedimentary biogeochemical cycling have also been recognized (Hewson et al., 2007; Patten et al., 2008). These new insights all underscore the point that we have not yet discerned all the important nutrient controls and interactions in the reef ecosystem.

The fact that symbiotic associations on reefs are more complex than we have realized to date, is further demonstrated by work in the Caribbean using $\delta^{15}N$ values, which demonstrated that in some Montastrea cavernosa coral colonies nitrogen is obtained by zooxanthellae from cyanobacterial endosymbiotic nitrogen fixers. This ability appears to increase with depth, and dependency on heterotrophy. Greater depth also translates to less photosynthetically active zooxanthellae in the coral colonies and therefore less oxygen evolution which benefits the oxygen-sensitive diazotrophic symbionts (Lesser et al., 2007). This raises multiple questions about nutrient feedback loops between the coral host, symbiotic dinoflagellates and the cyanobacteria in terms of what role nitrogen ultimately plays as a "limiting and regulatory element" in these symbiotic associations (Lesser et al., 2007). This is just a small indication of how much more is yet to be unraveled in terms of the intricate mutualistic relationships involved in coral reef ecosystem functioning. It may prove to be that the symbiotic relationship between bacteria and corals, as well as other invertebrate hosts, is just as integral to the coral as a whole, as their relationship with symbiotic dinoflagellates (zooxanthellae).

Other new insights gained recently include the potential importance of atmospheric deposition, including the role of dust, as bearer of nutrients (Barile and Lapointe, 2005), as well as pathogens and metals (Garrison et al., 2003; Prospero et al., 2005). Another previously under-valued component in nutrient cycling in reef environments is the ''secret-garden'' of benthic microalgae (or microphytobenthos) which have emerged as major primary producers in coral reef systems and major mediators of nutrient flux at the sediment interface (Heil et al., 2004; MacIntyre et al., 1996; Werner et al., 2008). The one theme unifying all recent aspects of work on nutrient cycling on reefs is the incredible complexity of nutrient dynamics in these

systems. Recent results also underscore the need to further elaborate the details of these interactive dynamics, as we bring to bear the tools of molecular biology, remote sensing and geochemistry, as well as other technologies to these questions. By doing so, we may gain a better understanding of the diverse mutualistic and symbiotic relationships that are integral components in the coral reef nitrogen cycle.

2. NITROGEN CYCLE PROCESSES

Coral reefs are areas of intense nitrogen cycling and may contribute to the larger biogeochemical cycling of C and N in the ocean (Capone, 1996a,b; Crossland *et al.*, 1991; see also Carpenter and Capone, Chapter 4, this volume) (Fig. 21.1). Nitrogen fixation appears to satisfy much of the demand for new N in these systems and may provide a substantial input to the marine N cycle beyond the immediate reef area. High rates of nitrification also occur and likely contribute to N_2O fluxes to the atmosphere, although more research is needed in this area (Capone, 1996b). All of the major features of the marine N–cycle are mediated by biological, rather than chemical processes (Webb, 1981), which is in contrast, for instance, to phosphorus cycling (D'Elia, 1988). In addition to its role as a nutrient, because of its potential to be
Figure 21.1 Microbial nitrogen cycling processes in sedimentary environments on a coral reef: (A) nitrogen fixation; (B) ammonification; (C) nitrification; (D) dissimilatory nitrate reduction and denitrification; (E) assimilatory nitrite/nitrate reduction; (F) ammonium immobilization and assimilation. Adapted from D'Elia and Wiebe (1990). Anammox (the anaerobic oxidation of NH_4^+ with NO_2 yielding N_2^-) is not represented, as it has not yet been shown to occur on coral reefs, but may be found to be important in reef sediments.

transformed among various oxidation states, species of nitrogen can act as a reductant or oxidant in energetic reactions (D'Elia and Wiebe, 1990). Aspects of the major pathways of nitrogen on coral reefs which include: nitrogen fixation (Fig. 21.1A); ammonification (Fig. 21.1B); nitrification (Fig. 21.1C); denitrification (Fig. 21.1D); uptake and regeneration (Fig. 21.1E and F), have been reviewed previously (D'Elia and Wiebe, 1990 and references therein), and are summarized in Fig. 21.1.Coral reef sediments can contain relatively high nitrogen concentrations with values generally 10-fold or greater than in the water column (Capone *et al.*, 1992; Corredor and Capone, 1985; Corredor and Morell, 1985; D'Elia and Wiebe, 1990; Hatcher and Frith, 1985; O'Neil and Capone, 1989).

Nitrogen occurs in a range of forms in the reef environment. Concentrations of nitrate and ammonium in reef environments vary by an order of magnitude in the water column ranging from ~0.05–0.5 μM. Nitrite is usually below 1 μM. DON is usually the form of nitrogen in highest concentration in the reef water column ranging typically from 5–50 μM (Atkinson and Falter, 2003; Crossland, 1983; Table 21.1). Nitrogen concentrations in porewater can be several orders of magnitude higher than the water column. Reef porewaters can be anoxic within a matter of cm in many cases and values of nitrate range from 1–6 μM, with ammonium concentrations ranging from 2–80 μM (Atkinson and Falter, 2003; Capone *et al.*, 1992), although higher values can be seen in altered systems (e.g., values up to 300 μM, see Corredor and Morrell, 1985; Entsch *et al.*, 1983; Hines *et al.*, 1992).

Since nitrogen concentrations in pore water are higher than in the water column, there is often a net flux of nutrients out of the sediments (Williams *et al.*, 1985). This may be of particular importance in areas of low flushing and pooling in reef areas (Szmant-Froelich, 1983; Szmant, 2002). However, these processes are also quite variable in space and time due to various factors including sediment type, hydrodynamics and loading (Corredor and Morrell, 1985).

In most marine ecosystems, the largest N fluxes occur between inorganic and organic pools of nitrogen. The net incorporation of inorganic nitrogen into organic nitrogen is generally attributed to photoautotrophs. Regenerative processes, including the production of NH_4^+, are usually associated with heterotrophic processes although depending on the C:N ratio of the organic matter being consumed, heterotrophs can also account for net N immobilization (Kirchman, 1994). For comparative purposes, areal rates of net phytoplankton productivity in oligotrophic waters typically account for 0.3–0.7 mol N m^{-2} year^{-1} (Berger *et al.*, 1987; DeVooys, 1979), whereas coral reef net production may account for areal demands of N in excess of 43 mol N m^{-2} year^{-1} (Capone, 1996a; Smith, 1984).

Regeneration within the sediments as well as a variety of sites within the coral reef structure itself are all extremely important (Capone, 1996a; DiSalvo, 1971; Szmant-Froelich, 1983). This efficient regeneration of nutrients fuels the intense productivity of the coral reef system and results in a tendency to export a smaller percentage of total production than other marine systems (D'Elia and Wiebe, 1990). Therefore, regeneration of N in coral reefs must meet demands (Charpy-Roubaud and Larkum, 2005).

Table 21.1 Nitrogen concentration in tropical coral reef sediments and overlying water columns

2.1. Nitrogen fixation

Nitrogen fixation (see also Chapter 4 by Carpenter and Capone, this volume), the process by which certain prokaryotes can reduce atmospheric N_2 gas to ammonium via the nitrogenase enzyme pathways has long been thought to be important linchpin of nitrogen cycling and productivity in coral reef systems (D'Elia and Wiebe, 1999; Larkum *et al.*, 1988 Fig. 21.1A). The first direct demonstration of the importance of nitrogen fixation in reef environments by cyanobacteria (originally hypothesized by Odum and Odum, 1955), was in the Symbios project (Crossland and Barnes, 1976; Hanson and Gundersen, 1977; Wiebe *et al.*, 1975). Indeed, nitrogen fixation has been subsequently posited as "*a prominent component of the nitrogen-cycle on coral reefs which may relieve N limitation and make a globally significant contribution to overall marine N inputs*" (Capone, 1996a).

Many studies since the 1970s found high rates of nitrogen fixation (see also Chapter 4 Capone and Carpenter, this volume). In fact, nitrogen fixation on coral reefs has been reported at rates that at times exceed that of intensive legumous crops (Szmant, 2002; Webb et al., 1975). This energetically demanding process in cyanobacteria is powered by the high light flux and recycled phosphorus. Heterotrophic diazotrophic activity is supported by a combination of recycled P and organic matter (D'Elia, 1988).

In addition to nitrogen fixation associated with the extensive sediments in and around reef flats (Capone et al., 1992; Corredor and Morrell, 1985; O'Neil and Capone, 1989; Wilkinson et al., 1984; Mayajima et al., 2001; Hewson and Fuhrman, 2006; Werner et al., 2008), nitrogen fixation activity has been detected associated with live corals (Williams et al., 1987; Lesser et al., 2007), and coral skeletons (Crossland and Barnes, 1976; Larkum, 1988; Shashar et al., 1994a,b; Davey et al., 2008) as well as with epiphytes on macroalgae (Capone et al., 1977; France et al., 1998; O'Neil and Capone, 1996) and by cyanobacterial mats. Nitrogenase activity has also been measured on limestone reef surfaces (Charpy-Roubaud et al., 2001), including exposed atoll rim areas of various sorts, largely attributable to cyanobacteria. In Tikehau Lagoon, French Polynesia, for instance, nitrogen fixation on these surfaces accounted for 25–28% of the total nitrogen demand for benthic primary productivity (Charpy-Roubaud et al., 2001; Charpy-Roubaud and Larkum, 2005). Rates of nitrogen fixation in sediments, while lower than rates in localized areas or in mats of cyanobacteria (Iizumi et al., 1990; Charpy et al., 2000; Bauer et al., 2008), when integrated over the large areal extent of sedimentary environments can make a significant contribution to the overall coral reef nitrogen economy (Capone, 1996a; Capone et al., 1992; O'Neil and Capone, 1989). Low $\delta^{15}N$ signatures noted in reef macrophytes and coral tissue provide further evidence that much of the nitrogen in reef systems is derived from nitrogen fixation (France et al., 1998; Yamamuro et al., 1995). Nitrogen fixation can also occur in the lagoon of coral atolls and may contribute to nitrogen economies in these systems.

Nitrogen fixation also occurs in the lagoonal waters of coral reefs and this may contribute to the nitrogen economy of these systems as well. Biegala and Raimbault (2008) recently reported on the relatively high densities of diazotrophic coccoid cyanobacteria in coral lagoon waters of New Caledonia.

Rates of nitrogen fixation in reef environments are variable and can be affected by the presences of grazers. Grazing by Acanther plancii, the crown of thorns starfish on corals resulted in high rates of nitrogen fixation on the coral skeletons after the outbreak of this starfish (Larkum, 1988). Similarly, the sea urchin Diadema antillarum was shown to significantly increase nitrogen fixation when grazing on "algal turf" in reef environments, as compared to areas where no sea urchins were present. The "diminutive" tightly cropped "algal turf" assemblage contained a significant proportion of cyanobacteria in addition to benthic diatoms and dinoflagellates (Williams and Carpenter, 1997). Grazers also aid in nitrogen cycling by excreting nitrogenous waste which enhances algal turf, while simultaneously cropping it (Williams and Carpenter, 1997 see below). Fish grazing may also be important in maintaining rates of nitrogen fixation on reefs, by keeping other benthic algae in check. Some diazotrophic cyanobacteria are less palatable than other algae, as they often have chemical deterrents, and also tend to be less nutritionally complete, lacking some essential fatty acids, and hence macroalgae are often preferred by grazers (Capper et al., 2005; O'Neil, 1999). Therefore, cyanobacteria may have less competition for growing space and expand into areas where the more palatable species have been removed by grazers (Wilkinson and Sammarco, 1983).

A major fraction of total benthic nitrogen fixation on a global scale may come from shallow coral reef environments (Capone, 1983). However, whereas rates of pelagic nitrogen fixation have been steadily refined by surveys of the filamentous cyanobacterium *Trichodesmium* (Capone *et al.*, 2005), novel geochemical approaches (Mahaffey, 2005), and the emergent recognition of other important contributors such as unicellular nitrogen fixers (Montoya *et al.*, 2004), nitrogen fixation in coral reef environments remains under-sampled and likely underestimated. Nitrogen fixation by benthic or symbiotic cyanobacteria (Charpy *et al.*, 2007; Lesser *et al.*, 2007; Bauer *et al.*, 2008; Davey *et al.*, 2008) as well as heterotrophic bacteria including those epiphytic on macroalgae and coral surfaces (Davey *et al.*, 2008), have yet to be fully elucidated (Koop *et al.*, 2001; O'Neil and Capone, 1989, 1996; Hewson *et al.*, 2007; Werner *et al.*, 2008). The diazotrophic community may in fact be changing as a consequence of coastal eutrophication. Nitrogen fixation could either decrease due to nitrogen loading, or increase in response to inputs of limiting factors such as phosphorus or micronutrients such as Fe, decreases in N:P loading ratios, or as a result of organic loadings and stimulation of heterotrophic N_2 fixation directly through provision of organic substrates or indirectly through the increase in local anoxic zones.

Black band disease (BBD), which is caused by a consortium of cyanobacteria and microbes may be diazotrophic (Frias-Lopez *et al.*, 2002, 2003). This hypothesis was recently suggested by a molecular study of bacterial communities associated with BBD which yielded a 16sRNA sequence 97% homologous with the nitrogen fixing pelagic cyanobacterium *Trichodesmium tenue*. This led the authors to speculate that nitrogen fixation might be carried out in the oxygen depleted microzones of the BBD assemblage (Frias-Lopez *et al.*, 2002). More work is needed to test this hypothesis in a rigorous manner as subsequent work on isolated *Phormidium corallyticum* (formerly *Oscillatoria corallinae*) from Florida corals with BBD tested negative for nitrogen fixation (acetylene reduction) activity (Richardson and Kuta, 2003).

Invertebrate diazotrophic symbioses have been reported from reef systems including reef sponges that acquire fixed nitrogen via associated cyanobacteria (Wilkinson and Fay, 1979). Symbiotic cyanobacteria and bacteria are found in almost all marine sponges (Mohamed *et al.*, 2006; Thacker, 2005) and may form mutualistic associations with hosts especially if the symbiont provides fixed C or N. The cyanobacterium *Oscillatoria spongieliae* has been found within several species of sponges including the reef sponge *Dysidea herbacea* on the Great Barrier Reef (GBR) (Flowers *et al.*, 1998; Ridley *et al.*, 2005). *Synechococcus* has also been described from several species of sponge, which are genetically distinct from free living planktonic species of *Synechococcus* (Thacker, 2005). In some instances metabolic products (e.g., fixed carbon) are translocated from symbiont to host (Arillo *et al.*, 1993). However, in most cases the relationship between host and symbiont are not well defined (Ridley *et al.*, 2005).

Potential translocation of N from nitrogen fixers to hosts has also been investigated. Nitrogenase activity was reportedly associated with an intact *Procholoron*-Ascidian association (*Lissoclinum* sp.) (Paerl, 1984), although activity could not be directly detected by the isolated symbiont (Odintsov, 1991). It was subsequently determined that at least a portion of the cellular N was derived (directly or indirectly) from N_2 fixation, based on the low isotopic ratio of $^{15}N/^{14}N$ in *Lissoclinum* sp. associations (Kline and Lewin, 1999). Diazotrophs have also been found associated with corals (Frias-Lopez *et al.*, 2002; Rohwer *et al.*, 2001, 2002; Shashar *et al.*, 1994a,b)

with nitrogen fixation measured in some live corals (Shashar *et al.*, 1994a,b; Williams *et al.*, 1987). More recently the presence of a diazotrophic coccoid cyanobacteria has also been reported in the tissues of certain species of the coral *Montastrea* (Lesser *et al.*, 2004). Interestingly it has been further demonstrated through δ N analyes that the zooxanthellae from Caribbean colonies of *Montastraea cavernosa* colonies which contain the endosymbiotic cyanobacteria acquire N from the nitrogen fixing cyanobacteria rather than the coral host (Lesser *et al.*, 2007).

2.2. Nitrification

Nitrification has been conventionally viewed as the two step process by which certain groups of chemoautotrophic bacteria oxidize ammonium to nitrite and subsequently, another group of chemoautotrophic bacteria, oxidize nitrite to nitrate (Fig. 21.1C) (see Chapter 5 by Ward, this volume). Nitrification generally occurs in aerobic zones throughout the marine environment, and can occur at high rates in coral reef ecosystems (Capone *et al.*, 1992; Corredor and Capone, 1985; Corredor *et al.*, 1988; Johnstone *et al.*, 1990; Wafar *et al.*, 1990; Webb *et al.*, 1975). Nitrification in reef lagoons can oxidize ammonium recently released from nitrogen fixation or regenerative processes (Webb and Wiebe, 1975). Nitrification is also thought to be a major source of N_2O in marine systems, and may contribute to the overall weak marine N_2O flux to the atmosphere (Capone, 1996b) (see also Chapter 2 by Bange, this volume).

Nitrification on coral reefs was first noted when net nitrate production was measured at Eniwetok Atoll. This, in conjunction with the isolation of a species of nitrifying bacteria, *Nitrobacter agilis*, was taken as strong evidence for nitrification as a significant process in the reef system (Webb and Wiebe, 1975). Ammonium oxidation and nitrite oxidation were presumed to be closely coupled as there was not a build up of the intermediary product nitrite (D'Elia and Wiebe, 1990). Coral reef sediments in Puerto Rico showed nitrification rates that were highest in the upper few centimeters of sediment, with a second peak at $\sim$20 cm (Corredor and Capone, 1985). Nitrifying bacteria have also been identified as sponge symbionts on reefs in the Caribbean (Corredor *et al.*, 1988). Later studies investigating the relationship between four sponge species including the Caribbean coral reef species *Chondrilla nucla* found that highest rates of nitrate release were associated with sponges that had cyanobacterial endosymbionts (Diaz and Ward, 1997) suggesting that sponge-mediated nitrification may be very common in tropical benthic communities and may constitute a large input of oxidized nitrogen in these systems (see Chapter 27, Foster and O'Mullin, this volume). However, further research is needed to elucidate the details of these pathways.

Recently research has revealed that nitrification is not exclusively associated with chemoautotrophic bacteria of the β and γ proteobacteria, but occurs in many Crenarcheaota as well (Francis *et al.*, 2005; Konneke *et al.*, 2005; Wuchter *et al.*, 2006) who may in fact may dominate this process in seawater (Wuchter *et al.*, 2006) (see Chapter 5 by Ward, this volume). The extent that archael nitrification occurs in coral reef habitats remains to be determined. Ammonium oxidation has also been shown to occur anoxically in some marine sediments at the expense of NO_2^- (Thamdrup and Dalsgaard, 2002) (see Chapter 6, Devol, this volume).

This process is termed ''Anammox'' for ''anaerobic ammonium oxidation'' and is catalyzed by a specialized group of planctomycetes bacteria first discovered in sewage reactors (Strous and Jetten, 2004). Again, the importance of Anammox in coral reef environments has not yet been considered.

2.3. Dissimilatory nitrate reduction and denitrification

There are two pathways of dissimilatory nitrate reduction, generally thought to be mediated by anaerobic, or facultatively anaerobic bacteria, using NO_3^- as a terminal electron acceptor in respiration (Fig. 21.1D and F) (see Chapter 6, Devol, this volume). One pathway leads to production of ammonium, and may act as an internal cycling loop within the system (D'Elia and Wiebe, 1990). The other pathway, denitrification, ends in production of N_2O and/or N_2 gas, which can then be lost from the system to the atmosphere.

Denitrification was originally dismissed as an important process on reefs as it was thought that anaerobic processes were unlikely to occur in a seemingly aerobic environment and, additionally, high amounts of nitrate export had been observed (D'Elia and Wiebe, 1990; Wiebe, 1976). However, denitrification does indeed occur within these systems and has been measured in a number of reef environments with highly variable rates obtained (Capone et al., 1992; Corredor and Capone, 1985; Johnstone et al., 1990; Koop et al., 2001; O'Neil and Capone, 1996; Seitzinger and D'Elia, 1985; Smith, 1984; Williams et al., 1985). This may be related to differences in substrate availability as well as differences in sediment organic and nutrient content (Koop et al., 2001; O'Neil and Capone, 1996). Thus, the quantitative importance of dentrification within reef sediments and the reef matrix after the deposition of particulate organic matter remains a large unknown (Furnas, 2003).

Additionally, the anammox reaction mentioned earlier results in the reduction of NO_2^- with the production of N_2 gas. Recent direct tracer evidence from both marine sediments (Thamdrup and Dalsgaard, 2002) (see Chapter 6, Devol, this volume) and several anoxic water column systems (Hamersley et al., 2007; Kuypers et al., 2005) has shown that the anammox pathway, rather than conventional denitrification, can be a significant and, at times, predominant source of N_2 production. Future studies of combined N loss from reefal environments should also consider this pathway.

2.4. Nitrogen acquisition and uptake

Uptake of combined N by organisms for growth is an aspect of the nitrogen cycle that has been relatively well studied for the coral/algal symbiosis (D'Elia and Webb, 1977; Webb and Wiebe, 1978; Blythell, 1990a,b). Other organisms in the reef environment, including macroalgae, benthic microalgae and phytoplankton as well as many heterotrophic prokaryotes have the capacity to take up combined nitrogen.

Oxidized forms of nitrogen such as nitrate, need to first be reduced to ammonium before their incorporation into biomass. Nitrate is first reduced by the enzyme assimilatory nitrate reductase to nitrite. Assimilatory nitrite reduction subsequently reduces the nitrite to ammonium (D'Elia and Webb, 1977) (Fig. 21.1E) (see Chapter 7, Mulholland and Lomas, this volume).

In most marine ecosystems primary productivity is concentrated in water column phytoplankton, but the bulk of coral reef productivity occurs in the benthos and can be attributed to coral zooxanthellae, turf algae and benthic micro and macroalgae (Larkum, 1983; Taylor, 1983a,b). Benthic microalgae (also called microphytobenthos, Macintyre et al., 1996) are a diverse assemblage of diatoms, dinoflagellates, and cyanobacteria which are poorly understood with regard to the influence of their productivity and abundance to nutrient dynamics relative to other nutrient processes on coral reefs (Heil et al., 2004). Benthic microalgae are ubiquitous and abundant in the clear well lit environments of many coral reefs, and can have chlorophyll values $100\times$ that of the integrated water column above them. Areal rates of photosynthesis by these turfs rival terrestrial systems and imply substantial N demand (Heil et al., 2004; Werner et al., 2008).

Benthic microalgae in and on reef sediments may derive some of their nutrients from the sediments as appreciable ammonium levels have been reported (Capone et al., 1992; Heil et al., 2004; Johnstone et al., 1990). Increases in benthic microalgae with nutrient enrichment suggest that these populations can also access nutrients in the water column, which result from regenerative processes within the water column. Benthic microalgae are also net O_2 producers which may influence nutrient dynamics, particularly nitrification and denitrification by changing redox profiles as well as the nutrient exchange across the sediment water interface.

2.5. Invertebrate/symbioses

Perhaps the most significant evolutionary adaptations for sustained high productivity in oligotrophic seas are the symbiotic relationships that lead to efficient retention and recycling of nutrients in these systems (Hoegh-Guldberg, 1999; Miller and Yellowlees, 1989). The multitude of algal–invertebrate symbioses that have evolved in reef environments to efficiently recycle nutrients is a testament to this strategy (Muscatine and Porter, 1977). Nitrogen transformations are the centerpieces of these associations (Taylor, 1983a) with the symbiotic dinoflagellates (zooxanthellae) providing C for translocation from photosynthesis to coral animal host, and the transfer of N from animal waste to the symbiotic algae (Taylor, 1983b; Wilkerson and Trench, 1986) (Fig. 21.2). Other, diverse but less well characterized symbioses occur in coral reef environments including microbes associated with sponges (e.g., Garson et al., 1998; Mohamed and Hill, 2006; Thacker, 2005; Wilkerson and Fay, 1979; see also Chapter 27, Foster and O'Mullin this volume), giant clams (e.g., Ambariyanto and Hoegh-Guldberg, 1999; Fitt et al., 1995; Summons et al., 1986; Wilkerson and Trench, 1986), anemones (e.g., Cook et al., 1988, 1992; Wang and Douglas, 1997); scyphozoan jellyfish (e.g., Wilkerson and Kremer, 1992), and Ascidians as well as N transfer from endosymbiotic, diazotrophic cyanobacteria to symbiotic dinoflagellates within coral (Lesser, 2007). Aspects of each of these symbiotic associations revolve around interactions with nitrogen.

Animals in general are not able to take up inorganic nitrogen directly (Muscatine et al., 1979), and usually excrete reduced nitrogenous wastes into the surrounding water (Rahav et al., 1989). Algal–invertebrate symbioses of coral reefs are an exception to this
Figure 21.2 Nutrient availability changes the relationship between microalgal symbionts and coral hosts (adapted from Dubinsky and Stambler, 1996; Furnas, 2003). Under low nutrient conditions zooxanthellae translocate photosynthate to corals for growth, calcification and reproduction. Under higher nutrients, zooxanthellae increase in abundance and keep more of the photosynthate for themselves; translocating less to host coral for metabolic needs.

generalization (Cook *et al.*, 1987, 1988; Cook *et al.*, 1992; Miller and Yellowlees, 1989). In particular, the algal–anthozoan symbioses have been termed the ''physiological chimera between alga and animal'' (Furla *et al.*, 2005). Corals can take up both dissolved inorganic (e.g., Badgley *et al.*, 2006; Crossland and Barnes, 1977; Grover *et al.*, 2003a,b; Tanaka *et al.*, 2006) and organic nitrogen (e.g., Hoegh-Guldberg and Williamson, 1999; Grover *et al.*, 2006), as well as ingesting particulate nitrogen (e.g., Anthony, 2000; Lawn and McFarlane, 1991; Mills *et al.*, 2004; Ribes *et al.*, 2003).

The amount of nitrogen available to corals is a function of both particulate host feeding as well as inorganic N uptake which can be effected by nutritional history (Piniak and Lipshultz, 2004). Corals and other sessile organisms can acquire necessary nutrients by harvesting zooplankton, microbes and detritus from the water column directly (Erez, 1990; Lawn and McFarlane, 1991; Porter, 1974, 1978) through mucus-netting strategies, or indirectly by capture of protozoa that graze on bacteria. These trapping processes are so efficient it has been termed ''the wall of mouths'' (Yonge, 1930) and are one of the matrix of factors that permit coral reefs to support high biomass concentrations in oligotrophic waters. Corals can gain up to 70% of their nitrogen budget from particulate sources and microbes which account for 30–45% of the incorporated particulate matter (Bak *et al.*, 1998).

A second pathway is by the uptake up dissolved inorganic nitrogen (DIN) by the symbiont. The inorganic nitrogen may itself derive from recycling of animal wastes which are then retained by the symbionts in exchange for photosynthate released back to the host (Muscatine *et al.*, 1989; Piniak and Lipschultz, 2004; Wang and

Douglas, 1998, see below). Alternatively, the symbiont may obtain inorganic nitrogen either in reduced (e.g., ammonium) or oxidized forms (e.g., nitrate) directly from seawater (Bythell, 1990a,b; Ferrier-Pages *et al.*, 2001; Marubini and Davies, 1996; Wilkerson and Trench, 1986). The latter is often a light dependent process (Grover *et al.*, 2003a,b). It has further been demonstrated that both intact corals (D'Elia and Web, 1977), as well as isolated zooxanthellae, can take up both nitrate and ammonium (Bythell, 1988; Grover *et al.*, 2003a,b). This net uptake can account for approximately 30% of the daily nitrogen requirement for tissue growth, gamete production and DON production (Bythell, 1988, 1990a,b).

Summons and Osmond (1981) first demonstrated light dependent uptake of ^{15}N labeled nitrate, ammonium and urea by zooxanthellae which they attributed to the glutamine synthetase–glutamate synthase (GS-GOGAT) pathway. Anderson and Burris (1987) directly confirmed GS activity in symbionts isolated from corals and in pure culture (see also Miller and Yellowlees, 1989). In contrast, in giant clams Yellowlees *et al.* (1994) reported ammonium assimilation in zooxanthellae was catalyzed by the glutamate dehydrogenase enzyme (GDH). Exactly how this mechanism works has not been fully elucidated as both the symbionts and host appear to contain the enzyme GDH (Wilkerson and Muscatine, 1984; Yellowlees *et al.*, 1994). The model proposed by D'Elia *et al.* (1983) suggested a "depletion-diffusion" model for ammonium uptake, where the symbiont takes up ammonium at a rate that depletes the concentration in the tissue and allows for diffusion of nutrient through the animal tissues. In sea anemones with zooxanthellae there is evidence of uptake and translocation of ammonium derived nitrogen using ^{15}N tracers (Lipschultz and Cook, 2002).

The symbiotic dinoflagellates (zooxanthellae) are responsible for the uptake of the inorganic nitrogen, subsequently synthesizing organic compounds that are translocated to the host (Wang and Douglas, 1999). Whereas early workers focused on the release of glycerol by the dinoflagellate symbionts, Muscatine first showed that alanine was also an important metabolite (Muscatine, 1980). The symbionts thus allow coral systems to retain and incorporate inorganic nitrogen at micromolar, and down to nanomolar, concentrations (Muscatine and D'Elia, 1978; Grover *et al.*, 2002). Translocation of the amino acid aspartate from symbiotic dinoflagellates to their anemone hosts can occur (Swanson and Hoegh-Guldberg, 1998). Other studies have revealed the incorporation of aspartate into proteins that are deposited rapidly as skeletal organic matrix (Allemand *et al.*, 1998). This may be indicative of pathways of protein synthesis that are unique for the skeletal matrix and different from the general coral protein metabolism, or due to endolithic algal communities within the coral skeleton (Hoegh-Guldberg, 2004a,b).

Experiments with nitrogen additions have given some insight into the role of nitrogen in the algal-coral symbiosis relationship. Additions of ammonium and ammonium + phosphate increased zooxanthellae density, their protein synthesis rates (Muscatine *et al.*, 1989), as well as the amount of chlorophyll and nitrogen per symbiont (Snidvongs and Kinzie, 1994). More recently, Tanaka *et al.* (2006) demonstrated that 50% of $^{15}NO_3{}^-$ and ^{13}C delivered to the coral *Acropora pulchra* was taken up and appear in the host in organic forms demonstrating translocation from the zooxanthellae. The C:N ratio of the translocated organic matter appeared to change

based on the N availability for the zooxanthellae. The incorporated organic ^{15}N seems to be recycled within the coral-algal symbiotic system, with high C:N compound such as lipids and carbohydrates being more rapidly utilized than lower C:N compounds such as proteins and nucleic acids (Tanaka et al., 2006).

Yet other pathways of nitrogen acquisition may exist. Symbionts are able to take up dissolved free amino acids (DFAA) (Ferrier, 1991; Hoegh-Guldberg and Williamson, 1999). In the coral Pocillopora damicornis, DFAA uptake from seawater can account for ~11% of the nitrogen demands in the coral. Uptake of DFAA has also been shown by the giant clam Tridacna maxima (Ambariyanto and Hoegh-Guldberg, 1999). This may be an important episodic source of nitrogen for corals during times of local fish migrations and the activity of other grazers that result in algal cell breakage or exudation which increase DON concentration on the reef (Hoegh-Guldberg and Willamson, 1999). More recently, concentration dependent uptake of ^{15}N-urea was demonstrated in the coral Stylophora pistillata (Grover et al., 2006). Uptake kinetics suggested adaptation of the corals to low seawater concentrations of urea and, when compared to uptake rates of ambient ammonium and nitrate concentrations, urea was preferred to nitrate. Urea therefore may also be an important episodic source of nitrogen as well.

Zooxanthellae provide much of the coral's energy, transferring up to 95% of the symbiotic algae's photosynthate to the host (Fine and Loya, 2002; Muscatine, 1990). In the absence of zooxanthellae (e.g., in cases of coral bleaching and the loss of algal symbionts due to stress, Hoegh-Guldberg, 1999), translocation of photosynthetic carbon can also take place between algae living in the coral skeleton (endoltihic algae), and the coral host (Fine and Loya, 2002; Schlichter and Kerisch, 1995). Thus, endolithic organisms (e.g., bacteria, fungi and algae) living within the coral skeleton may also be potential nutrient sources (Fine and Loya, 2002; Le Campion-Alsumard et al., 1995; Kushmaro and Kramarsky-Winter, 2004). Ferrer and Szmant (1998) estimated that 55–60% of the nitrogen required by the coral can be satisfied by these sources. Recent work indicates that these symbiotic and mutualistic relationships are even more varied, complex and dynamic than previously thought (Fine and Loya, 2002; Furnas, 2003).

Reef sponges (Wilkinson and Fay, 1979) and some corals may acquire fixed nitrogen from associated diazotrophic cyanobacteria (Frias-Lopez et al., 2002; Lesser et al., 2004; Rohwer et al., 2001, 2002; Shashar et al., 1994a,b, see also Chapter 4, Capone and Carpenter, this volume). The nutritional significance of these alternative pathways remains to be fully evaluated.

2.6. Microbial populations

Recent research has shown the diversity and potential significance of microbial communities living in and on coral reefs (Kushmaro and Kramarsky-Winter, 2004; Rohwer et al., 2002) with an implicit role in nitrogen uptake, packaging and regeneration Bacterial productivity within cavities in the reef framework is higher than that in open water surrounding the reef (Scheffers et al., 2005) (see Chapter 8, Bronk and Steinberg, this volume), and the ecological role of bacteria living in coral mucus and skeletons is just now being elucidated. Cyanobacteria have

also been detected in the mucus layer of corals (Ritchie and Smith, 2004; Rohwer et al., 2001) and specialized bacteria may also protect the coral animal from opportunistic pathogens by having antibacterial or toxic properties. However, the role of the microbial populations of the coral surface mucopolysaccharide layer (SML) in terms of nitrogen dynamics has not yet been fully studied. One might hypothesize possible roles involving N immobilization, regeneration, nitrification and nitrogen fixation, amongst others.

Microbial populations in reef ecosystems may serve directly as nutrient sources for higher organisms. They are known to have a low C:N ratio in general and the use of the SML bacterial community in particular as a food source has been demonstrated (Ritchie and Smith, 2004; Sorokin, 1973). With respect to nutrient acquisition, microbes are effective in sequestering nutrients due to their high affinity transport systems and large surface to volume ratios. In nutrient poor waters, prokaryotes scavenge nutrients at much lower concentrations than eukaryotes, and assimilate most of the limiting nutrients thereby restricting primary productivity (Kirchman, 2000; Rohwer and Kelly, 2004). Coral-associated microbes may also be in direct competition with their host for water column nutrients (Rohwer et al., 2002). Given the ability of prokaryotes for nutrient uptake, corals may use microbes to ''fish'' for nutrients i.e. cultivation gardening for certain beneficial microbes by excreting organic matter in the form of mucus (Ducklow, 1990; Saffo, 1992).

Microbes may in some cases also act as pathogens causing harm to corals. Recent work has shown that reefs that are more eutrophied, often have denser stands of macro- and micro-algae (see below). The algae produces carbon substrates, which in turn then enhance the proliferation of bacteria on live coral surfaces which can cause the corals to die, enabling more substrate for algal growth (Smith et al., 2006).

2.7. Ammonification and regeneration

Given the high gross productivity of reefs, the majority of this production must be supported by the retention and internal recycling of nitrogen (Szmant-Froelich, 1983 Fig. 21.3). The pathway of ammonium production from organic matter is often referred to as ammonification (Fig. 21.1B). Ammonium is released through grazing processes in which fish, echinoderms, zooplankton, filter feeders (including sponges) as well as detritivores (such as worms), and bacteria recycle organic nitrogen and excrete it (D'Elia and Wiebe, 1990; D'Elia, 1988; Szmant-Froelich, 1983). Coral reef fish have excretory products very high in nitrogen (N:P = 48), with ammonium as the most important source of DIN and excretory products that are enriched in P (N:P = 8). Coral growth is higher in the presence of reef fish, particularly resting fish such as grunts, which forage and then return to the reef to rest in large aggregations (Meyer and Schultz, 1985).

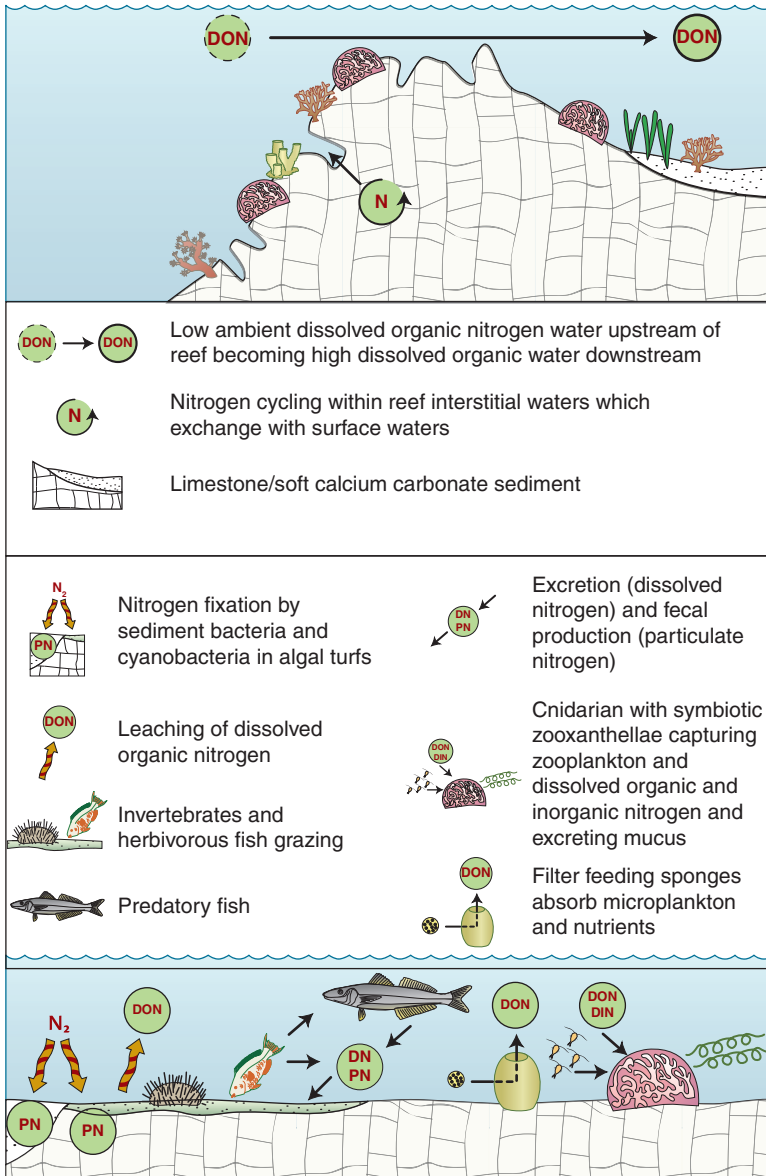
Regeneration of organic nitrogen may occur in various components of the reef including within the diverse symbiotic associations (see Section 2.5). In addition to the surrounding sediments (DiSalvo, 1969; Entsch et al., 1983; Rasheed et al., 2002), structures on the reef proper may be important sources of regeneration of nutrients, including ''porewater'' within the coral skeletons themselves (Risk and


Figure 21.3 Generalized nutrient pathways and means of trophic cycling and regeneration on reefs (adapted from Szmant-Froelich, 1983); showing the importance of nitrogen cycling and regeneration within the interstices of the coral structure and from grazers.

Muller, 1983). All these loci serve important ''biocatalytic'' function in terms of regeneration of organic matter and release of nutrients to the coral reef (Rasheed *et al.*, 2002). Up to 70% of reef volume can be attributed to the myriad of nooks and crannies that trap sediments, fecal pellet and decaying organic matter (Ginsburg, 1983; Szmant-Froelich, 1983; Szmant, 2002). Regenerated inorganic species can

then percolate through the porous structures. Elevated nutrients have indeed been measured in reef cavities and interstices (DiSalvo, 1971; Andrews and Muller, 1983; Szmant-Froehlich, 1983, 2002), which can be introduced to the reef through "burps" (Szmant-Froelich, 1983) of nutrient-enriched water through holes and fissures that provide reef organisms with pulses of nutrients (Fig. 21.3). Cavities within the reef structure are areas of high bacterial activity and hence nutrient regeneration (Scheffers *et al.*, 2004, 2005). In a study in Curacao, open water bacterial productivity was limited by both N and P, whereas reef crevice bacteria were only limited by P (Scheffers *et al.*, 2005). N limitation appears to be circumvented in these interstices through remineralization processes which can, in turn, increase inorganic N concentrations in the overlying reef waters through exchange with the ambient water (Scheffers *et al.*, 2005).

Rasheed *et al.* (2002) determined that nutrient concentrations in these regenerative spaces within the reef framework were 1–3 times higher than surrounding water column values, corresponding to fluxes of 14.5 mmol m^{-2} day^{-1} for ammonium; 7.7 mmol m^{-2} day^{-1} for nitrate and 0.9 mmol m^{-2} day^{-1} for nitrite. Nutrients within the sediments were 15–80 times higher than the water column values, corresponding to a diffusive flux of 0.06 mmol m^{-2} day^{-1} for ammonium; 0.03 mmol m^{-2} day^{-1}; for nitrate and 0.01 mmol m^{-2} day^{-1} for nitrite; underscoring the importance of these sites in trapping organic matter and regenerating nutrients (Rasheed *et al.*, 2002).

Recycling of nutrients between coral hosts and symbiotic dinoflagellates (zooxanthellae) is a key reef process (see Section II above). Zooxanthellae take up the ammonium excreted by the coral animal, therefore this waste N is not released to the wider system (Muscatine and D'Elia, 1978; Wilkerson and Trench, 1986). Recycling of N by the coral host could satisfy all the nitrogen needs of the symbiotic algae (Crossland and Barnes, 1974, 1977).

Transfer of ammonium and other nitrogenous waste may aid in the process of coral calcification. Enhanced calcification was noted in experiments when ammonium and urea were added to corals (Crossland and Barnes, 1974). The authors suggested that excretory ammonia may combine with protons released when bicarbonate is converted to carbonate. Their model suggested that at the site of calcification, the hydrolysis of urea formed by the breakdown of allantoins yields CO_2 and NH_3. The CO_2 could provide a carbonate source for calcification and the NH_3 would then neutralize and remove protons from the calcifying milieu. However, Taylor (1983a,b) re-analyzing their study suggested it was more reasonable to attribute the enhancement of calcification by ammonium and urea to the stimulation of symbiont photosynthesis. Kinsey and Davies (1979) showed a decrease in coral calcification with the addition of nitrogen and phosphorus, but suggested this was more probably attributable to P effects rather than N (see Elevated Nutrients on Coral Reefs Experiment (ENCORE) case study below).

Much of the regenerated nitrogen on the reef ultimately is derived from nitrogen introduced to the system through grazing. Grazer interactions also help recycle nutrients with fish and invertebrates grazing benthic microalgae. Benthic microalgae can act as a nutrient trap for regenerated nutrients including N, and have been

shown to increase with increasing levels of ammonium (Uthicke, 2001; Uthicke and Klumpp, 1997). Benthic microalgae have been observed to increase in the presence of holothurian grazers (Uthicke, 2001), due to ammonium release. This constitutes an important component of a benthic retention mechanism akin to the pelagic microbial loop (Uthicke, 2001).

Recently there has been a growing awareness of the importance of coral mucus to the overall productivity and retention of nutrients in the reef system (Wild *et al.*, 2004a). Up to 50% of the carbon assimilated by zooxanthellae may be exuded as mucus, which protects the coral colony against fouling, dessication and sedimentation. A previously unrecognized aspect of mucus within these systems is that it efficiently traps organic particulate matter from the water column, including bacteria known to fix both N and C thereby increasing the nutritional quality in coral associated communities. In a study in Australia, Wild *et al.* (2004a) found that coral mucus could increase both its N and C content up to 3 orders of magnitude in 2 h. Bacteria are much better than corals at assimilating nutrients at low concentrations (Knowlton and Rower, 2003) and coral associated bacteria may scavenge limiting nutrients, including iron and vitamins, which are then harvested by the corals themselves. This is supported by the observation that some corals eat their own mucus (Coles and Strathmann, 1973). These enriched mucus-particle aggregates subsequently provided 10–20% of the total organic carbon supply to the sediments, maintaining nutrients for heterotrophs and remineralization processes within the coral reef system (Wild *et al.*, 2004a). Coral mucus and organic flux from mass spawning events back to the benthos from the overlying water column may affect sediment biogeochemistry in reef environments by enhancing the organic content of sediments and affecting microbial processes and nutrient processing (Wild *et al.*, 2004a,b,c; 2005, 2008).

3. NITROGEN PERTURBATIONS TO REEFS

The rapid decline in coral reefs over the last few decades clearly has resulted from multiple stressors from various sources including exposure to excess nitrogen which can have direct effects on corals and their symbionts (Stambler *et al.,* 1991; Dubinsky and Stambler, 1996; Furnas, 2003; Mora, 2008) (Fig. 21.2). Nutrients can have direct physiological effects on corals by reducing growth or reproduction rates. Nutrients can affect corals indirectly by: increasing susceptibility to bleaching and disease, affecting the coral-zooxanthellae symbiosis (Bruno *et al.*, 2003), or by causing phase shifts in community structure (Knowlton, 2001; Szmant, 2002). Food webs in coral reef systems can become highly altered with the removal of predators providing ''top–down'' control and increases in nutrients providing ''bottom up'' control. (Hughes *et al.*, 1999, 2007; Lapointe, 1997, 1999, 2004a,b; Szmant, 2002). With increased nutrients, coral reefs change from symbiosis-dominated systems with tight recycling of nutrients to regions with a higher proportion of macroalgae, with subsequent succession to heterotrophic filter feeders (Fabricius, 2005).

Coral reefs are not stable, static communities living in benign environments, but rather are very dynamic ecosystems which are subject to frequent natural physical disturbance on times scales which vary from minutes to years (Furnas, 2003; Furnas

et al., 2005). Despite their inherent resilience, coral reefs are nonetheless threatened world wide, with an estimated 140,000 km^2 lost in the last few decades and more than half of the world's coral reefs listed at high or medium risk with more than 80% of the reefs in SE Asia under medium to high threat from activities such as over-development and over-exploitation (Brown, 1987; Bryant *et al.*, 1998; Dubinsky and Stambler, 1996; Hoegh-Guldberg, 1999, Hughes *et al.*, 2003). The resilience of the system becomes weaker with more accumulated impacts (McClanahan *et al.*, 2002).

Impacts of overfishing, global climate change and the increase in coral disease (including coral-bleaching) (Bellwood *et al.*, 2006; Hoegh-Guldberg, 1999; Hughes *et al.*, 1999, 2003, 2007; Jackson *et al.*, 2001; Pandolfi *et al.*, 2003; Smith and Buddenmeier, 1992; Wilkinson and Buddemeier, 1994; Mora, 2008) are emergent areas of interest in coral reef research. There has been much debate in the literature over which factors (e.g., nutrients, loss of grazers, terrestrial runoff and sedimentation; climate change etc.) are the most deleterious. These factors may have synergistic or antagonistic effects, which may vary in differing regions and reefs (e.g., Aronson *et al.*, 2003; Boesch *et al.*, 2001; Fabricius, 2005; Hughes *et al.*, 1999, 2003; Jackson *et al.*, 2001; Lapointe, 1997, 1999, 2004a,b; Pandolfi *et al.*, 2003; Szmant, 2001, 2002). These problems may be further exacerbated by increasing urbanization and other changing land usages which can subsequently result in amplified runoff of nutrients, fertilizers contaminants and increased sediment loading (Furnas, 2003; Hutchins *et al.*, 2005) resulting in general coastal eutrophication (Bell, 1992; Costa *et al.*, 2000; Fabricius, 2005; Furnas and Brodie, 1996; Koop *et al.*, 2001).

Threats to reefs can be either acute or chronic (Edinger *et al.*, 1998). Acute is here defined as ''dramatic damage in a short period of time,'' which includes destructive fishing practices, anchor damage, ship groundings, cyclones or hurricanes, or disease or predation (e.g., *Acanthaster* outbreaks) (Brodie *et al.*, 2005). Chronic threats alter the physical or biological environment on a long term basis, and cause long term damage to coral reefs. Nutrient inputs including sewage; increased sedimentation (particulate nutrients), resulting in nearshore eutrophication (Tomascik *et al.*, 1993) can manifest themselves in both modes. Chronic stresses may be more detrimental to the long term health of coral reef ecosystem than acute stresses (Kuntz *et al.*, 2005). Combinations of stressors are associated with threshold responses, as well as ''ecological surprises'' which can include disease and pathogen breakouts (Brodie *et al.*, 2005; Bruno *et al.*, 2003; Knowlton, 2001).

Whether reefs will have the resilience to recover from multiple anthropogenic stresses (Hughes and Connell, 1999) is a major issue of concern to scientists and resource managers. Recent studies have highlighted the serious decline in water quality in coastal environments, including coral reef areas (Fabricius, 2005; Hutchins *et al.*, 2005; Kuntz *et al.*, 2005; Wilkinson, 2002; Barile, 2004).

3.1. Inorganic nitrogen increases

3.1.1. Effects on coral colonies and life cycle

Elevated nutrients (ammonium, nitrate and phosphate) may derive from multiple sources (see above) and can directly affect both adult coral colonies as well as reproduction and recruitment of larvae in a number of ways (Fabricius, 2005).

Nutrient induced perturbations include changes in biochemical composition of the corals (Marubini and Atkinson, 1996; Stambler *et al.*, 1991), skeletal growth (both positive and negative) (Ferrier-Pages *et al.*, 2000), calcification (Marubini and Atkinson, 1999), reproductive potential (Tomascik, 1991), and density of algal symbionts (Dubinsky and Stambler, 1996) (Fig. 21.2). When corals are in low nutrient environments, zooxanthellae produce photosynthate in excess of their capacity to take up nutrients. This excess organic carbon is then available to the host for growth, calcification and reproduction (Fig. 21.2. left panel). Under high nutrient conditions the zooxanthellae preferentially keep the organic carbon for their own growth, increasing symbiont numbers, but decreasing the transfer to the coral host, which decreases the coral's calicification and reproduction (Furnas, 2003). The long term ecological implications of these often subtle changes in symbiont and host interactions and translocation of organic matter and energy away from coral growth and reproduction, have not been fully elucidated (Furnas, 2003). Direct effects of DIN on both corals reproduction and coral adults has recently been summarized by Fabricius *et al.* (2005, and references therein).

3.1.2. Algal increases and grazer decreases

One manifestation of excess nutrients, and specifically N, on reefs is algal overgrowth (Barile, 2004; Lapointe, 1997; McCook, 1999, 2001; Reaka-Kudla *et al.*, 1997; Scheffers *et al.*, 2005; Szmant 2002). Excess nitrogen may also enable, or act synergistically, with other stressors to increase and expedite, the spread of disease within coral communities (Rosenberg and Loya, 2004, refs therein; Kuntz *et al.*, 2005). The determination of factors that lead to algal overgrowth on reefs has been an important, and at times controversial issue, as to whether increased nutrients (including N), or loss of grazers has given rise to the problem. In a special issue in the journal *Coral Reef* on the topic, Szmant (2001) summarizes the problem: *"It is clear from the studies in this issue that several factors are conspiring to change the dynamics of coral reef algal communities from those we observed (but did not study very well) in the early and middle decades of the past century, to those present now. These factors appear to differ in degree among localities."*

In the same special issue, McCook *et al.* (2001) provide an extensive review of coral—algal interactions which may be characterized as positive, neutral or negative. Positive effects include symbiotic algal–coral interactions; neutral interactions include situations where grazing and algal growth are balanced and negative effects of algae on corals which include both direct or indirect influences. Direct negative effects often involve competition or the direct overgrowth and/or invasion of coral by algae. An example of this is the algae *Coralliophila hurysmansii* which causes tissue swelling on the coral. Indirect effects include interactions such as those with the algae *Antrichium tenue* which has a mucus layer that traps sediments (and possibly microbes). This layer increases microbial processes which help turn the algal–coral interactions from a neutral relationship to a negative one, thereby taking on the characteristics of disease, with increased nutrients as the trigger (Willis *et al.*, 2004). Some other indirect affects include reduction in physical space for coral growth and recruitment of coral larvae due to algal coverage, and allelopathic activity (Kuffner and Paul, 2004; McCook *et al.*, 2001). Recent research suggests that overgrowth of algae can cause mortality of corals from enhanced microbial activity on coral

surfaces. This may in turn be a result of algal exudates, which then allows more free surface area for algal growth (Smith *et al.*, 2006). Other evidence indicates that algal exudates can also suppress fecundity, recruitment and survival (Hughes *et al.*, 2007).

Nutrient stimulation of algal growth may often only be visible in the absence of grazers (Hughes, 1994; Furnas, 2003). Concomitant with nutrient increase, reefs are experiencing a major reduction in grazers that help keep the system in balance (Hughes, 1994; Jackson *et al.*, 2001; Pandolfi *et al.*, 2003). In some instances this may promote a phase shift from corals to macroalgae, and a resultant loss of resilience in recovery to other perturbations such as storms and climate change and diseases (Bellwood *et al.*, 2004). For instance, Caribbean reef decline was preceded by a dwindling of fish stocks, along with simultaneous increases in nutrients and sediment runoff from the land (Hughes, 1994; Jackson *et al.*, 2001). Similarly, on the GBR, inputs of sediment and nutrients have increased by four times that of pre-European settlement (McCulloch *et al.*, 2003; Williams, 2002) and macro grazer populations of sea–turtles and dugong have decreased dramatically along with larger predator fish populations (Bellwood *et al.*, 2004). Additionally, some effects of nutrients and disease may be exacerbated by sea surface warming which can also lead to coral bleaching. What effect this will have on long term coral reef health is presently unknown (Buddemeier and Fauntin, 1993; Koop *et al.*, 2001; Smith and Buddenmeier, 1992; Szmant, 2002).

3.1.3. Effects of runoff and sedimentation

Although coral reef environments are generally characterized as low nutrient environments, there are some areas in which intermittent sources of nutrients are added by seasonal runoff reaching reef environments (Furnas, 2003; Gabric and Bell, 1993; Kinsey, 1991; Marsh, 1977). In the GBR region for instance, coastal river inputs of sediments and nutrients has increased fourfold over the last ∼150 years (Brodie *et al.*, 2003) and the dissolved nitrogen fraction of this runoff is widely dispersed in the GBR system (Devlin and Brodie, 2005). Land development including increases in impervious surfaces as well as processes that lead to increased erosion such as agricultural grazing can amplify runoff of sediments during rain events such as observed on Molokai, a high relief, heavily ranched portion of Hawaii that is an area of local concern and study currently (Chaston, 2006).

Terrestrial runoff is a major concern for areas with coral reefs. Nutrient enrichment, sedimentation, and turbidity can all degrade reefs at local scales (Fabricius, 2005). While there are some coastal coral reefs that can flourish in relatively high nutrient and high levels of particulate matter, they tend to be restricted in depth to ∼10 m; whereas in clearer offshore reefal systems they may extend to >40 m (Fabricius, 2005). Some corals can use the particulate matter for nutrition. However, there is a fine line, between increased nutrient availability for the coral for ingestion and the tipping point at which the corals are unable to cope with sedimentation and silting affects. (Anthony, 2000; Anthony and Fabricius, 2000; Fabricius and Wolanski, 2000; Mills and Sebens, 2004; Mills *et al.*, 2004).

Other anthropogenic, terrestrial sources of nitrogen to reefs include groundwater (D'Elia *et al.*, 1981; Littler *et al.*, 2006), and sewage (Hanson and Gundersen, 1976; Lapointe *et al.*, 2005a,b; Risk and Erdmann, 2000; Szmant Froelich, 2002). Since

1960, the use of nitrogen fertilizer globally on an annual basis has increased by a factor of six (Fabricius, 2005; Matson *et al.*, 1997). Fertilizer loss off the land is a major source of anthropogenic nutrients to coral reefs in many regions (Mitchell *et al.*, 2005). In some areas, roosting seabirds can be a major episodic contributor of guano and nitrogen input (Albert *et al.*, 2005; Furnas *et al.*, 2005; Smith and Johnson, 1995). Some of the effects of terrestrial runoff including sediment and nutrient enrichment on coral reefs have recently been summarized by Fabricius (2005).

Gradients of reef health, community structure, biodiversity, and ecological function in near-shore coral reef systems are often associated with environmental gradients influenced by terrestrial runoff (Fabricius, 2005; Fabricius and De'ath, 2004, Fabricius *et al.*, 2005). However, the exact cause of runoff related effects are controversial (e.g., nutrients vs. sediments vs. toxicants vs. fresh-water input) (Szmant, 2002).

Although coral growth itself may be positive in polluted reefs, increased nutrients can cause net reef erosion. Therefore the paradoxical combination of normal coral growth and net reef erosion needs to both be taken into consideration for any whole reef perspective approach to coral reef health (Edinger *et al.*, 2000).

In terms of nitrogen inputs, the effects of terrestrial run-off to marine systems may be better understood in a biogeochemical context and the gradients in microbial processing of nutrients (Alongi and McKinnon, 2005). For instance, denitrification in the coastal zone may help reduce the amount of N that is transported to offshore reefs (Seitzinger, 1988) and coastal habitats such as mangrove and intertidal zones may provide significant protection buffers for offshore coral reefs by trapping, transforming and storing sediments and organic matter. While intact coastlines may be able to mitigate some of the runoff effects, these vital areas are under increasing development pressure worldwide with large scale clearing of mangrove and coastal vegetation as well as the steady increase in impervious surfaces. These synergistic effects may therefore increase the effective load of nutrients reaching coral reef environments (Furnas *et al.*, 2005).

3.1.4. Sewage

Sewage pollution remains a concern in many coral reef regions, particularly in developing nations, and is widely considered as one of the major causes of the demise of coral reef health (Smith *et al.,* 1981; Brown and Howard, 1985; Edinger *et al.*, 1998, Furnas *et al.*, 2005; Ginsburg and Glynn, 1994; Hatcher and Frith, 1985; Johannes, 1975; Wilkinson, 1993). It is not only a concern from an environmental health perspective but for human health as well (Colwell, 2004).

Documented effects of sewage impacts on reefs include increased particulate and sediment load resulting in smothering of corals, lower photosynthetic rate by corals, increased bioerosion, hypoxia, algal overgrowth (see above) as well as changes in community structure and shifts towards filter-feeding heterotrophic organisms (Risk and Erdmann, 2000). In Indonesia, Edinger *et al.* (1998) found that reefs subjected to land based pollution (sewage, sedimentation and or industrial pollution) had a reduction in diversity of 30–50% at 3 m and a 40–60% reduction of diversity at 10 m, relative to unpolluted reefs.

Wastewater nutrients and animal wastes are generally enriched in ^{15}N, the heavy stable isotope of nitrogen (Sammarco *et al.,* 1999; Heikoop *et al.*, 2000).

^{15}N-signatures have been used as a tracer of fertilizer input to corals reefs in Bali (Marion *et al.*, 2005). New methods of tracking sewage plumes through using ^{15}N/^{14}N or δ^{15}N-signatures in bioindicator organisms such as stomatopods, macro-algae, mangroves, and corals (Heikoop *et al.*, 2001; Risk and Erdmann, 2000; Risk and Heikoop, 1997; Mendes *et al.*, 1997) have recently been implemented in some reef areas thereby providing a measure of integrated water quality over longer time scales rather than the snapshot of water quality obtained with discrete chemical measurements of nutrients (Costanzo *et al.*, 2001, 2005; Hoegh-Guldberg *et al.*, 2004; Muscatine *et al.*, 2005; Udy *et al.*, 2005). For instance, coral tissue δ^{15}N from *Porites lobata* was significantly higher in sewage affected reefs than reference sites in 70% of impacted reef sites in Indonesia (Heikoop *et al.*, 2001). Excess nitrogen can lead to increased zooxanthellae density and ultimately decreases in translocation of carbon and nitrogen to the coral host as the coral loses control of the symbiotic relationship, with the symbionts increasing in number and holding onto their photosynthate for their own growth (Fig. 21.2) (Heikoop *et al.*, 2001); this suggests that sewage derived nitrogen can disrupt normal coral–zooxanthellae physiology.

One very clear cut case where nutrient input, and in particular nitrogen, has had a serious and demonstrable deleterious effect on coral reefs is Kaneohe Bay, Hawaii (Smith *et al.*, 1981; Hanson and Gundersen, 1976; Szmant, 2002). A sewage outfall caused a major growth of the green "bubble" algae *Valonia* which overgrew the corals which then died. The sewage outfall was moved and some improvement in the system was seen. However the fragile balance had been disrupted, and the sediments contained a long memory of nutrients. Subsequently non-point sources became a problem at Kaneohe Bay as well and it is still not back to its original condition. This is partly due to organic matter accumulation, which is being observed in many reef systems (D'Elia and Wiebe, 1990; Furnas, 2003) as inputs of nutrients, particularly N, are exceeding losses. The impaired system of Kanehoe Bay was further damaged, due to loss of herbivores, and the introduction of the invasive algae *Dictyoshpaeria cavernosa* (Stimson *et al.*, 2001).

Increased nitrogen can also increase phytoplankton in the water column as well as macroalgal abundance, particularly in areas where over-fishing has occurred (Hughes *et al.*, 2003; McCook, 2001; McCook *et al.*, 2001; Szmant, 2002). The increase in BBD also appears to be increasing in prevalence which may also be associated with elevated nutrients input and or sewage outflows (Antonius, 1988; Bruckner *et al.*, 1997; Taylor, 1983a,b). Kuta and Richardson (2002) found a positive relationship between elevated nitrite and BBD incidence, but no positive correlation with nitrate, ammonium, or phosphate. BBD is, however, routinely observed on pristine reefs far from acute nutrient perturbations. Therefore, the exact relationship between BBD and water quality remains unknown.

3.2. Sea surface warming, coral disease and nitrogen dynamics

Global climate change is a major threat to coral reefs (Phinney *et al.*, 2006 and references therein), with reefs already exhibiting climate warming effects in terms of coral bleaching due to zooxanthellae expulsion (Brown, 1997; Hughes *et al.*, 2003). Thermal sensitivity of reef-building corals may prove to be the "Achilles

heel'' in terms of reef ecosystem resilience (Graham *et al.*, 2006). Climate change may further exacerbate population phase shifts in degraded reefs with bleaching coral mortality providing more space for macroalgae, and filamentous cyanobacteria and less space for coral recruitment to help recovery on over-fished and/or eutrophied reefs (Hughes *et al.*, 2007; Kuffner and Paul, 2004).

What direct effects climate change will have on various aspects of nitrogen cycling on reefs including coral bleaching events and zooxanthellae expulsion, remains to be seen. The subsequent consequences for nitrogen conservation and nitrogen acquisition of the corals and other symbioses, on the reef will undoubtedly be affected as the balance between symbionts and host interaction is very sensitive to environmental conditions (Knowlton, 2001).

Rising average sea surface temperatures resulting from global climate change may increase the amount of nitrogen fixed globally (Karl *et al.*, 2002) and in reef environments specifically (Paul *et al.*, 2005) due to both increased physiological rates of nitrogen fixation as well as increasing cyanobacterial populations (Paerl and Husiman, 2008). Recent research has also demonstrated an increased rate of nitrogen fixation on coral skeletons that have been subjected to bleaching events, which in turn may increase the availability of nitrogen in these systems for an extended period beyond the initial bleaching event. The scale of these events are predicted to become more prevalent, this may increase suitable substrate for diazotrophy as a result of climate change (Davey *et al.*, 2008). Similarly, increases in macroalgal populations (Lapointe *et al.*, 2005a,b; McCook *et al.*, 2001) may also increase the surface area available for both diazotrophic heterotrophic bacteria and cyanobacteria.

Warming conditions could also lead to the increase in the prevalence of harmful cyanobacterial assemblages such as the toxin producing genus *Lyngbya* (e.g., Albert *et al.*, 2005; Paul *et al.*, 2005), as well as species that have been linked with BBD in corals including *Phormidium* and others (e.g., *Oscillatoria submembranaceae; Beggiatoa; Desulfovibrio; Phormidium corallyticum*) (Rosenberg and Loya, 2004 and references therein). The prevalence of BBD in the Caribbean increases during the warmest months of the year when temperatures are above 30°C (Richardson, 2004).

4. Elevated Nutrients on Coral Reefs Experiment (ENCORE)

A replicated *in situ* fertilization experiment was conducted on the GBR at One Tree Reef Lagoon, Australia during 1993–1996 (Larkum and Koop, 1997). This experiment (ENCORE) was specifically designed to address nutrient effects *in situ* based on previous smaller scale fertilization studies in micro-atolls in One Tree Island lagoon (Kinsey and Davies, 1979; Kinsey and Domm, 1974). Laboratory results, and small scale mesocosm experiments had, to that point, indicated that nutrients additions could perturb the natural physiology of corals and some other invertebrate reef organisms (Belda *et al.*, 1993; Ferrier-Pages *et al.*, 1998; Hoegh-Guldberg and Smith, 1989; Jokiel *et al.*, 1994; Muller-Parker *et al.*, 1994; Muscatine *et al.*, 1989), but evidence directly from the field and simultaneous assessment of

different reef organisms and processes were largely lacking (Hoegh-Guldberg, 2004a,b; Koop *et al.*, 2001).

While increasing nutrient loads were perceived as deleterious, what the precise responses that different reef organisms would have was unknown. Therefore, part of the aim of the ENCORE study was to identify organisms or community response factors which could be used as indicators of ecosystem degradation (Steven and Larkum, 1993). Twelve micro-atolls, or patch reefs were fertilized with N (ammonium chloride), P (sodium phosphate) and N + P over the course of 3 years. Dosing with nutrients occurred to the internal ''lagoons'' of each micro-atoll during the ∼4–5 h of each low tide when they were physically isolated from the larger lagoon. During the first ∼ year of the experiment the atolls were dosed at N levels that were approximately 2 times ambient (average ∼0.7–11 μM). During the second year the dosage was increased to approximately 6 times ambient (∼0.7–36 μM) (Steven and Atkinson, 2003).

The results of these experiments are summarized in Fig. 21.4. Overall the parameters that were most responsive to nutrient enrichment were coral fertilization, benthic microbial processes, stomatopod recruitment and symbiont numbers (Koop *et al.*, 2001). In terms of direct effects to nitrogen cycling, nitrogen fixation increased in P fertilized plots and decreased in the N treatments, whereas denitrification increased in the N and N + P treatments and macroalgae showed rapid uptake of N (Koop *et al.*, 2001; O'Neil and Capone, 1996). Other effects that were seen in the +N treatments included reduced fecundity, fertilization and settlement in corals as well as reduced lipid content in the corals (Harrison and Ward, 2001; Koop *et al.*, 2001; Ward and Harrison, 2000). Increased number of zooxanthellae in corals and the giant clam *Tridacna* were also observed; as well as increased N:P and reduced NH_4^+ uptake capacity in the giant clams. In the +P treatments; coral reproduction was affected with reduced settlement of larvae and smaller eggs, as well as increased mortality in adult corals. Corals also had increased linear extension, but were more fragile. Some species of coral had more zooxanthellae and increased lipid content. *Tridacna* had decreased N:P. Macroalgae showed reduced alkaline phosphatase activity. In the +N+P treatments, there was a mixed result, with coral reproduction again affected in terms of reduced fecundity, and settlement as well as increased mortality. Corals had increased linear extension but were more fragile; zooxthanthellae numbers stayed the same, but corals showed a reduction in lipids. There was rapid uptake by macroalgae of both N and P and reduced alkaline phosphatase activity. There was reduced stomatopod recruitment. *Tridacna* had no change in N:P but increased zooxanethellae (Fig. 21.4).

What was not observed, however, was a massive overgrowth of algae. Overgrowth of algae in response to nutrients may in fact only be detectable in the absence of grazers in over-fished areas (McCook *et al.*, 2001). As a protected research area within the Great Barrier Marine Park, One Tree Island has an abundant fish population; therefore underscoring the probable importance of top-down control with a healthy grazing fish population for the health and resilience of a system under nutrient stress (Hughes *et al.*, 2007). The increased +N and P inputs increased denitrification in the sediments, while P inputs increased sedimentary nitrogen fixation. Increased denitrification with P enrichment may have been due to
Figure 21.4 Summary of the major effects of elevated nitrogen on coral reef processes from the ENCORE project, showing a gradation in responsiveness to nutrient additions; as well as the individual effects of +N; +P as well as combined effects of +N+P.

concomitant increases in nitrogen fixation providing substrates for denitrification (Fig. 21.4). This suggests a very dynamic feed–back capacity of the reef system which allows it to respond to changes in nutrients (Capone, 1996a). While the potential for denitrification on reefs has been demonstrated (Johnstone *et al.*, 1990; O'Neil and Capone, 1996), the information on its quantitative significance is poorly constrained (Capone, 1996a). Part of the missing picture in the ENCORE study was that changes in the sedimentary benthic microalgal (BMA) community, and nutrient

uptake by this important component of the benthic community were not fully quantified (Koop *et al.*, 2001).

δ^{15}N isotope signatures in two species of corals from +N treatments provided evidence that 50–100% of the overall nitrogen budget of enriched corals could come from ammonium suggesting that dissolved nutrients can have a significant effect on nitrogen uptake and dominated both the δ^{15}N signature of both the symbiont and the host. It also suggested that the nutrient history of the reef may be recorded within the organic components of the symbiotic dinoflagellates, as well as the corals and the skeletal associates which may therefore possibly be used as indicators of the chronology of nutrient concentrations surrounding a coral during its lifetime (Hoegh-Guldberg, 2004a,b; Marion *et al.*, 2005).

5. CONCLUSION

The nitrogen cycle is key to high productivity and healthy ecosystem functioning on coral reefs. By trying to unravel the complex interaction and specific roles of each component of the reef ecosystem and coral holobiont with regard to the uptake, exchange and transformation of nitrogen, insight may be gained into "how corals have come to dominate tropical near-shore systems and how they may be able to adapt to changing environmental conditions" (Rohwer and Kelley, 2004).

As threats to coral reefs worldwide have grown, the urgency to better understand the basic natural functioning in these systems has also grown in order to be better able to assess these impacts on reefs. All aspects of nutrient cycling are undergoing change with increases in anthropogenic nutrification, and multiple perturbations including increased sedimentation, runoff and levels of pollutants. Therefore it is important to continue to gain more insight into nitrogen cycling in coral reefs ecosystems as the ability of coral reefs to "adapt to these perturbations in the past is no guarantee of resilience in the future" (Hughes, 1994). We must, as Bellwood *et al.* (2004) suggest, confront our global coral reef crisis worldwide and reassess our current management practices (Hughes *et al.*, 2003; Phinney *et al.,* 2006 and references therein).

Nitrogen Dynamics of Coastal Salt Marshes

Charles S. Hopkinson *and* Anne E. Giblin

Contents

1. Introduction

Salt marshes are among the most productive ecosystems in the world—rivaling that of intensively cultivated agriculture (Odum, 1971). This high production is attributable to several factors, including nutrient enrichment from watershed runoff and tidal mixing (Day *et al.*, 1989). These are important components of estuarine systems because they provide a food source to both estuarine and coastal ocean consumers, serve as habitat for numerous young and adult estuarine organisms, provide refuge for larval and juvenile organisms, and regulate important components of estuarine chemical cycles. Nitrogen (N) dynamics have been well studied since N is the most limiting element of salt marsh primary production. However, their location, at the land–sea interface, places salt marshes in the path of ever-increasing N loads from land, raising concern about their susceptibility to eutrophication and interest in their potential for removing the N before it enters estuarine and coastal ocean waters.

In this review we provide a very brief background on salt marshes and then focus on: (1) the role of N in regulating primary production, plant zonation, and community structure, (2) the input and output N budget of salt marshes, and (3) the cycling of N in the plant-sediment system. We also include a brief discussion of marshes and

eutrophication and place marshes in the context of the global N cycle. We did not discuss the potentially important role of salt marsh microalgae in N dynamics and in support of secondary production, focusing instead on marsh macrophytes.

2. BACKGROUND

Estuarine salt marshes are intertidal wetlands vegetated by salt tolerant, non-woody, rooted, vascular plants. They are found in temperate, boreal and arctic biogeographic provinces worldwide and have an areal extent of 3.8×10^5 km^2 (Maltby, 1988). In tropical provinces, salt marsh vegetation is replaced by mangrove forests, which are not included in this review. Worldwide, over 600 species of plants grow in salt marshes (Chapman, 1974). Species diversity is lowest in the arctic (Jefferies, 1977) and generally increases toward the tropics. The most extensive salt marshes occur in estuarine systems with abundant rainfall or river runoff, muddy to sandy coasts, and moderate climate (Day *et al.*, 1989). Atlantic and Gulf of Mexico salt marshes (including oligohaline, tidal marshes) are floristically rich with 347 vascular plant species in 177 genera in 75 families (Duncan, 1974). Pacific coast marshes are less rich with 78 species between Barrow, Alaska and Baja California (MacDonald and Barbour, 1974). Only 28 vascular plant species are reported for a Hudson Bay salt marsh (Kershaw, 1976). Although salt marshes are rich in flora, they are dominated by only a few species. Atlantic and Gulf Coast marshes of the US are dominated mostly by *Spartina alterniflora* Loisel., *Spartina patens* (Ait.) Muhl., *Salicornia* sp., and *Juncus* sp. Salt marshes of the US west coast are dominated by *Spartina foliosa* Trin., *Salicornia virginica* L., and *Distichlis spicata* (L.) Greene. *Puccinellia phryganodes* (trin.) Scrib. and Merr. and *Carex subspathacea* Wormsk dominate in the Hudson Bay region. *Puccinellia maritime, Halimione portulcoides, Suaeda maritime*, and *Limonium vulgare* historically dominated salt marshes in northern Europe. Over the last several decades the hybrid *Spartina anglica* has become more common and in some cases dominant in northern Europe (e.g., Morris and Jensen, 1998). Non-native species of *Spartina* have also taken over salt marshes or mud flats on US Pacific coasts, and in New Zealand, Tasmania, and China (Valiela, 2006).

Salt marshes are exposed to a unique combination of environmental variables, including strong salinity gradients, fluctuating water levels and water tables, and anaerobic, waterlogged sediments. There are distinct patterns of species distribution and biogeochemical zonation in salt marshes that arise from gradients in elevation and porewater drainage (Haines and Dunn, 1976). Elevation typically increases with distance away from tidal creeks and bays, which results in differences in tidal flooding frequency and duration. In expansive marshes, elevation sometimes plateaus or even decreases in interior marsh areas, far from tidal creeks (e.g., Louisiana, DeLaune *et al.*, 1976). Drainage decreases away from creekbanks (Harvey *et al.*, 1987; Howes and Goehringer, 1994; Nestler, 1977; Riedeberg, 1978), which can result in hypersaline conditions when flooding is infrequent. Probably the most important effects of flooding and drainage are in the sediment chemical environment (Osgood and Zieman, 1998). Flooding and porewater drainage affect sediment oxygen

availability and redox potential. These in turn affect solubility of various elements both beneficial and toxic to plant and animal life (Patrick and DeLaune, 1977). Redox potentials vary from $>+400$ mV in the upper few centimeters of frequently flooded and drained sediments to <-200 mV at greater depths and poorly drained sediments (Howes *et al.*, 1981). There are important interactions among the ionic forms of N, Mn, Fe, and S along the redox potential gradient. These strong horizontal and vertical depth gradients also change seasonally with the growth and senescence of the dominant macrophytes. This rich biogeochemical diversity leads to a wide array of possible microbial N transformations but also greatly complicates the full quantification of the marsh N cycle.

3. Nitrogen Cycling Processes in Salt Marshes

3.1. Nitrogen and salt marsh plants and communities

Nitrogen plays a major role in controlling the dynamics of marsh plants and plant communities. Two excellent reviews on the physiological ecology and effects of N-enrichment on intertidal marsh plants include Haines and Dunn (1985) and Morris (1991). Supply of N affects: (1) plant production and biomass, (2) plant architecture, resource allocation, and tissue N content, (3) plant species composition, and (4) marsh community structure.

3.1.1. Plant production and biomass

It has long been observed that there are strong spatial gradients in marsh plant shoot density, annual productivity and standing stock of roots and rhizomes in salt marsh systems (Gallagher, 1974; Gallagher *et al.*, 1972). Highest levels of biomass and productivity are found in creekbank marshes or in areas with good porewater drainage. It has also been observed that the differences in biomass and productivity are not due to genetic differences between short and tall forms of *S. alterniflora* (Shea *et al.*, 1975; Valiela *et al.*, 1978) and that differences can be reversed by N fertilization (Broome *et al.*, 1975; Gallagher, 1975; Patrick and DeLaune, 1976; Sullivan and Daiber, 1974; Valiela and Teal, 1974).

The strong growth response of marsh plants to N fertilization suggests that porewater inorganic N concentrations are limiting primary production. Under laboratory conditions with aerated sediments, however, those same concentrations of inorganic N (50–200 μM) can support maximal uptake rates. Comparisons of V_{max} and K_m determined from aerobic culture experiments with field measurements of available NH_4^+ suggest no lack of the inorganic N necessary for *S. alterniflora* to grow well (Morris, 1984). NH_4^+ concentrations in short *S. alterniflora* marshes are often 1–2 orders of magnitude higher than K_m values determined in aerobic solution culture experiments. Thus N limitation is not due to scarcity of available N per se, but is instead a secondary effect of factors that restrict uptake of limiting nutrients.

Other laboratory culture experiments on NH_4^+-uptake kinetics in *S. alterniflora* and *S. patens* showed that anaerobic conditions, salinity, and H_2S concentrations decrease the ability of marsh plants to take up N (Bradley and Morris, 1990; Morris, 1984).

Reductions in $V_{\max}$ under anaerobic conditions are even greater with increased salinity (3 vs 32 ppt). Dissolved sulfide concentrations as low as 0.25 mM inhibit NH_4^+ uptake and stop uptake at concentrations greater than 2.0 mM. N uptake by *S. patens* is more sensitive to salinity and anoxia than is uptake by *S. alterniflora*. High salinity influences N availability to marsh plants in two ways. Haines and Dunn (1976) suggested that competitive inhibition of NH_4^+ uptake by Na^+ could result in increased energy expenditure for NH_4^+ uptake at high salinities, thus reducing the energy available for plant growth (Jefferies, 1981). Marsh halophytes also change internal N allocation in response to saline conditions. Salt is actively excluded from the transpiration stream as H_2O passes through the plant (Antlfinger and Dunn, 1983). Many halophytes, including *S. alterniflora, S. patens*, and *Limonium* sp., have salt excreting glands (Anderson, 1974). NaCl that is taken up is sequestered in vacuoles in most halophytes, thereby protecting the cytoplasmic metabolic machinery. To balance the low osmotic potential in the vacuoles, the free amino acid proline and the quaternary ammonium compound, glycinebetaine, are produced and accumulate in the cytoplasm (Cavalieri and Huang, 1981). Cavalieri and Huang estimated that up to a third of the total leaf N could be in the form of proline and glycinebetaine. The higher the sediment salinity, the greater the proportion of the already limited N supply that is allocated for osmoregulation. Accumulation of these compounds by salt stressed plants can significantly reduce the N available for growth.

Anaerobic respiration in marsh plant roots contributes to an apparent N limitation. Many halophytes respond to oxygen deficiency in plant roots by switching to fermentation as a means of producing ATP. The presence of alcohol dehydrogenase activity is a measure of alcoholic fermentation in *S. alterniflora* and *S. patens*. Concentrations of ethanol, lactate, alanine, and malate increase under conditions of decreased redox potential (Burdick *et al.*, 1989; Mendelssohn *et al.*, 1981). Reduced plant growth may be ascribed to a decrease in carbon (C) available for growth resulting from the increased consumption of glucose during fermentation and subsequent diffusion and loss of ethanol from the roots. Field data suggest that H_2S concentrations further reduce energy yield in plant roots (Koch *et al.*, 1990). Apparently, sulfide limits the potential for root anoxic energy production, which further reduces the energy available for root N uptake.

The current general explanation for local patterns in salt marsh primary production is that sediment drainage, such as that found in streamside locations of the marsh, creates a less reduced sediment substrate and prevents the accumulation of toxic levels of hydrogen sulfide and high levels of salinity. Sediment aeration also reduces the potential for root anaerobic fermentation, which is stimulated by oxygen deficiency. By allowing air entry, drainage also influences the production rate of H_2S and soluble iron concentrations (King *et al.*, 1981; Mendelssohn and Seneca, 1980). This combination of factors helps to alleviate apparent N limitation and results in creekside zones being more productive than the less drained, interior sites. By experimentally enhancing marsh porewater drainage, Wiegert *et al.* (1983) demonstrated that plant productivity can be enhanced and the effects of water logging reversed.

The much lower level of apparent N limitation in creek banks also explains why fertilization has a much greater effect on inland plants than on creekside plants,

which may show no response at all to fertilization (Valiela *et al.*, 1978). An indirect effect of N fertilization and increased plant growth is greater evapotranspiration, which leads to increased air entry and higher sediment redox potentials (Howes *et al.*, 1981). Oxidation in the rhizosphere increases nutrient availability, which further increases nutrient uptake by the plants.

3.1.2. Plant architecture

Nitrogen availability, as mediated by edaphic factors that limit plant NH_4^+ uptake, also influences plant morphology, tissue N concentrations and the allocation of plant resources. Fertilized short *Spartina alterniflora* comes to resemble tall form *S. alterniflora* in leaf width, stem diameter and general appearance (Rogers *et al.*, 1998). Tissue N is dramatically increased in short form *S. alterniflora* receiving N fertilizer (Covin and Zedler, 1988; Gallagher, 1975). Fertilization increases branching in *S. virginica* (Boyer *et al.*, 2001). N availability also influences root topology and diameter. Bouma *et al.* (2001) suggested that herringbone root systems are most efficient in terms of nutrients gained per C invested and that dichotomous root systems offer a greater potential for exploring the sediment, which contributes to potential competitiveness of plants growing in N limited sediments.

NH_4^+ supply influences the allocation of C resources between rhizomes and shoots (Haines and Dunn, 1976; Rogers *et al.*, 1998; Valiela *et al.*, 1976). Morris showed that rhizome–shoot ratios ranged between 0.35 at a high rate of N supply to 0.93 at a low rate of N supply. Although aerial and rhizome production were stimulated by increased N supply, total root production did not differ significantly between treatments (Morris, 1982). Nitrogen supply affects plant developmental processes as opposed to the specific rate of photosynthesis. Root to shoot ratios increase as plant growth becomes limited by nutrients (Mooney, 1972), and this response decreases plant production independently of any changes in weight-specific rates of photosynthesis by decreasing the growth rate of leaves. In Morris's experiments with *Spartina*, there was an insignificant effect of N supply on specific growth rate, but a 4-fold difference between treatments in total net production, and the major determinant of this difference was the effect of N supply on plant development.

3.1.3. Marsh plant community structure

Numerous studies have demonstrated an effect of N supply on marsh plant succession, the distribution of high and low marsh species, and plant invasions. Many of these studies have illustrated the linkage between these changes and N-enrichment due to human development adjacent to marshes or urbanization (Bertness *et al.*, 2004; Chambers *et al.*, 1998; Wigand *et al.*, 2001). N-enrichment promotes the invasion of *Phragmites* into the salt marsh. By reducing the N competitive ability of high marsh plants, *Phragmites* can invade these areas and then by shading short plants typical of the high marsh become a monoculture. A long-term fertilization experiment identified the interactions between marsh elevation, disturbance and N availability in creating mosaics of short and tall forms of *S. alterniflora*, bare patches, *Salicornia europaea, S. patens*, and *D. spicata* (Valiela, 1995).

In southern New England, an effect of N-enrichment is to shift the boundary between low marsh, *S. alterniflora,* and high marsh, *S. patens*. Thus *S. alterniflora* occupies an increasingly large area of the marsh relative to *S. patens*. The distribution of *S. alterniflora* and *S. patens* is a product of both plant competition for nutrients and stress tolerance (Bertness *et al.*, 2002; Emery *et al.*, 2001; Levine *et al.*, 1998). The low elevation border for *S. alterniflora* is set by the physical stress of flooding, while the high elevation border, which marks the boundary between *S. alterniflora* and *S. patens,* is set by plant competition for nutrients. Competitively superior plants dominate the high marsh habitats, whereas stress-tolerant plants dominate the low marsh (Bertness *et al.*, 2002; Emery *et al.*, 2001; Levine *et al.*, 1998). With N-enrichment, the border between low and high marsh plants moves up in elevation; *S. alterniflora* displaces *S. patens*, which in turn competitively displaces *Juncus gerardi*. Similar changes have been observed in other salt marsh systems (Rogers *et al.*, 1998), including southern California, where *S. virginica* is superior to *S. foliosa* in competing for N (Covin and Zedler, 1988) and in European low marshes, where fertilization promotes the growth of *Suaeda maritima*, which then displaces *P. maritima* by shading it (Kiehl *et al.*, 1997). Likewise, N-enrichment can accelerate plant succession in salt marshes, with displacement of short, early successional plants, such as *L. vulgare*, with taller, more mature plants, such as *Elymus pycnanthus* and *Artemisia maritima* (van Wijnen and Bakker, 1999).

3.1.4. Salt marsh community structure

When N supplies are increased, salt marsh communities behave similarly to more widely studied terrestrial grassland and forest communities (Southwood, 1973; Tilman, 1988). Nitrogen enrichment can structure marsh communities by mediating both plant competitive and facilitative interactions and plant-herbivore interactions. For example, Levine *et al.* (1998) showed that nutrients mediate *Iva frutescens* and *J. gerardi* competitive and facilitative interactions, which has an indirect effect on aphid populations. Other studies showed the plant-herbivore effect to be propagated even to a third trophic level (Gratton and Denno, 2003). Community affects can be mediated by changes in plant architecture, plant N content or shifts in plant community structure. For example, studies have shown that nutrients can have positive effects on the abundance and distribution of insect herbivores by increasing the nutrient content of host plants (e.g., Bowdish and Stiling, 1998; Onuf *et al.*, 1977; Vince *et al.*, 1981). Changes in plant community structure, such as occur with *Phragmites* expansion can in turn lead to a reduction in total plant and animal biodiversity as many native species of plants are replaced by the cosmopolitan species (Chambers *et al.*, 1999).

There is less information on how salt marsh community structure affects N cycling within a marsh. Clearly the partial or complete loss of salt marsh vegetation by disturbance can lead to dramatic changes in the N cycle. In the Canadian arctic, intense grazing by geese reduces plant N uptake, total N stocks and increases the rate of N fixation by cyanobacteria (Wilson and Jefferies, 1996; Walker *et al.*, 2003). When areas are invaded by non-native *Spartina* species, there can be significant changes in the uptake and loss of N from sediments mediated by plants, and changes in sediment redox chemistry (Hacker and Dethier, 2006; Lee, 2003). These changes also likely

affect N cycling although this has not been well studied. Studies of N budgets in different vegetation zones of marshes show considerable differences between sites but it is difficult to separate out the role of the vegetation from physical factors (Bouchard and Lefeuvre, 2000). Because marsh plants change the physical structure of the habitat where they live, there are dynamic feedbacks between plant growth, organic matter deposition and nutrient availability (Tyler and Zieman, 1999).

3.2. Nitrogen budgets for salt marshes

There is tremendous geographic variability in the spatial orientation and connections of salt marshes within estuaries and of estuaries with adjacent uplands and the ocean (Fig. 22.1). This paper focuses on the salt marsh ecosystem and associated tidal creeks and not the larger estuarine ecosystem, which may include deeper and extensive bays and sounds. However, it should be recognized that some marshes, especially those that do not have freshwater inputs from rivers, have no true open estuarine area and directly exchange with the ocean. Salt marshes are linked to adjacent terrestrial environments through water and material inputs from rivers, groundwater and precipitation. In cases where the majority of these inputs first pass though the open
Figure 22.1 Geography of a salt marsh ecosystem showing linkages to atmosphere, terrestrial run-off via rivers and groundwater and the coastal ocean. See text for a description of boundaries used in this review of nitrogen dynamics.

estuarine area it can be quite difficult to quantify the portion that actually reaches the marsh. Quantifying the role of salt marshes in exchanging nutrients with the coastal ocean is similarly difficult and comparisons across systems further complicated by various studies defining system boundaries differently. Exchanges even between the marsh platform and the adjacent tidal creeks can be very difficult to quantify because flow paths change over a tidal cycle. The marsh surface exchanges dissolved and particulate materials with creeks during high tides, while at low tide, porewater drainage tends to export materials from the marsh platform (Fig. 22.2).

In the following four sections we present the major components that must be considered in constructing whole ecosystem N budgets for a salt marsh: (1) Internal standing stocks of N in organic and inorganic pools, (2) abiotic and biotic sources of N from the atmosphere and terrestrial systems, (3) sinks of N either as long-term accretion in marsh sediments or gaseous losses to the atmosphere, and (4) abiotic and biotic exchanges of N with adjacent estuarine systems.

3.2.1. Plant and sediment stocks

The amounts of the various forms of N in salt marshes vary considerably geographically (Table 22.1). Percent N by weight in marsh sediments ranges from about 0.15% in U.S. southeastern marshes to 2% in organic rich, New England marshes. Differences are primarily attributable to the organic content, which varies inversely with bulk density. Peaty marshes have low bulk density, while sediments with low organic content, such as those in Georgia salt marshes, have a higher bulk density. Total N content ranges from about 420 to 1260 g N m^{-2} integrated over 30 cm depth. Most N is in particulate form (organic and fixed N). Dissolved stocks are more than 2 orders of magnitude lower. Of the dissolved stocks of N, the largest stock is dissolved organic N, followed by NH_4^+, and then NO_3^-. Nitrate is only present in the thin, surface oxidized layer and perhaps immediately adjacent to roots in the rhizosphere. NH_4^+ is present both in dissolved (free) and extractable forms (e.g., 1 N KCl), with the dissolved form increasing with increasing salinity (Gardner et al., 1991). At seawater strength salinity, free and extractable forms are roughly
Figure 22.2 Diagram of major nitrogen stocks, fluxes and transformations in a salt marsh–tidal creek system.

equivalent. Free NH_4^+ concentrations typically increase with depth and can approach 1 mM in concentration. Porewater DON is measured infrequently, even though it generally makes up 45–80% of total dissolved N.

Live and dead plants are additional major stocks of N in salt marshes (Table 22.1). Tissue N concentrations are higher in aboveground tissues than roots and rhizomes and range from about 0.6% N in mature culms to >2% N in rapidly growing shoots. The total stock of N in aboveground plant tissues ranges from 0 (winter) to about 14 g N m^{-2} at the time of peak live standing crop (late summer). Root and rhizome concentrations of N are lower than in culms but because of the much larger standing crop of belowground tissues, the total mass of plant N is higher (up to 22.4 g N m^{-2}). Following the death of roots and rhizomes, a large percentage of N is rapidly leached. However, N content of dead plant material increases upon further decomposition as microbes immobilize inorganic N (see later section on decomposition).

3.2.2. Inputs

The major sources and pathways by which allochthonous sources of N enter salt marshes are from their watersheds including surface water (rivers) and groundwater. Additional N is delivered from airsheds via atmospheric deposition (wet and dry deposition, see Chapter 9 by Seitzinger and Harrison, this volume), from adjoining seas via tidal exchange, and N$_2$ gas in the atmosphere via biological N fixation (see Fig. 22.2 and Chapter 2 by Carpenter and Capone, this volume). The magnitude and relative importance of the various sources seem site specific. As salt marshes are but components of the larger estuarine system and connections with adjacent waters are tied to water level fluctuations, it is difficult to scale inputs to the entire estuary to salt marsh portions of an estuary. For example, riverine inputs to an estuarine bay may pass through to the ocean with little exposure to salt marshes on the bay flanks. Ground water inputs may be more effectively processed, as marshes often border upland regions where groundwater enters (Teal and Howes, 2000).

Riverine Inputs The magnitude of N loading to estuaries from rivers has received considerable attention over the past several decades due to the estuarine eutrophication problem, which is largely driven by excessive riverine and groundwater N inputs (NRC, 2000, see Chapter 9 by Seitzinger and Harrison, this volume). Generally this attention is at the scale of entire estuaries and does not partition loading to various subsections of an estuary, such as salt marshes. On an areal basis estuaries are among the most heavily "fertilized" ecosystems on Earth, because of the their small size relative to the large size of N-leaky watersheds entering them (see Chapter 3 by, Boynton and Kemp, this volume). Several reviews of Scott Nixon indicate that estuarine loading can exceed 40 g N m^{-2} year^{-1}. This rate is twice that typically applied to intensively managed agricultural systems (e.g., 20 g N m^{-2} year^{-1}). The percentage of riverine N inputs to an estuary that actually enters a salt marsh is not well known. Primary factors controlling this input would include the frequency and duration of tidal flooding, seasonal water saturation of marsh sediments, the efficiency of the marsh in "removing" N from floodwaters during inundation, the degree to which inputs are removed by other processes in the estuary (e.g., denitrification, algal uptake), and river water transit time in the estuary. Further discussion of this can be found in Chapter 1 by Boynton and Kemp, this volume.

Groundwater Inputs The majority of freshwater N runoff from land is from rivers with groundwater contributing 6–10% (Burnett *et al.*, 2003). However for salt marshes and estuaries adjacent to topographically low relief uplands, considerable N can be transported by groundwater flow (Valiela and Teal, 1979; Valiela *et al.*, 1978). The importance of groundwater N transport is likely to be greatest in long narrow marshes with a long upland border but small total area, such as the pocket marshes of southern New England and the fringing marshes of Chesapeake Bay and its sub-estuaries. Where urban and residential developments occur on uplands immediately adjacent to salt marshes, there has been a well-documented increase in dissolved inorganic N concentrations (primarily NO_3^-) in groundwater (Moore *et al.*, 2006; Valiela *et al.*, 1990; Weston *et al.*, 2006). Some of the most-studied salt marsh systems in the U.S. have nutrient budgets dominated by groundwater inputs, including Great Sippewissett Marsh in Massachusetts, Flax Pond in New York, North Inlet in South Carolina, and Tomales Bay in California (during summer) (see Chapter 9 by Seitzinger and Harrison, this volume).

Groundwater fluxes have been identified and quantified by a variety of approaches, including seepage chambers, thermal infrared photography, hydraulic modeling (Nuttle and Harvey, 1995), salt balances (Howes *et al.*, 1996; Valiela *et al.*, 1978), tracer additions and ^{228}Ra and ^{226}Ra isotope budgets (Krest and Harvey, 2003) (for overall review see Tobias *et al.*, 2001a). Employing the radium mass balance approach, Krest *et al.* (2000) estimated that groundwater and DIN inputs to the North Inlet salt marsh ecosystem were sufficient in magnitude to support the net primary productivity of the ecosystems and to account for the known export of nutrients from the marsh. Discharge from the marsh was 20–40 l m^{-2} day^{-1}, which represents 5% of the average tidal prism. Inorganic N flux from the marsh to tidal creeks was 12 g N m^{-2} year^{-1} over the annual cycle.

Groundwater inputs are often patchy and highly dependent on specific flow paths in relation to patchy wetland deposits, including silts, clays, and organic matter (Harvey and Odum, 1990; Hemond and Fifield, 1982; Hemond *et al.*, 1984; Shultz and Ruppel, 2002; Snyder *et al.*, 2004). Flow can be focused through highly permeable sands between silt and clay lenses. Portnoy *et al.* (1998) employed a combination of thermal infrared photography and seepage meters to quantify water and DIN inputs to Nauset Marsh, Massachusetts. Seepage meters were used to quantify flow rates and nutrient concentrations and photography was used to spatially extrapolate to the larger estuarine system. In Nauset marsh groundwater discharge occurred in high-velocity seeps immediately seaward of the upland-fringing salt marsh and thus did not constitute a direct input to the marsh ecosystem. This pattern has also been observed in the Virginia coastal plain, where low permeability tidal marsh peat forces most discharge through subtidal sediments (Harvey and Odum, 1990) or tidal creek bottoms (Howes *et al.*, 1996). In Sippewissett Marsh a combination of seepage chamber and salt balance approaches were used to determine the magnitude and location of groundwater inputs. As with Nauset marsh, there was little passage through salt marsh peats, but there was substantial input at the upland-marsh border of the overall system. However, in some cases groundwater N interacts more directly with the marsh (Tobias *et al.*, 2001b,c). The estimated N input from groundwater varies annually in relation to variation in groundwater levels of the

upland aquifer, and spatially with the degree of watershed development. Along the entire coast of South Carolina groundwater inputs to the coastal zone average about 5 g N m^{-2} year^{-1} (Krest *et al.*, 2000); in the more heavily populated coast of Massachusetts, average groundwater inputs to Sippewissett marsh were greater than 12 g N m^{-2} year^{-1} (Valiela *et al.*, 1978).

Atmospheric Inputs Dissolved N is deposited in precipitation (wet deposition) and as gases and particles (dry deposition). Wet deposition (rain, snow, sleet, cloud water) contains a variety of N compounds, most of which are available for biological utilization, including NO_3^-, NH_4^+ and organic (amino acids, urea) species (Peierls and Paerl, 1997; Seitzinger and Sanders, 1999). Dry deposition includes gaseous compounds or aerosols that are deposited on terrestrial or aquatic surfaces through sedimentation, interception, and diffusion processes. The most abundant gaseous N compounds are NH_3 and nitric acid vapor. Direct atmospheric N deposition (wet and dry deposition directly onto the system, as opposed to riverine transport of N deposited within the watershed) is recognized as a potentially important source of new N to salt marsh systems, but it is rarely quantified. To a large extent this is attributable to the difficulty of measuring dry deposition; dry deposition is often assumed to equal that of wet N deposition (Fisher and Oppenheimer, 1991; Paerl *et al.*, 2002). Paerl (1985) and Fisher and Oppenheimer (1991) first showed the potential importance of atmospheric deposition in their studies of the Neuse River estuary, Pamlico Sound and Chesapeake Bay. Available evidence indicates that direct deposition onto the marsh surface alone contributes 1–40% of the total N input to marshes, depending in large part on the relative area of the estuary and its watershed (Nixon *et al.*, 1996; Valigura *et al.*, 2000). In estuaries where the ratio of the area of the estuary to the area of its watershed is greater than 0.2:1, direct atmospheric deposition usually makes up 20% or more of the total N loading (Valigura *et al.*, 2000).

The magnitude of N deposition is geographically quite variable and depends primarily on the extent of the estuarine airshed and the level of industrial fossil fuel combustion in that airshed. At a more local scale, gaseous NH_3, which is directly emitted into the atmosphere from agricultural sources such as fertilizer application and confined animal operations (Paerl *et al.*, 2002), can be a major component of N deposition (Whitall *et al.*, 2003). In estuarine marshes of the Middle Atlantic States, where both agricultural and fossil fuel sources are high, wet and dry N deposition are about 2.2 g N m^{-2} year $^{-1}$. In the New England region atmospheric deposition ranges from about 0.5 to 2 g N m^{-2} year^{-1} (Driscoll *et al.*, 2003). In the Plum Island Sound marshes in northern New England, wet and dry deposition were estimated at about 1.7 g N m^{-2} year $^{-1}$ (Williams *et al.*, 2004); N deposition is about 1.1 g N m^{-2} year^{-1} in Cape Cod, Massachusetts marshes.

Several nationwide monitoring networks in the U.S. collect data that can be used to estimate N deposition. These include the NCDC for precipitation, NADP for precipitation chemistry and the Clean Air Status and Trends Network (CASTNet) for dry deposition. Few of these sites are in coastal systems, however, so caution must be taken when using these data.

Fixation The process of N fixation is carried out by an incredible diversity of organisms, including heterocystous and nonheterocystous cyanobacteria, aerobic, facultative anaerobic and anaerobic eubacteria, and by photosynthetic bacteria

(Bagwell *et al.*, 2001; Currin and Paerl, 1998a,b; Currin *et al.*, 1996; Gandy and Yoch, 1988; Lovell *et al.*, 2000; Piceno *et al.*, 1999). N fixation is conducted by heterotrophs, chemolithotrophs and photoautotrophs. It is conducted in marsh sediments, in surface marsh algal mats, in the plant rhizosphere and in the plant phyllosphere. N-fixing bacteria have been detected invading plant roots in the outermost and innermost cortical layer (Patriquin, 1978).

N-fixation activity typically is estimated indirectly as the rate of reduction of acetylene to ethylene. This approach avoids the difficulty of measuring changes in N_2 gas in an atmosphere with 80% N_2 content. While the method is sensitive, there are a number of assumptions made in its application, including the conversion factor from acetylene reduced to N_2 fixed. The conversion factor most commonly used is 3:1 or sometimes 3:2, but this has been directly measured in only two cases in salt marsh systems (Carpenter *et al.*, 1978; Currin *et al.*, 1996).

The distribution of N-fixation activity throughout the salt marsh is determined by several factors. N fixation is temperature dependent (Carpenter *et al.*, 1978; Patriquin, 1978) with Q_{10} values above 2 (Whiting and Morris, 1986). Lack of available light seems to restrict the importance of photoautotrophic N fixers in the vegetated marsh. By comparing light vs. dark incubations investigators found less than 10% (Teal *et al.*, 1979) to 25% (Tyler *et al.*, 2003) of the fixation due to autotrophs with the rest due to heterotrophic fixers. In contrast, in pans, creek banks, algal mats, and on standing dead plants, autotrophic fixation can dominate (Abd Aziz and Nedwell, 1986; Carpenter *et al.*, 1978; Currin and Paerl, 1998a,b; Joye and Paerl, 1994). Fixation can also be inhibited by high oxygen levels, which inhibit the nitrogenase enzyme, so fixation may be temporally separated from photosynthesis. This implies that autrotrophic fixation is underestimated using light vs. dark comparisons (Currin and Paerl, 1998b; Currin *et al.*, 1996). Hetero-trophic fixation requires labile organic matter as an energy source for reducing N_2. Some investigators have found a positive correlation between fixation activity and sediment primary productivity, detrital inputs, sediment C content and/or glucose additions (Hanson, 1983; Herbert, 1975; Langis *et al.*, 1991; Talbot *et al.*, 1988). But Hanson (1977a) also observed a long-term decrease in N fixation following glucose additions to sediments, presumably because microbes outcompeted plants for avail-able N, which in turn suppressed plant root production and organic C exudation. Finally, many investigators have found that high concentrations of inorganic N can inhibit fixation (Carpenter *et al.*, 1978; Hanson, 1977a; Teal *et al.*, 1979; Van Raalte *et al.*, 1974; Yoch and Whiting, 1986).

Vertical distribution of N-fixation activity is typically highest in the plant rhizosphere in the zone of maximum root production (Carpenter *et al.*, 1978; Casselman *et al.*, 1981; Hanson, 1977b), considerably lower at the sediment surface and lowest in the phyllosphere (Hanson, 1977b): up to 51 g N m^{-2} year^{-1} in rhizosphere and 0.5 g N m^{-2} year^{-1} in the phyllosphere. Surface cyanobacterial activity can be 3× higher for heterocystous cyanobacteria than for nonheterocystous cyanobacterial species (Currin *et al.*, 1996). Horizontal distribution of activity is also related to the pattern of plant productivity, being higher in the creekbank, tall *S. alterniflora* zone and lower in interior or high marshes (DeLaune and Patrick, 1990; Teal *et al.*, 1979). Fixation rates range from about less than 0.05 g N m^{-2} year^{-1} in

the Puccinellia/Spartina zone in Colne Point marshes (Abd Aziz and Nedwell, 1986) to more than 17 g N m^{-2} year^{-1} for a *S. anglica* marsh (Jones, 1974). Most rates of fixation in U.S. marshes fall between 2 and 15 g N m^{-2} year^{-1} (Table 22.2). Only a few investigators have attempted to calculate fixation rates integrated over the entire marsh system and these range from 0.33 g N m^{-2} year^{-1} for the Colne Point marsh, U.K. (Abd Aziz and Nedwell, 1986), to 6.8 g N m^{-2} year^{-1} for the Great Sippewissett marsh in Massachusetts U.S.A. (Valiela and Teal, 1979).

Nitrogen fixation rates in marshes are highest in salt marsh pannes (Valiela and Teal, 1979) and cyanobacterial mats where lack of vegetation allows higher light levels. Heavily grazed *Puccinellia* marshes in arctic Canada had three times the fixation rates as nearby ungrazed areas (Bazeley and Jefferies, 1989). Young marshes, and constructed marshes with more open canopies, also tend to have higher rates than closed canopy mature marshes. For example, fixation rates in a recently planted marsh in North Carolina were nearly 50 times greater than the adjacent, natural marsh (Currin *et al.*, 1996). However, light may not be the only explanation for differences in fixation between sites. Fixation rates in young marshes on Hog Island, Virginia, were three times greater than in the mature marsh, yet experiments did not indicate light limitation (Tyler *et al.*, 2003). The authors suggest that fixation decreases over the course of succession in marshes because the availability of N increases over time. Of course exceptions to the pattern of higher fixation in young marshes have been reported; fixation rates were uniformly low in both a natural and constructed marsh in San Diego, California, perhaps due to very low C availability (Langis *et al.*, 1991).

3.2.3. Exchanges

Tidal Exchange Beginning in the early 1960s there was a great deal of interest in determining the role that marshes might play in supporting coastal food webs through the ''outwelling'' of organic matter from extensive intertidal marshes to the sea (Teal, 1962, reviewed by Hopkinson, 1988 and Childers *et al.*, 2000). While the initial outwelling focus was on organic C, studies attempting to quantify organic matter flux soon included inorganic and organic forms of nutrients as well (Pomeroy *et al.*, 1967). Few studies attempted to quantify the exchange of material from marsh to the coastal ocean in the true sense of outwelling as described by Odum (1968), rather studies typically focused on quantifying fluxes between subsystems of an estuary (Fig. 22.1), for example between estuarine bay and ocean (Dame *et al.*, 1986), between tidal creeks and larger estuarine bays (Axelrad *et al.*, 1976; Heinle and Flemer, 1976), or between intertidal marsh and adjacent tidal creeks (Wolaver *et al.*, 1980).

Exchange of N between salt marshes and adjacent tidal creek waters follows two primary flowpaths: (1) Vertical flux (including diffusion, erosion, and deposition) between the vegetated marsh sediment and tidal water followed by horizontal move-ment (advection) across the marsh surface and (2) subsurface, lateral drainage (or seepage) of interstitial water from marsh sediments (advection) across the intertidal creek face (Fig. 22.2). Movements of water are key in calculating exchanges and care must be taken in interpreting water level dynamics (Gardner and Reeves (2002). Most often N exchange has been measured at the mouths of narrow, shallow channels connecting small marsh creeksheds to larger basins (Fig. 22.1, creek –estuary exchange). This approach measures the net balance of processes occurring both on the marsh,

AR refers to the acetylene reduction method, and the ratio (3:2 or 3:1) refers to the conversion factor between acetylene reduced to N_2 fixed. In two cases where this ratio was measured using ^{15}N, the method is marked as calibrated.

creekbank, mudflats and in the channel (e.g., water column, sediments, reefs), and precludes the separation of specific flowpaths connecting surface and subsurface marsh sediments with adjacent creek waters. Marsh flume and creekbank hydraulic approaches (see Childers and Day, 1990b; Harvey and Odum, 1990; Hemond and Fifield, 1982; Nuttle and Portnoy, 1992) effectively separate surface and subsurface flux pathways (Fig. 22.1 "marsh –creek exchange; also see Childers, 1994).

Tidal range is a major factor regulating the relative strength of surface and subsurface flux pathways (Childers, 1994). Individual studies show considerable spatial and temporal variability in N fluxes: some show marshes to be net sinks of N (i.e., import from tidal waters greater than export to tidal waters, e.g., DeLaune *et al.*, 1989), others net sources (e.g., White and Howes, 1994b). Still other studies (Table 22.3) show marshes to import inorganic N and export organic N (e.g., Whiting *et al.*, 1989), while others import particulate N but export dissolved N (e.g., Jordan *et al.*, 1983). Jordan *et al.* (1983) concluded that the primary role of marshes is to transform particulate to dissolved forms rather than act as sources or sinks. Summarizing results from southeastern U.S. studies, Childers (1994) and Childers *et al.* (1999, 2000) concluded that tidal range was the primary factor

Table 22.3 Estimated net annual nitrogen exchange (g N m^{-2} year^{-1}) during inundation and drainage of the vegetated marsh at North Inlet, SC. PN and DON represent particulate and dissolved organic nitrogen.

	PN	DON	NH$_4^+$	NO$_x$	Total flux
Inundation	3.3	−5.9	2.9	0.62	0.9
Drainage	−2.4	−2.8	−0.18	−0.01	−5.4
Net Flux	0.9	−8.7	2.7	0.61	−4.5

A negative flux indicates an export of nitrogen from marsh to creek. From Whiting *et al.* (1989).

controlling the magnitude, direction and flowpath of exchange. Where tidal ranges are low, marsh-tidal creek water exchanges of inorganic and organic N are primarily intertidal (horizontal across marsh surface) and flume fluxes measured in these marshes are export-dominated. At higher tidal ranges, horizontal subsurface flow and subtidal benthic advection become important as marshes tend to take up nutrients and organic matter from the inundating water column while exporting these constituents to adjacent tidal creeks by subsurface flow and subtidal advection (Chambers and Odum, 1990; Harvey *et al.*, 1987; Whiting and Childers, 1989). Measurement of particulate fluxes in flumes is particularly problematic and there is anecdotal evidence that most particulate fluxes occur during extreme events, such as hurricanes or intense rains. Particulate fluxes can only occur via horizontal surface flowpaths, so do not fit the Childers schema, with respect to tidal range.

Another major control on tidal exchange appears to be marsh geomorphic age (Boorman *et al.*, 1992; Childers, 1994; Childers *et al.*, 2000; Tyler and Zieman, 1999; Valiela *et al.*, 2000). Young, immature marshes in estuaries are often lower in elevation and flood with greater frequency. With tidal ranges greater than about 1 m, immature marshes appear to take up nutrients and organic matter at rates 1.5 to 3 times higher than in old, mature marshes. Particulate N fluxes probably also follow this pattern, as Friedrichs and Perry (2001) conclude that particle (mineral and organic) deposition increases with increasing flooding frequency, depth and duration, which would tend to be greater in low elevation, immature marshes.

There are few estimates of total N exchange with salt marshes as most studies have not measured all forms of N. Valiela *et al.* (2000) estimated net exchange qualitatively by tabulating directional flux of individual forms of N for many salt marshes, regardless of whether all forms were measured. They took the aggregate results from all the marshes to represent overall export or import characteristics and found that a majority of salt marshes export N. For all forms of N, with the exception of nitrate, the aggregate data suggest that a majority of salt marshes exported N. That in aggregate, marshes export N to adjacent tidal creeks does not imply that they are net exporters to all adjacent systems or that they do not accumulate N *in situ*. Obviously there are other sources that enable marshes to both accumulate and export N to adjacent tidal waters.

Nutrient Transport by Fish Migration Many estuarine organisms can readily migrate between tidal creeks and the marsh platform and this migration can represent an appreciable flux of inorganic and organic N. Direct measurements of aquatic faunal

densities from a variety of salt marsh estuaries demonstrate that these animals utilize the marsh surface for feeding and to escape predation (see review by Kneib, 2000). The N flux pathway consists of larval or juvenile organisms residing on the marsh during early life stages, increasing in biomass by consuming marsh detritus or resident flora and fauna, and then migrating to estuarine waters at later stages in their lifecycle. Alternatively marsh fauna can be grazed by wading birds (Bildstein *et al.*, 1992), or consumed by large carnivorous fish during extreme high tides. These pathways represent a flux of particulate organic N from marshes to adjacent estuarine waters and in some cases the coastal ocean (Deegan, 1993; Deegan *et al.*, 2000). Deegan determined that migration of menhaden from Mississippi River deltaic marshes to the Gulf of Mexico represented a flux of 3.1 g N m^{-2} year^{-1}. While not all this N originated on marshes, many other species are involved in this pathway in addition to menhaden, and thus macrofaunal migration can represent a significant flux of N from marshes to estuarine waters. In a recent review of this process, Teal and Howes (2000) concluded that marshes as a whole do grow fish, but until more studies quantify their contribution to the N budget, we will not know if the magnitude of the flux measured in Louisiana marshes is typical.

3.2.4. Outputs

Denitrification and Gaseous N Losses Denitrification is of particular interest in estuaries because it represents the primary process reducing the effects of N-enrichment from anthropogenic sources (see Chapter 3 by Devol, this volume). The perceived low susceptibility of salt marsh estuarine systems to N-enrichment and eutrophication is often attributed to high rates of denitrification (NRC, 2000). It has been suggested that through denitrification and burial, fringing salt marshes also play an important role in intercepting land-derived nutrients and thereby helping to prevent eutrophication in downstream ecosystems, such as sea grass meadows (Valiela and Cole, 2002). However, in spite of the widespread belief that denitrification is an important process, we find relatively few studies of gaseous N loss from marshes.

The relative importance of various forms of N lost to the atmosphere has been shown clearly. N_2 is the primary form of N lost during denitrification in salt marshes (Cartaxana and Lloyd, 1999; Smith *et al.*, 1983). NO and N_2O losses are orders of magnitude smaller by comparison. Maximal rates of N_2O loss normally do not exceed 0.14 mg N m^{-2} day^{-1} (Smith *et al.*, 1983). NH_3 volatilization, while not a component of denitrification, is another form of gaseous N loss in salt marsh systems. It too is orders of magnitude lower than rates of N_2 loss due to the fairly low sediment pH values (<8) in most marsh sediments (Koop-Jakobsen, 2003; Smith *et al.*, 1983).

Measuring denitrification in any natural system has proved challenging in part due to the difficulty of measuring small changes in N_2 against a relatively large background concentration (Cornwell *et al.*, 1999; Groffman *et al.*, 2006, see Chapter 1 by McCarthy and Bronk, this volume). For a variety of reasons, marshes present especially difficult additional challenges. Tidal inundation and drainage, as well as oxidation of the plant rhizosphere, lead to a spatially complex and temporally dynamic redox environment in vegetated sediments, which may favor coupled nitrification and denitrification (Risgaard-Petersen and Jensen, 1997). In theory,

the marsh plant rhizosphere should be a *hot spot* of nitrification and denitrification due to plant roots, which provide oxygen and labile organic matter. This has been demonstrated in a laboratory setting for fresh water marsh sediments dominated by *Juncus effuses* using ^{15}N (Reddy *et al.*, 1989) and in submerged seagrass sediments (Caffrey and Kemp, 1992), but data from salt marsh systems are sparse.

Because of the difficulty of measuring denitrification in salt marshes, a wide variety of approaches have been taken. It is telling that of the 16 studies where we found denitrification rates reported for salt and brackish marshes, twelve different methods were employed (Table 22.4). In earlier studies, acetylene inhibition was the method of choice. Although this is one of the simpler and more sensitive methods of measuring denitrification, acetylene reduction also blocks nitrification. In systems where coupled nitrification/denitrification is important, the acetylene reduction technique can seriously underestimate denitrification if experiments permit NO_3 concentrations to drop significantly (Groffman *et al.*, 2006; Seitzinger *et al.*, 1993). In the few cases where direct and coupled nitrification/ denitrification have been separately quantified both are important. The relative importance of the two processes varies depending upon location in the marsh, the presence of benthic algae, and the availability of nitrate and organic matter (Hamersley and Howes, 2005; Tobias *et al.*, 2003). Four studies that used acetylene inhibition reported denitrification rates that cluster at the lower end of all reported rates for salt marshes, suggesting that this technique may not be optimum for these environments.

More recent improvements in denitrification measurement have relied on the use of stable isotopes or the direct measurement of N_2 fluxes. Direct N_2 flux techniques measure net denitrification (denitrification-N_2 fixation) and in some cases investigators corrected the reported values for fixation, while in others only net values were reported (Table 22.4). A variety of approaches have been tried to apply these techniques to the vegetated marsh platform. Some investigators have applied the techniques under exposed conditions (Kaplan *et al.*, 1979), while others have measured rates under submerged conditions (Davis *et al.*, 2004). Isotopic methods have ranged from short-term use of the isotope pairing method of Nielson (1992) (Ericksson *et al.*, 2003), to N_2O pool dilution (Anderson *et al.*, 1997), and to measurement of the short-(Hamersley and Howes, 2005) and long-term fate of ^{15}N added *in situ* (White and Howes, 1994b). Most studies have been conducted during the growing season; only a few were carried out frequently enough to realistically estimate annual averages. Due to the difficulty of dealing with tall plants in chambers, most studies have excluded live culms during the measurement period. Hamersley and Howes (2005) showed that measurements applied *in vitro* to sediments isolated from plants and other environmental factors may greatly underestimate the true rate of denitrification. Similarly Reddy *et al.* (1989) found almost no denitrification in freshwater marsh microcosms without plants. It should be noted that the measurements of Hamersley and Howes (2005) were made over a period of days. A comparison of their measured *in situ* values to those of other investigators using *in vivo* methods (Table 22.4) suggests that for short-term measurements, the methodological problems of removing the plants may not be as severe as they are in longer-term laboratory studies.

The method used for each study is listed. Depending upon the method, the study may have measured gross denitrification (total production of N$_2$ from nitrate reduction) or the net rate of N$_2$ flux (the difference between fixation and denitrification). Negative numbers indicate a net uptake of N$_2$ by the sediments.

$\star$ Rates given are in mg N m^{-2} day^{-1}.

The published rates of denitrification in vegetated sediments range from 0 to more than 100 mg N m^{-2} day^{-1} (Table 22.4). Median values of 14–28 mg N m^{-2} day^{-1} are in general higher than those reported for other environments including estuaries and continental shelves (see Chapter 18 by Boynton and Kemp, this volume). Given the available data, it is difficult to determine if rates in sediments from the vegetated marsh are significantly different from rates measured in small creeks draining the marsh. Both sites can have very high rates. Kaplan *et al.* (1979) reported that rates were highest in creek bottoms and the tall *S. alterniflora* zone, while the lowest rates were found in the vegetated high marsh. Similarly Ericksson *et al.* (2003) found higher rates in creek sediments than vegetated sediments. Other studies found that rates were higher in vegetated sediments than in nearby creek bottoms (Abd Aziz and Nedwell, 1986; Davis *et al.*, 2004; DeLaune *et al.*, 1998; Koch *et al.*, 1992).

Denitrification may also be important in marsh sediments that receive nitrate-rich groundwater inputs. Tobias *et al.* (2001a,b) investigated a plume of groundwater in a mesohaline marsh using isotopic methods *in situ*. They estimated that denitrification rates could be as high has 504 mg N m^{-2} h^{-1} during times when groundwater discharge was high; at this rate, denitrification could remove up to 90% of the nitrate load to the marsh. Addy *et al.* (2002, 2005) found substantial denitrification activity in groundwater passing under a salt marsh. In contrast Nowicki *et al.* (1999) found that the majority of nitrate-rich groundwater passed under the marsh and that the nearby creeks were the major site of denitrification. In marshes, as in all systems, denitrification is a function of both reactivity and hydrologic conductivity (e.g., Bohlke and Denver (1995). Until there are more studies in marshes with different groundwater flow paths, the overall importance of denitrification in groundwater as it enters marshes cannot be evaluated, but it warrants further investigation.

Anammox is the anaerobic reduction of ammonium to N$_2$ using nitrite as the terminal electron acceptor. This process can contribute significantly to benthic N$_2$ production in some marine environments, but studies to date have found that the importance of anammox in organic rich coastal sediments is low (Engstrom *et al.*, 2005). Anammox may be of minor importance in organic rich salt marshes as well.

Observations and experiments show that availability of NO$_3$$^-$(Koch *et al.*, 1992; Tobias *et al.*, 2003), labile organic matter, and oxygen (required for nitrification) are the primary factors controlling the rate of denitrification (Cornwell *et al.*, 1999; Kaplan *et al.*, 1979; Koch *et al.*, 1992; Sherr and Payne, 1978; Thompson *et al.*, 1995). Although it would be expected that denitrification would increase with increased N loading, previous studies have not always found a clear relationship (Kaplan *et al.*, 1979), or found that net denitrification (net N$_2$ flux) decreased with loading (Davis *et al.*, 2004). However, Wigand *et al.* (2004) and Lee *et al.* (1997) found that potential denitrification increased along a eutrophication gradient. Hamersley and Howes (2005) found denitrification rates in fertilized salt marsh plots were more than an order of magnitude higher than nearby control areas. They suggested that under conditions of high N loading, competition for N between microbes and plants is reduced or eliminated resulting in very high denitrification rates. Understanding the effect of elevated nutrient inputs on denitrification is further complicated by two recent findings. First, high rates of

denitrification in marshes may be due in part to phosphorus limitation of microbial heterotrophs and that increased P can decrease denitrification (Sundareshwar et al., 2003). Some studies on the denitrification response to fertilization were done in sites receiving N+P while others were conducted in sites only receiving N. Second, the N composition of fertilizer (inorganic vs. organic) may determine the degree to which denitrification is stimulated (Enwall et al., 2005).

In spite of the difference of approaches, the overall picture that emerges is that denitrification typically ranges between 2–40 g N m^{-2} year^{-1} and is a significant loss term in salt marsh N budgets. Because some of these measurements are net fluxes, and because of methodological problems, we suspect that these rates may be underestimates (in some cases, large underestimates). At present there seems to be insufficient data to say with confidence how denitrification rates are altered by N-enrichment or eutrophication, but this is clearly a critical question.

Sediment Accumulation Marshes must keep pace with increases in sea level rise to survive. The net accretion of salt marsh sediments in conjunction with sea level rise is another potentially important flux of N in salt marsh ecosystems. Generally marsh elevation increases in parallel with sea level rise (Valiela, 2006). In most cases rates of N storage have been measured using sediment bulk density and N content with direct measurements of vertical accretion using ^{137}Cs or ^{210}Pb (Craft et al., 1993; Merrill and Cornwell, 2000) or calculated from independent measures of local relative sea level rise (Anderson et al., 1997; White and Howes, 1994b). These yield long-term averages for specific locations. Less frequently, short-term rates of N accretion have been directly measured using sedimentation plates or marker horizons on the marsh surface (see for example DeLaune et al., 1981) and flumes (Childers and Day, 1990a,b). Increasingly researchers are employing sediment elevation tables (SET; Boumans and Day, 1993; Cahoon et al., 2002) to estimate both short-and long-term changes in sediment elevation. Estimates of N inputs required to balance long-term accumulation of N in sediments span a wide range, 1–50 g N m 2–1 year^{-1} (Table 22.5), with median values between 2 and 4 g N m^{-2} year^{-1}. The wide range is due in part to the difficulty of designing a sampling scheme that realistically takes into consideration episodic events (storms, hurricanes) when rates are generally at their highest (Childers and Day, 1990a) and to finding truly representative sites. The majority of studies have been conducted in depositional areas and generally erosional sites are not considered (c.f. Chmura et al., 2003). For example, while DeLaune et al. (1981) report high rates of sedimentation on the surface of brackish marshes in Four League Bay, Louisiana, an overall budget of the entire area, which takes into account regions where marsh is being lost, demonstrates the N loss by burial is much less (17 g N m^{-2} year^{-1} vs <5 g N m^2 year^{-1} -DeLaune et al., 1989).

Although the data on N burial is somewhat sparse, Chmura et al. (2003) compiled an extensive data set on rates of C sequestration in tidal saline wetlands, which included more than 110 salt marsh sites. They concluded that on average salt marshes store 210 g C m^{-2} year^{-1}. Sediment C/N data for salt marshes has been compiled by Valiela (1983) and Craft et al., 1991 and while this data also comprises a wide range of values the majority of the sites have C/N values that fall between 14 and 30. Combining estimates of C accretion and C/N ratios, yields an overall

Table 22.5 Burial rates of nitrogen Rates were calculated using several methods, assuming accretion has kept up with relative sea level rise (SLR), a budget of organic matter inputs and losses (OM budget), mass accretion rates using radiometric dating techniques (^{137}Cs or ^{210}Pb), or net particulate nitrogen (net PN) budgets to the marsh or in tidal creeks. GSW stands for Great Sippewissett Marsh

average N accumulation rate of 7–15 g N m^{-2} year^{-1}. This rate compares reasonably well with N burial rates measured directly (Table 22.5): median -10.7 and average -13.9 g N m^{-2} year^{-1}.

Many factors interact to control wetland accretion and N plays a potentially interesting indirect role. There have been a number of studies and models examining how marsh plant species composition, production and allocation to above and belowground biomass and decomposition, sedimentation, erosion and compaction interact to determine accretion rates (Cahoon, 1994; Friedrichs and Perry, 2001; Morris and Bowden, 1986; Reed, 2000). How this balance is affected by increased N inputs to the coastal zone is still not well understood. Nutrient inputs stimulate plant production but in some cases also alter the relative abundance of marsh plants toward species with less belowground storage (Levine et al., 1998), which could possibly result in lower rates of peat formation. Nutrient enrichments increased sediment respiration and lead to some loss of peat in a fertilized marsh in South Carolina (Morris and Bradley, 1999) but 30 years of N addition increased accretion rates in Great Sippewissett marsh in Massachusetts (Valiela et al. unpublished).

3.3. Recycling

3.3.1. Decomposition

The primary fate of marsh macrophyte tissues is decomposition and incorporation into detrital food chains. Herbivory typically is not a major trophic pathway in salt marsh systems (but see Bertness et al., 2004 and Pomeroy and Wiegert, 1981). Nitrogen plays a critical role during decomposition and detrital processing. The quality of salt marsh detritus as a food source for consumers depends to a large degree on the availability of N for assimilation and growth (Tenore, 1984). Decomposition is primarily a microbial process and qualitatively similar to that of other aquatic macrophytes and terrestrial plants. It occurs in three phases: a short, rapid weight loss period with leaching of soluble compounds, a microbial degradation phase with concomitant leaching of hydrolyzed substances, and a final, slow phase either associated with enzymatic alteration of plant and bacterial biomolecules (Ogawa et al., 2001; Tremblay and Benner, 2006) or with humification (Rybczyk et al., 1996; Valiela et al., 1985a).

Nitrogen is essential to the microbial community decomposing litter and can limit the decomposition rate. The N needed in decomposition can come either from the litter or the surrounding soil and water. During decomposition both the mass of N and the C/N ratio of litter change. Initial N content of aboveground S. alterniflora litter ranges from about 0.6% to 0.9% (DW) and from 0.5% to 0.6% for belowground tissues (Hopkinson and Schubauer, 1984; Marinucci, 1982). C/N ratios increase during the first stage of decomposition and then decrease afterward (e.g., from 100–150:1 then down to 8–12:1). There is a net increase or immobilization of N during decomposition. Controlled experiments, ^{15}N tracers and the change in N compounds of bacterial origin reveal that by the midpoint in decomposition, 50–65% of the total detrital N pool is from external sources and a major part of the N incorporation is microbially mediated and of microbial origin (Tremblay and Benner, 2006; White and Howes, 1994a). The presence of bacterial organic matter

in decomposing litter has been confirmed by the occurrence of biomarkers unique to bacteria, muramic acid, only prevalent in bacteria (D-amino acids), or virtually absent from higher plants (galactosamine) (Tremblay and Benner, 2006). The increase in fungal and bacterial biomass on decomposing litter represents only a minor component of the increase in N over time, as several studies have found few recognizable microbial cells or living bacteria or fungi (White and Howes, 1994b). For aboveground decomposition, fungal biomass can contain 12–22% of the N in litter, while bacteria contribute about 1/10 that (Marinucci et al., 1983). Under subaqueous conditions, where fungi are of minor importance, 60–75% of the N and 20–40% of the C in highly decomposed detritus are not from the original plant tissues but are mostly from heterotrophic bacteria (Tremblay and Benner, 2006). The microbial contribution to N is mostly from the remains of bacteria, including exudates like mucopolysaccharides and exoenzymes (Lee et al., 1980; Rice and Hanson, 1984). Reactivity of bacterial detritus (that produced by bacteria during their decomposition of plant detritus) is similar to that of plant detritus. Only a minor fraction of bacterial detritus escapes rapid biodegradation and the relationship between bacterial activity and N immobilization is consistent with an enzymatically mediated preservation mechanism (Tremblay and Benner, 2006). The sequestration of external N into decaying *S. alterniflora* represents an important mechanism for retaining N in salt marsh ecosystems.

Lignin is one of the most resistant compounds in plant litter to decomposition and its content relative to total mass or ligno-cellulose content is a good predictor of decomposition rate. Up to 50% of the initial litter N is present as lignin. There is a rapid increase in relative lignin content during the first phase of decomposition (Benner et al., 1991; Klap et al., 1999), as the cellulose and hemicellulose fractions are preferentially degraded. While the lignin content stabilizes over the next two years of decomposition, there is continuous modification of the lignin polymer during this time. During a final humification stage, condensation reactions between quinines, derived from phenolics, and amines have been proposed as an important mechanism in N immobilization and preservation.

Lignin decomposition rates are substantially lower in the absence of molecular oxygen (Benner et al., 1991), which results in decomposition rates decreasing from the sediment surface through the partially oxygenated rhizosphere to deeper anoxic sediments. However, comparison of lignin production rates with estimates of accretion of organic matter in sediments suggests that most of the annual input to sediments of *S. alterniflora* lignin is removed through complete remineralization to CO_2 (Benner et al., 1991). One explanation for the decreased decomposition rate of lignin in anaerobic sediments is the great reduction in fungal activity. Fungi are the primary organisms responsible for lignin decomposition and they are obligate aerobes (Valiela, 1995).

The turnover of N in marsh plant litter is difficult to determine because of the immobilization that occurs during decomposition. Carbon loss cannot be used as a proxy for N turnover because C and N decomposition are decoupled and C is also immobilized during decomposition (Tremblay and Benner, 2006). Based on the decrease in mass of ^{15}N-labeled detritus from the White and Howes experiment (1994b), we calculate N turnover rates to exceed C during the leaching phase of

decomposition and then to be lower during the next two phases. Over an annual cycle, rates are similar (about 1.4 year^{-1}). As temperature is a primary control on decomposition rate, we can expect turnover rates to vary across geographic gradients.

3.3.2. Inorganic nitrogen dynamics

Ammonification, nitrification, and dissimilatory reduction of nitrate to ammonium (DNRA) are difficult processes to quantify, especially in the presence of high densities of marsh macrophytes. Conducting measurements in small cores introduces a suite of artifacts that are difficult to evaluate. Coring prevents further oxidation of the rhizosphere and production of labile C exudates by living plant roots. The process of coring results in roots being cut, which then leads to increases in acetate concentrations (Hines *et al.*, 1994; Howes *et al.*, 1985). Tracer approaches have been employed *in situ* and in the laboratory with and without macrophytes to assess the rhizosphere effect and to estimate plant N uptake and microbial N immobilization. These techniques are typically done with tracer level additions of ^{15}N ammonium or nitrate to sediment or overlying floodwater. Isotope dilution approaches can provide information on rates of gross production and uptake, and net production of various N species in sediments (Blackburn, 1979; Koike and Hattori, 1978) although care must be taken to meet the assumptions of isotope dilution techniques (Schimel, 1996).

Ammonification   Ammonification is the process whereby organic N is mineralized to NH_4^+. It is the first step in organic N decomposition and is often referred to as N mineralization Ammonification in combination with DNRA must balance plant uptake requirements, microbial immobilization, and NH_4^+ leaching to flood waters and creekbank drainage. Quantification of ammonification can be done by examining total ammonium accumulation in cores, by using harvest or litter bag methods and C/N ratios to calculate N turnover (Hopkinson and Schubauer, 1984; White and Howes, 1994b) or by $^{15}NH_4$ pool dilution (Anderson *et al.*, 1997; Bowden, 1984). Short-term pool dilution and ammonium accumulation yield data that represent gross mineralization while longer-term harvest methods approximate net values. Because salt marsh sediments are sites of high belowground production and decomposition, ammonification rates tend to be higher than those of unvegetated coastal marine sediments and similar to rates seen in seagrass beds (see rates in Herbert, 1999). In spite of the fairly large ammonium pool in salt marsh sediments, turnover rates are often short. Tobias *et al.* (2001b) reported a turnover time of 5–14 days for the ammonium pool in a Virginia salt marsh (based on NH_4^+ concentration of 500–1000 μM). Ammonification rates were highest near the surface and in the rhizosphere and decreased with depth, because of declining organic N quality. Anderson *et al.* (1997) found gross ammonification rates at Phillips Creek Virginia of 84 g N m^{-2} year^{-1}. Net values for Great Sippewissett Marsh, Massachusetts and Sapelo Island, Georgia were on the order of 15 and 20 g N m^{-2} year^{-1} respectively. Few investigators have examined controls. In a New England tidal marsh, Bowden (1986) estimated an annual rate of ammonification of 53 g N m^{-2} year^{-1} (to 10 cm), and found ammonification rates varied inversely with sediment lignin content.

Nitrification   Nitrification has been measured using isotope techniques similar to those used for gross ammonification but the much lower concentrations of nitrate in salt marsh sediments, and the more rapid turnover times make the techniques more difficult to apply (see Chapter 11 by Ward, this volume). Alternatively, non–isotopic techniques have been used that involve measuring ammonium accumulation with and without nitrification inhibitors but these are difficult to use if there are other substantial sinks of ammonium. Because of these difficulties many investigators have relied on potential nitrification measurements to examine spatial and temporal patterns and to examine how the microbial community correlates to rates (Bernhard *et al.*, 2005; Dollhopf *et al.*, 2005). In spite of the low concentrations of nitrate in salt marsh sediments, nitrification rates integrated below the rhizosphere have ranged from about 1/10 to 1/2 of the rate of ammonification (Anderson *et al.*, 1997; Bowden, 1986; Tobias *et al.*, 2001b). In tidal creek sediments the amount of ammonium nitrified spans a similarly large range (Tobias *et al.*, 2003). In many systems the fate of most of this nitrate appears to be denitrification. Even larger percentages of ammonium may be nitrified in fringing marshes receiving groundwater inputs from uplands where ammonium–rich porewater mixes with oxic groundwater and in sediments experiencing tidal infiltration and drainage (Tobias *et al.*, 2001a). Controls on nitrification are O_2 availability and NH_4^+ concentrations but elevated salinity (Seitzinger *et al.*, 1991) may play a role and sulfide levels (Joye and Hollibaugh, 1995) can severely inhibit nitrification.

Ammonium Uptake   Standard ^{15}N-NH_4^+ addition experiments have demonstrated, that in the presence of marsh plants, upwards of 95% of remineralized ammonium in marsh sediments is taken up by marsh plants prior to nitrification (Buresh *et al.*, 1981; Smith and DeLaune, 1985). In the absence of plants however, microbes decomposing high C/N plant detritus immobilize 15%. Once immobilized, further transformations or losses of this "organic associated fraction" are not detectable with current methods (Smith and DeLaune, 1985). These patterns are in agreement with bulk litter decomposition studies. NH_4^+ isotope dilution experiments conducted in the absence of plant roots show that a much larger percentage of remineralized ammonium is microbially immobilized. That plants secure a larger percentage of available NH_4^+ than decomposers or nitrifiers suggests that plants outcompete sediment microbes for inorganic ammonium. Another pathway of NH_4^+ uptake would be that by microalgae on the sediment surface and macrophyte culms. But as far as we know there has been little examination of this process in salt marshes.

DNRA has been identified as an important process under some conditions in estuarine sediments (Koike and Sorensen, 1988) Relatively few studies have been conducted in salt marshes. Abd Aziz and Nedwell (1986) could not measure the release of labeled nitrate as N_2 gas and concluded DNRA must greatly exceed denitrification. Tuerk and Aelion (2005) found that more than 30% of nitrate added to marsh sediments was quickly converted to ammonium. Tobias *et al.* (2001b) measured the relative importance of nitrate reduction to a marsh–aquifer ecotone and found that when groundwater discharge was low, nitrification rates were also low and the majority of the nitrate produced was denitrified. During high

discharge periods, nitrification rates greatly increased but while denitrification to N_2 increased two fold, 30% of the nitrate produced was reduced to ammonium (Tobias *et al.*, 2001c). In contrast, other studies have suggested that the importance of DNRA relative to denitrification is greatest when nitrate concentrations are low or the ratio of electron donors is high relative to NO_3^- (Herbert and Nedwell, 1990). Several studies have found that strongly reducing conditions favor DNRA (An and Gardner, 2002; Buresh and Patrick, 1981; Smith *et al.*, 1982). Because DNRA is a process that retains, rather than removes nitrate from salt marshes, the shunting of nitrate to DNRA under high nitrate loading tends to decrease the ability of marshes to remove anthropogenic N.

3.3.3. Marsh macrophyte nitrogen dynamics

Quantitatively some of the largest internal fluxes of N in the salt marsh ecosystem are associated with the growth and death of the emergent marsh macrophytes (Hopkinson and Schubauer, 1984; White and Howes, 1994c). All rooted macrophytes obtain inorganic N (NH_4^+ preferentially) from sediments and incorporate it into new plant biomass, both aboveground and belowground tissues. Upon senescence a portion of the aboveground N is translocated belowground where it is stored in roots and rhizomes for use the following season, while the remainder is either leached from the plant or remains in dead plant parts (Table 22.6).

Mass balance and isotopic tracer approaches have been used to quantify N fluxes associated with marsh plant growth and death. One study in a very productive, medium form of *S. alterniflora* from a Georgia salt marsh shows that total uptake of N by roots of *S. alterniflora* was 34.8 g N m^{-2} year^{-1}. Of this 43% was lost by death or leaching from aboveground plant parts, while the rest was lost by death of roots and rhizomes. Total transfer of N from below-to aboveground tissues was 33 g N m^{-2}

Table 22.6 Nitrogen fluxes associated with growth and death of marsh plants: short and medium forms of *Spartina alterniflora* and *Zizaniopis miliacea* (White and Howes, 1994c; Hopkinson and Schubauer, 1984)

	Short form *S. alterniflora*	Medium form *S. alterniflora*	*Zizaniopis miliacea*
New root uptake	21.8	34.8	57
Aboveground Retranslocation	3.7	33	39
Belowground Translocation	1.4	17.9	10.1
Root death	19.5	19.7	28.2
Aboveground death	2.9	14.4	14.9
Aboveground leaching	0.4	0.7	13.9

Zizaniopis is a fresh marsh plant and is included by way of comparison to illustrate the potential importance of N availability in controlling recycling efficiency, seen here as the profligate leaching of N from dead *Zizaniopis*. Units—g N m^{-2} year^{-1}

year^{-1}, 46% of which was new N taken up from the sediment. Of the N transferred aboveground, 14.4 g was lost to detritus upon culm death, 0.7 g was leached from the living culms, and 17.9 was translocated from senescing leaves to rhizomes for storage or immediate transfer to actively growing shoots. The high degree of N conservation in *Spartina*, low leachability, and retraction from senescent tissue are consistent with plant growth being N limited.

These results are in general agreement with patterns observed for a much less productive, short form of *S. alterniflora* in a New England salt marsh (White and Howes, 1994c). Using an isotopic approach, White and Howes (1994c) concluded that the fate of translocated N was not in support of next years aboveground production. While the relative percentage translocated was similar in the two studies (38% and 54% of aboveground uptake), the estimated importance of translocated N for next season's aboveground growth differed substantially. From the ^{15}N tracer, White and Howes (1994c) determined that none of the translocated N was retranslocated aboveground the following season. Hopkinson and Schubuaer assumed from mass balance considerations that it was all reused.

The high degree of N reuse in salt marsh macrophytes is consistent with them being N limited. By way of comparison, in a fresh water riverine system with high N loading, *Zizaniopsis* shows relatively little internal N recycling and high leaching loss upon death (Hopkinson, 1992). There is the indication that nutrients turn over more rapidly and nutrient cycles are less retentive and conservative as systems become more open and nutrient inputs increase. The degree of system closure and N availability appears to be a major factor controlling nutrient retention and cycling in wetland ecosystems.

3.3.4. Summary of salt marsh nitrogen fluxes

The magnitude of N fluxes internal to salt marshes and between salt marshes and adjacent systems are summarized in Table 22.7. The largest fluxes are typically internal to the system and involve the uptake of inorganic N by marsh macrophytes, plant death, organic matter decomposition and remineralization of organic matter in and on marsh sediments. The turnover of N in salt marsh sediments can be estimated by comparing these internal N fluxes to the standing stock of N in salt marsh sediments (460–1300 g N m^{-2} to 30 cm—see Table 22.1). Based on the annual rate of plant N uptake, the turnover rate of N ranges from about 0.03 year^{-1} to 0.09 year^{-1}. The turnover rate of inorganic forms of N is much higher, being as high as 54 year^{-1} for NH$_4^+$.

Inputs, outputs and exchanges of N with systems adjacent to salt marshes are generally much smaller in magnitude than internal fluxes (Table 22.7). The source and relative importance of various external inputs of N to salt marshes varies from system to system. While the input of N from rivers is potentially large, most of this N is probably not taken up by salt marshes but is processed in aquatic portions of estuaries or routed to the open ocean. On average, the largest input is from N fixation (2–15 g N m^{-2} year^{-1}), followed by atmospheric deposition (0.5–2.2 g N m^{-2} year^{-1}). Groundwater inputs are a major source of N in some smaller salt marshes with developed uplands such as found in the northeastern United States.

Table 22.7 Summary of the range of values found for major salt marsh nitrogen fluxes both internal to the system and with adjacent ecosystems

Category	Description	Flux $(g\,N\,m^{-2}\,year^{-1})$
Inputs	Rivers (estuarine average)	28
	Groundwater	0–12.6
	Atmosphere	0.5–2.2
	Fixation	2–15
Cross-system exchanges	Tidal (negative = export)	−4.5+12
	Fish	3.1 (export)
Outputs or accumulation	Denitrification	2–20
	Sediments	4–16 (accumulation)
Internal cycling	Decomposition	1.4 $year^{-1}$
	Ammonification	5–53
	NH_4^+ uptake/immobilization	15% of ammonification
	Nitrification	1/10–1/3 of ammonification
	Dissimilatory nitrate reduction	15% of nitrification
Plant cycling	Root uptake	21–57
	Aboveground uptake	4–39
	Aboveground death	3–15
	Aboveground leaching	0.4–14
	Translocation belowground	1–18
	Belowground death	20–28
	Retranslocation aboveground	0–18

Values for different categories often represent ranges from very different systems based on a variety of assumptions. Values should not be averaged.

Major outputs of N include denitrification, and burial (sediment accumulation). On average denitrification is similar to N fixation in magnitude (Table 22.5 and Fig. 22.3). In the few cases where both fluxes have been quantified for an entire marsh system, denitrification usually exceeds fixation (e.g., Great Sippewissett Marsh; Valiela and Teal, 1979). There are exceptions; in the Barataria Basin marshes of Louisiana, fixation exceeds denitrification by 6 g N m^{-2} year^{-1} (10 vs 4 g N m^{-2} year^{-1}). Some specific habitats, such as microbial mats (Joye and Paerl, 1994) and transplanted young marshes (Currin *et al.*, 1996) also have fixation rates that are much greater than denitrification. The burial of N can also be substantial, varying in importance in relation to rates of sea level rise. Burial rates are similar in magnitude to fixation (Fig. 22.3). Where studied, fish migration has been shown to be an important component of N exchange between tidal waters and salt marshes, but it has received little attention in most salt marsh studies. The flux with the greatest variability between systems is tidal exchange of dissolved and particulate forms of N.

The N budget of Great Sippewissett marsh published in 1979 is still the only one we have found that measured all of the major inputs and outputs on a seasonal basis
Figure 22.3 Summary of values of the internal sources and sinks of nitrogen in marshes from studies in Tables 22.2, 22.4 and 22.5.

in all of the major zones on the marsh platform and in small tidal creeks (Valiela and Teal, 1979 Fig. 22.4). This budget provides an example of the role of marshes in the coastal landscape, but the reader should keep in mind that this small, groundwater–dominated pocket marsh in the US northeast might not be representative of all marshes. For this system, marsh sinks (denitrification and burial) remove 11.21 g N m^{-2}
Figure 22.4 Summary of the nitrogen budget of Great Sippewissett Marsh, Massachusetts, USA (Valiela and Teal, 1979). All fluxes are in g N m^2 year^{-1}.

year^{-1}, which is a large percentage of the land based and atmospheric N inputs to the marsh (13.47 g N m^{-2} year^{-1}). However, fixation adds another 6.78 g N m^{-2} year^{-1} to the marsh, so the net removal of N from the land and the atmosphere is 4.43 g N m^2 year^{-1}, or 33%. This can be compared to the N exported at the mouth (net export of 11.16 g N m^{-2} year^{-1}), which would suggest a smaller removal of land and atmospheric inputs (2.29 g N m^{-2} year^{-1} or 17%). Approximately 55% of inputs (from land and fixation) are exported to the ocean, with the remainder stored or denitrified. These balances make it clear that marshes can be both sinks and sources within the larger landscape.

4. Eutrophication and Management

There have been at least two studies examining the effects of applying sewage to salt marshes. The reader is directed to papers by Haines, Sherr and Chalmers for a review of these studies in a Georgia salt marsh (e.g., Chalmers *et al.*, 1976) and to papers by Valiela, Teal, and Howes for a Massachusetts tidal marsh (e.g., Valiela *et al.*, 1973, 1976, 1985b). A number of studies have also examined how anthropogenic nutrient inputs may be affecting salt marshes (Bertness *et al.*, 2002; Rosensweig, 1999; Warren and Niering, 1993). Unlike non-tidal, freshwater marshes, tidal salt marshes are typically not used for the treatment of wastewaters but by virtue of their location are receiving ever increasing N loads. The estuarine research and management community is greatly concerned about N-enrichment and eutrophication of estuaries (NRC, 2000). There is the general feeling that salt marsh dominated estuaries are less susceptible to N-enrichment (NRC, 2000), but the data to rigorously defend this assumption is lacking and in need of substantial future research.

Comparative evidence suggests that estuaries with salt marshes protect adjacent seagrass meadows from land-derived N loads (Valiela and Cole, 2002). The specific role that marshes play in actually reducing total external loads (land, atmospheric, oceanic) can be determined by the net balance between new internal inputs (fixation) and the internal sinks (denitrification and burial). Our examination of the literature suggests that denitrification and burial are of similar magnitudes on a system basis. As each of these processes equals or exceeds published rates of N fixation it appears that marshes can in fact play a role in protecting downstream coastal ecosystems from land and atmospheric N inputs. Valiela *et al.* (2000) suggest that salt marshes can play an effective role in systems with external loading rates up to 10 g N m^{-2} year^{-1}. However, if fixation decreases with increased loading, and denitrification increases with loading to the degree seen in some studies (Hamersley and Howes, 2005), then marshes may be effective at even higher loading rates. An exception to this pattern may be young or constructed salt marshes where fixation appears to exceed denitrification. In addition, by transforming dissolved inorganic N to organic forms (most of which have extremely long turnover times relative to NO$_3$) and temporally buffering N loads to downstream systems, all marshes could

play a substantial role in reducing some of the adverse effects of nutrient loading on seagrass meadows and open water systems. However, research to support this hypothesis is currently lacking.

5. ROLE OF SALT MARSHES IN GLOBAL NITROGEN BALANCE

Anthropogenic alterations of the global N cycle have increased our interest in quantifying global N sinks and source. Here we ask what role salt marshes might play in the global cycle. Based upon a global salt marsh area of 3.8×10^{11} m^2 (Maltby, 1988) and a median denitrification rate of 21 mg N m^{-2} day^{-1} (after eliminating negative net numbers which include fixation), marshes return about 3 Tg N year^{-1} to the atmosphere. This level of denitrification is less than the amount of denitrification taking place in estuarine subtidal sediments worldwide, estimated at 8 Tg N (Seitzinger *et al.*, 2006). While there may be some overlap in the small creek areas considered in our estimate and the subtidal sediments used in the Seitzinger *et al.* (2006) calculations, the majority of the 3 Tg N year^{-1} we calculate for marshes would be in addition to their estimate for estuaries as a whole (including marshes). Even when added together however, coastal areas are minor sinks for N when compared to continental shelves and oceanic oxygen minimum zones, which together remove more than 300 Tg N year^{-1} (Seitzinger *et al.*, 2006). We expect there to be large variances associated with these global estimates. While the magnitude of the error is hard to quantify, an indication of its size can be seen merely from the range of values associated with N cycling rates in Table 22.7, and this does not include any potential error in the estimate of global salt marsh area.

The loss of N through denitrification is partially offset by N fixation. Using the median N fixation rate of 12.6 mg N m^{-2} day^{-1}, total N fixation introduces about 1.7 Tg N year^{-1} into marshes.

Estimates of natural global N fixation range from 190 to 370 Tg N year^{-1} but in either case, marshes represent only a small fraction of the global total (Galloway *et al.*, 2004). However, it does mean that there is a net loss of combined N as N$_2$ in marshes at a rate of about 1.3 Tg N year^{-1}.

Although marshes may be only a small global sink for combined N, marshes do play a significant role in removing N from the coastal zone. If we again use the global marsh area and assume a burial rate of 7–15 g N m^{-2} year^{-1} then 2.6 to 5.7 Tg N year^{-1} is sequestered in marshes. When this is added to gaseous losses, on net balance marshes remove approximately 4–6 Tg N year^{-1}.

When compared to the total amount of N entering the coastal zone from anthropogenic sources, which now exceed 150 Tg N year^{-1}, the global contribution of marshes in removing anthropogenic N is small globally but relatively large in proportion to the total marsh area. However, if this removal is compared to the amount of N entering coastal areas then it is locally quite significant. Riverine inputs averaged for all coastal temperate systems between 23.5° and 66°N and S are 16.8 Tg N year^{-1} (Chapter 9 by Seitzinger and Harrison, this volume). Not all of this load enters estuaries, and this does not include groundwater or direct deposition. However, salt marshes may remove as much as 1/3 of this load.

6. Summary and Future Research Directions

1. Our current state of knowledge on the controls, and even the quantity of net gaseous fluxes of N_2 in salt marshes is poor due to the problems of applying existing methods to vegetated intertidal sediments. Methods need to be improved to enable measures of N_2 flux across the salt marsh sediment—atmosphere interface including marsh macrophytes. However, even with the limitation of existing methods, the number of studies on gaseous N fluxes in salt marshes is quite small and seasonal data is lacking.

2. In spite of the limitations of the data, this review has shown that most salt marshes appear to serve as a net sink for N. Very young marshes, or constructed marshes appear to be exceptions to this pattern. Although on a global basis marshes do not play a major role in the global N cycle, areal rates of N sequestration are high enough that marshes can play a significant local role in removing N.

3. Marshes have experienced increased input of anthropogenic N loads over the last century. There is growing evidence that fixation, denitrification and even sedimentation rates are altered by increased external N inputs but these responses need to be much better understood and quantified.

4. There are large fluxes of N between marshes and tidal creeks and between marsh/creek complexes and estuarine and coastal waters. The net direction of the fluxes is not consistent and the rules governing exchange are not well understood. A review of a small number of studies has suggested that marshes generally export N to coastal waters, although some specific forms, such as nitrate may be imported. Marshes play a large role in altering both the timing and the form of N flowing from land to sea. The degree to which this interaction buffers coastal systems from land-based nutrient inputs and supports estuarine food webs needs to be better understood.

SEAGRASS HABITATS

Karen J. McGlathery

Contents

1. INTRODUCTION

Seagrasses are marine flowering plants that comprise approximately 0.02% of the species of angiosperm flora, with >60 recognized species (den Hartog and Kuo, 2006; Hemminga and Duarte, 2000). They are distributed worldwide in the coastal zone of every continent except Antarctica, and are estimated to cover about 10% of coastal sediments (Charpy-Rouband and Sournia, 1990). Seagrasses are among the most productive ecosystems in the world, with annual rates of production similar to

that of salt marshes, coral reefs, and tropical rainforests (Valiela, 1995). As "foundation" species, seagrasses provide food resources and a three-dimensional habitat structure that supports a diverse array of algae, invertebrates, fish, and megafauna (e.g., turtles, dugongs). Many of these species are of high commercial value. Seagrasses are also tightly linked to adjacent ecosystems; they serve as both a nursery ground for juvenile fish that spend their adult lives in coral reefs or offshore (e.g., Jackson *et al.*, 2001) and export dissolved and particulate organic matter (e.g., Hemminga *et al.*, 1991). Finally, seagrass roots and rhizomes stabilize the seafloor, preventing sediment erosion/resuspension and promoting particle deposition (Gacia *et al.*, 2002; Kenworthy *et al.*, 1982; Koch, 1999). These ecosystem services make seagrasses a particularly valuable coastal resource. At the same time, seagrasses are vulnerable to environmental changes and recent studies have documented global declines in seagrass habitat, many of which are associated with anthropogenic stresses (Hauxwell and Valiela, 2004; see online list referenced in Orth *et al.*, 2006).

Seagrasses colonized the marine environment about 100 million years ago from either coastal land plant or freshwater plant ancestors (Den Hartog, 1970). To successfully adapt to marine conditions, these plants had to acquire characteristics for architecture in a high-energy environment, submarine pollination, and internal gas transport to shunt oxygen to the root zone (Hemminga and Duarte, 2000). Seagrass diversity is low compared to freshwater or terrestrial plant communities. There are 50 species in 12 genera representing only 2 families: Hydrocharitaceae and Potomogeonaceae. This number will likely change as new studies using DNA sequencing provide evidence of genetic diversity in seagrass meadows (Waycott *et al.*, 2006). Most seagrass meadows are monospecific; even the most speciose meadows, which occur in the Indo-Pacific and the Red Sea, have <12 species. Globally, there is a pattern of decreasing species diversity from the equatorial zone to higher latitudes. Most of the species diversity in seagrass meadows is related to the algae and fauna associated with the seagrasses. Within a species geographic range, high production rates are controlled by temperature, light, and nutrient availability. Adequate substrate and dessication are also important determinants of species distributions, as is disturbance, including storms, intense grazing, siltation, and excess nutrient loading (eutrophication). Most species are confined to sandy–muddy sediments, although a few species can grow over rock and in the intertidal zone.

Nitrogen (N) cycling processes in shallow coastal systems are influenced by seagrasses in several important ways. Seagrasses affect the timing and pathways of N processing through uptake and temporary retention in their tissue and the subsequent fate of this plant-bound N. In many (if not most) systems, N (and phosphorus) assimilation by seagrasses (and other primary producers) is of the same magnitude as watershed and atmospheric nutrient loading (Pedersen *et al.*, 2004). Thus, seagrasses and other marine primary producers are an important part of the estuarine filter and have a major impact on the fate and retention of nutrients as they transit through the system (McGlathery *et al.*, 2007). The possible fates of plant-bound N include mineralization and burial, grazing and subsequent excretion,

exudation, and advection/export of plant tissue. Seagrasses also influence physico-chemical conditions that affect the rates and pathways of bacterially and chemically mediated nutrient transformations such as mineralization, nitrification, N fixation, dissimilatory nitrate reduction to ammonium (DNRA), and sediment diagenesis. Changes in seagrass distribution and abundance in response to environmental change or restoration will likely have significant effects of the fate and transformations of N in nearshore coastal environments.

2. Nitrogen Inputs to Seagrass Ecosystems

Nitrogen inputs to seagrass ecosystems derive from both external sources of ''new'' N and internal sources of recycled N from sediment mineralization (and to a lesser extent from N excreted by consumers). The external sources of N to seagrasses include inputs from the watershed and airshed and bacterial N fixation within the system. Watershed nutrient inputs are enriched from fertilizer application, atmospheric deposition, and urban/domestic wastes, and are delivered to estuaries and coastal bays via surface and groundwater flow (see Seitzinger and Harrison, this volume). The production of inorganic fertilizer represents the single largest human alteration of the global N cycle, accounting for over half of the increase in bioavailable N (Galloway et al., 2003; Howarth et al., 2002; Vitousek et al., 1997). This is coincident with the explosive increase in coastal eutrophication from nutrient over-enrichment. The worldwide trend of increasing urbanization along the coastline, and shifts from forest to agricultural, suburban, and urban land use have accelerated delivery rates of nutrients and sediments to seagrass ecosystems (Nixon, 1997; Valiela et al., 1992). Atmospheric deposition of organic (DON) and inorganic N (NO_x) is enriched from the burning of fossil fuels, and is especially important in the N budget of shallow coastal bays and lagoons where seagrass abound and where the surface area to water volume ratio is high (Paerl, 1995). In some of these systems, the contribution of atmospheric N is of similar magnitude to that of groundwater N (Sigua and Tweedale, 2003). Nitrogen fixation accounts for 5–65% of seagrass N demand in diverse temperate and tropical systems (McGlathery et al., 1998; Welsh, 2000).

Internal recycling of N from sediment mineralization is a critically important N source for seagrasses, particularly in shallow coastal bays and lagoons that lack significant riverine inputs and where the sediment surface area is high relative to the volume of the water column (Chapter 8 by Bronk and Steinberg, this volume; Chapter 19 by Joye and Anderson, this volume; McGlathery et al., 2007). The nutrient demands of seagrasses appear to be met in large part by internal recycling of organic-bound nutrients in the sediment (Alcoverro et al., 2000; Hemminga et al., 1991; McGlathery et al., 2001a), although foliar uptake of ''external'' nutrients in the water column and root uptake of groundwater nutrients also may be important (Lepoint et al., 2002a; Stapel et al., 1996).

3. Nitrogen Controls on Production, Morphology, and Dynamics of Seagrasses

3.1. Evidence for nitrogen limitation

Nitrogen limitation is common in temperate coastal systems with siliclastic sediments (Howarth et al., 1988). However, benthic production in these systems is frequently limited by light availability rather than by nutrient availability (Dennison et al., 1987; Pedersen, 1995). The dichotomy of N limitation of primary production in temperate systems with siliclastic sediments and phosphorus (P) limitation in systems (typically tropical–subtropical) with carbonate sediments was first proposed by Short (1987), and has been attributed to (1) high rates of denitrification relative to N fixation (but see below) and (2) to the binding of P by carbonate sediments, which reduces P availability for plant uptake (Fourqurean et al., 1992; McGlathery et al., 1994; Morse et al., 1985; Short et al., 1990). However, there are many studies that show N limitation of seagrass or macroalgal growth in carbonate sediments (Erftemeijer et al., 1994; Ferdie and Fourqurean, 2004; McGlathery et al., 1992; Udy et al., 1999). The biogeochemical factors that may explain this variability include differences in sediment grain size (Erftemeijer et al., 1994), sorption–site saturation for P (McGlathery et al., 1994), and carbonate dissolution in the seagrass rhizosphere (Burdige and Zimmerman, 2002; Jensen et al., 1998; Long et al., 2008). There are also a few fertilization studies that indicate P limitation of seagrass growing in temperate systems or in sediments with low carbonate content (Harlin and Thorne-Miller, 1981; Murray et al., 1992; Perez et al., 1991). Clearly, species- and site-specific characteristics are more important than previously thought in determining N (versus P) limitation of seagrass.

For N-limited seagrass, an increase in ambient N concentrations, either in the sediment pore water or the water column, increases foliar or root uptake (Pedersen et al., 1997a,b; Perez-Lorens and Niell, 1995; Touchette and Burkholder, 2000). Higher N assimilation rates are indicated by increases in glutamine synthase or nitrate reductase activities (Pregnall et al., 1987; Touchette and Burkholder, 2000). Also, both the total tissue N content and specific N pools (nitrate, asparagines, glutamine) increase with higher N availability (e.g., Duarte, 1990; Erftemeijer et al., 1994; Terrados et al., 1999; Uddy and Dennison, 1997; Udy et al., 1999). The increase in tissue N content can be diluted by new growth if utilization is faster than uptake in high light environments (Peralta et al., 2002; Ruiz and Romero, 2001). If concentrations of NH_4^+ and NO_3^- exceed thresholds for upper tolerance limits, seagrass photosynthesis and growth decline (Burkholder et al., 1992, 1994; van Katwijk et al., 1997).

3.2. Nitrogen effects on seagrass architecture and production

Nitrogen enrichment changes specific morphologic characteristics as well as the allocation of plant biomass to aboveground and belowground tissues. Many studies report increases in leaf length and width, and shoot height and biomass in response to

N (and P) enrichment (e.g., Murray *et al.*, 1992; Terrados *et al.*, 1999; Udy and Dennison, 1997). Fertilization and nutrient gradient studies show that biomass allocation patterns change in predictable ways with increases in water column or sediment nutrient availability. The root–shoot ratio decreases with higher sediment nutrient availability, as plants allocate less biomass to root/rhizome tissue (Perez *et al.*, 1991; Powell *et al.*, 1989). When sediment nutrient concentrations are low, more biomass is allocated to belowground tissues to increase the surface area for nutrient uptake (Vogt *et al.*, 1993). There is insufficient information about how rhizome architecture changes with nutrient availability, including branching frequency and angle and internode length, although these characteristics are known to be as plastic in some species as leaf morphology.

Changes in biomass and productivity in response to nutrient enrichment are seen both at the individual and population levels. Responses of individual ramets include increases in leaf growth, length, and turnover (e.g., Lee and Dunton, 2000; Murray *et al.*, 1992; Udy and Dennison, 1997). At the population level, nutrient enrichment has been shown to increase both recruitment and shoot mortality (Perez *et al.*, 1991). Higher rates of mortality may be related to greater intra-specific competition for light, or to NH_4^+ or NO_3^- toxicity (Burkholder *et al.*, 1992; 1994; Hauxwell *et al.*, 2001; van Katwijk *et al.*, 1997; Perez *et al.*, 1994). The effects of N enrichment on allocation to flowering are not known, but may be important as this reproductive pathway requires substantial N resources.

3.3. Nitrogen effects on seagrass community structure and distribution

At the community level, N (and P) enrichment causes a shift in the dominance of primary producers, from seagrasses and perennial macroalgae to fast-growing macroalgae and phytoplankton (Duarte, 1995; Sand-Jensen and Borum, 1991; Valiela *et al.*, 1997). Increased nutrient loading related to anthropogenic activities appears to be responsible for 60% of the global seagrass loss (Short and Wyllie-Escheverria, 1996). Loss of seagrass is associated with shading from enhanced algal standing stocks (macroalgae, epiphytes, and/or phytoplankton; Hauxwell *et al.*, 2001, 2003; Neckles *et al.*, 1994; Nixon *et al.*, 2001; Short *et al.*, 1995; Twilley *et al.*, 1985). In addition, changes in the biogeochemical environment surrounding the seagrass roots and shoots, such as anoxia and increased sulfide and NH_4^+ concentrations, can lead to seagrass decline (Greve *et al.*, 2003; Hauxwell *et al.*, 2001). There is also evidence that in the more speciose tropical systems competition between seagrass species with N and P enrichment causes a shift in seagrass dominance before algal proliferation occurs (Fourqurean *et al.*, 1995; Udy and Dennison, 1997). Early indicators of eutrophication effects on seagrasses have been identified as increases in leaf elongation rates, shoot–root biomass ratios, and the ratio of leaf N to leaf mass, and a decrease in shoot density (Lee *et al.*, 2004; Nixon *et al.*, 2001).

In many systems, water column N concentrations set the maximum depth limit of seagrass by influencing phytoplankton biomass and light attenuation in the water column (Abal and Dennison, 1996; Nielsen *et al.*, 2002). Increased epiphyte biomass with higher N loading attenuates light at the scale of the seagrass blade (Brush and

Nixon, 2002; Howard and Short, 1986; Sand-Jensen, 1977), and can attenuate 10–90% of light potentially reaching the leaf surface. Also, bloom-forming macroalgae that form dense canopies up to 1 m thick over seagrass beds in high N waters can decrease light levels by >90% (Astill and Lavery, 2001; Krause-Jensen *et al.*, 1996; Peckol and Rivers, 1996), and particularly impact newly recruiting shoots that often lie entirely under, or within, the macroalgal mat (Hauxwell *et al.*, 2001). The reduction in seagrass photosynthesis that results from algal shading decreases oxygen translocation and release to the rhizosphere (Goodman *et al.*, 1995; but see Terrados *et al.*, 1999). This creates a positive feedback where the high concentrations of hydrogen sulfide that develop in the rhizosphere decrease nutrient uptake and plant energy status (Pregnall *et al.*, 1984), and result in further reductions in photosynthesis, growth, and leaf density, and sometimes, eventual mortality (Goodman *et al.*, 1995; Holmer and Bondgaard, 2001).

Benthic faunal communities are altered by changes in rates of primary production and a shift from seagrass to benthic algae with increased N loading (Diaz and Rosenberg, 1995; Grall and Chauvaud, 2002). During the early stages of nutrient enrichment, an increase in species richness, abundance, and biomass of macrofauna has been associated with an increase in food supply (Grall and Chauvaud, 2002). Also, several studies have shown that the structural complexity associated with increasing macroalgal biomass at low to moderate densities in seagrass beds reduces predation rates on mobile epifauna (e.g, crustaceans, fish) by providing more refuge (Isaksson *et al.*, 1994; Norkko, 1998; Pihl *et al.*, 1995; Raposa and Oviatt, 2000). As systems become more nutrient enriched and algal blooms occur, changes in oxygen and sulfide conditions cause the benthic infaunal community to shift from deep bioirrigating organisms to tube-building filter feeders which are less effective at mixing and irrigating the sediments (Henriksen *et al.*, 1980; Gray, 1989; Pearson and Rosenberg, 1978). Since these bioirrigating macrofauna stimulate coupled nitrification–denitrification in sediments by increasing the sediment surface area and oxygen penetration along burrow walls, and also the fluxes of water column nitrate into the sediments (Aller and Rude, 1988; Bronk and Steinberg, this volume; Joye and Anderson, this volume; Mayer *et al.*, 1995; Pelegri *et al.*, 1994), their loss will likely reduce the natural capacity of systems to buffer N loading. Ultimately, increased periods of sediment anoxia will result in a decrease in the abundance and diversity of benthic fauna and will reduce the role of seagrasses in supporting higher trophic levels (Deegan *et al.*, 2002; Gray, 1992, Norkko and Bonsdorff, 1996a,b).

4. Nitrogen Incorporation in Seagrass Biomass

Rates of N assimilation and retention vary with plant size, reflecting differences in relative surface area, and/or thickness (Sand-Jensen and Nielsen, 2004). In general, seagrasses have tissues that are lower in nutrients and higher in lignin, and have relatively lower photosynthetic potential and inherent growth rates, than benthic microalgae and ephemeral macroalgae (Duarte, 1995; Hein *et al.*, 1995). Seagrasses are able to meet their nutrient requirements in areas of relatively low

nutrient availability by reducing their dependence on nutrient sources through (1) exploiting tissue storage pools and (2) reclaiming nutrients from decaying tissues, and also by accessing sediment nutrient pools via their roots (Alcoverro *et al.*, 2000; Pedersen and Borum, 1993; Stapel and Hemminga, 1997).

4.1. Uptake

Seagrasses obtain nutrients both from sediment pore waters and from the overlying water column. Concentrations of inorganic N are typically one to several orders of magnitude higher in sediment pore waters than in the water column as a result of organic mineralization (Touchette and Burkholder, 2000) and nitrogen fixation in the sediment. Ammonium is the dominant source of inorganic N in the anoxic rhizosphere, with concentrations ranging from 1 to 200 M (Touchette and Burkholder, 2000). Leakage of oxygen from the lacunar system in the roots creates oxidized microzones where NH_4^+ is oxidized to NO_3^-; however, these microzones are limited to a few millimeters (Frederiksen and Glud, 2006) along the root tips, and bulk measurements of sediment pore water rarely detect NO_3^-. When NO_3^- is present in the pore water, it is more likely ''new'' N from groundwater inputs (McGlathery *et al.*, 2001a). In addition to inorganic forms of N, amino acids can contribute to seagrass nutrient demands, although there is relatively little work on DON uptake by seagrasses compared to marine algae (Bird *et al.*, 1998; Tyler *et al.*, 2003; Ward and Bronk, 2001).

The relative role of sediment versus water as a nutrient source to seagrasses depends on the concentrations of available nutrients for each source, the surface area of the leaves relative to the roots and their uptake capacities, and the thickness of the diffusive boundary layer surrounding the leaves and roots (Lepoint *et al.*, 2002a; Stapel *et al.*, 1996). These effects are important both within a single species where growth conditions vary, and between species with different morphologies. Earlier studies indicated that root uptake was the primary mechanism for meeting seagrass nutrient demands because of the high nutrient concentrations in sediment pore waters (e.g., Thursby and Harlin, 1982). There is considerable variation among species, however, and there is some evidence that root uptake can be limited by diffusion (Lee and Dunton, 1999; Stapel *et al.*, 1996). Several recent studies have shown that the contribution of leaf and root uptake is of approximately equal magnitude (Table 23.1; Lee and Dunton, 1999; Lepoint *et al.*, 2002a). Growth form also has an important influence on the relative importance of root vs. leaf uptake. Annual populations of the temperate seagrass, *Zostera marina*, may rely solely on leaf uptake, whereas perennial populations with greater root biomass have both significant root and leaf uptake (Hemminga *et al.*, 1994; Pedersen and Borum, 1993). As an extreme example, species such as *Phyllospadix torreyi* that grow on rocky substrate assimilate all nutrients through the leaves (Terrados and Williams, 1997). Because leaves can have relatively high nutrient uptake affinities, many seagrass species can assimilate N when water column concentrations are very low (Lee and Dunton, 1999; Pedersen *et al.*, 1997a,b). Water column nutrient enrichment may cause a shift from root to leaf uptake as the dominant process of nutrient acquisition. Nutrient uptake by seagrass leaves is influenced by the thickness of the diffusive

Table 23.1 Nitrogen uptake parameters for seagrass species based on Michaelis–Menten uptake kinetics

Seagrass species	Organ	Nutrient	V_{max} (μmol g DW^{-1}h^{-1})	K_m (μM)	$\alpha \cdot (V_{max}/K_m)$	Source
Temperate						
Z. marina	Leaf	NH_4^+	1.1–3.2			Short and McRoy (1984)
Z. marina	Leaf	NH_4^+	20.5	9.2	2.2	Thursby and Harlin (1982)
A. antarctica	Leaf	NH_4^+	5.9–43.1	9.5–74.3	0.6–0.8	Pedersen *et al.* (1997)
P. torreyi	Leaf	NH_4^+	96–204	9.3–34	6–10.3	Terrados and Williams (1997)
Z. marina	Leaf	NO_3^-		23		Iizumi and Hattori (1982)
P. torreyi	Leaf	NO_3^-	25–75	4.4–17	4.4–5.7	Terrados and Williams (1997)
Z. marina	Root	NH_4^+	0.9–2.9			Short and McRoy (1984)
Z. marina	Root	NH_4^+	211	104	0.5	Thursby and Harlin (1982)
Z. marina	Root	NH_4^+		30		Iizumi and Hattori (1982)
A. antarctica	Root	NH_4^+	1.1	4.7	0.2	Pedersen *et al.* (1997)
Tropical/subtropical						
Thalassia testudinum	Leaf	NH_4^+	8.3–16.4	7.6–15	0.6–2.8	Lee and Dunton (1999)
T. hemprechii	Leaf	NH_4^+	32–37	21	0.5–0.9	Stapel *et al.* (1996)
T. testudinum	Leaf	NO_3^-	3.7–6.5	2.2–38.5	0.2–1.7	Lee and Dunton (1999)
T. testudinum	Root	NH_4^+	8–73	34	0.03–0.3	Lee and Dunton (1999)

V_{max} is the maximum uptake rate, K_m is the half-saturaion constant, and α is the uptake efficiency at low nutrient levels (V_{max}/K_m).

boundary layer. Wave action may reduce the boundary layer thickness and enhance uptake by as much as an order of magnitude (Stevens and Hurd, 1997). Epiphytes also may reduce the boundary layer thickness under turbulent conditions by creating surface roughness, but they also compete with seagrasses for water column nutrients.

In a recent review of N and P metabolism in seagrasses, Touchette and Burkholder (2000) provide a detailed description of the mechanisms of NH_4^+ and NO_3^- uptake and assimilation. Nitrate is taken up via an active, inducible, protein-based transport system that is specific to NO_3^- and inhibited by anaerobic conditions. Ammonium uptake is apparently more complex, involving a low-affinity system based on passive movement of NH_4^+ through membrane channels, and a high-affinity system that requires the synthesis of proteins that transport NH_4^+ through membrane channels. Compared to marine algae, much less is known about organic N uptake. There is very limited evidence of species that are capable of both amino acid and urea uptake, and some that are not (Bird *et al.*, 1998; McRoy and Goering, 1974). Clearly, this is an area where more research is needed, especially for systems where concentrations of dissolved organic N exceed that of inorganic N in the water column (McGlathery *et al.*, 2001b).

Numerous estimates of Michaelis–Menten kinetic parameters for N uptake have been reported for both leaves and roots of various seagrass species, and show that uptake rates are both highly variable across species and between leaves and roots (Table 23.1). For most species, the uptake "affinity," which reflects the efficiency of nutrient uptake at low nutrient concentrations ($\alpha = V_{max}/K_m$), is generally higher for NH_4^+ than for NO_3^-. This indicates that many seagrasses are more efficient at NH_4^+ uptake, and this is consistent with the higher cost of NO_3^- reduction and assimilation. NH_4^+ uptake is also more efficient in leaves compared to roots (lower α for roots), which likely reflects the lower ambient concentrations in the water column than in the sediment porewaters. V_{max} reflects the uptake "capacity" (an indication of the number of active uptake sites; Touchette and Burkholder, 2000), and variability is so high that there appear to be no clear trends either between NO_3^- and NH_4^+ or between leaves and roots. A few studies have shown linear responses in both NH_4^+ and NO_3^- uptake for *Z. marina*, *Thalassia hemprichii*, and *Amphibolis antarctica*, rather than the substrate saturation of Michaelis–Menten kinetics (Paling and McComb, 1994; Roth and Pregnall, 1988; Stapel *et al.*, 1996). The reasons for these two kinds of responses in the same species is unknown, but might reflect an adaptation to a limiting and/or pulsed nutrient supply.

Once taken up into the plant cell, NH_4^+ is assimilated via the glutamine synthetase (GS)/glutamate synthase (GOGAT) pathway (see Touchette and Burkholder, 2000 for details). Ammonium typically does not accumulate in seagrass tissues, partly because of its toxicity to chloroplast function, and is rapidly assimilated into organic compounds. The same pattern has been shown for marine macroalgae (McGlathery *et al.*, 1996). Studies of GS activity in seagrasses (particularly *Z. marina* and *Posidonia oceanica*) indicate the importance of the leaves as well as the roots in NH_4^+ assimilation (Kraemer and Alberte, 1993; Kraemer *et al.*, 1997; Pregnall *et al.*, 1987). Temperature and light availability account for some of the seasonal differences in GS activity (Kraemer *et al.*, 1997), and ultimately, the supply of NH_4^+, carbon skeletons, and ATP from photosynthesis influence GS rates. Nitrate reduction to

NH_4^+ (via nitrite reduction) and subsequent assimilation into organic compounds is a more energy-expensive process. The activity of the enzyme nitrate reductase (NR) that catalyzes the initial reaction is induced by the presence of NO_3^- in the plant tissue and is influenced by light availability (see Touchette and Burkholder, 2000 for details). Nitrate reduction occurs both in the leaves and roots, but appears to be the highest in leaves where NO_3^- is typically stored in vacuoles and where energy and carbon skeletons are produced via photosynthesis. NR activity is usually directly related to carbohydrate availability. If carbohydrate availability is low, then NR response to enhanced NO_3^- availability also tends to be low (Touchette and Burkholder, 2001; Zimmerman *et al.*, 1987). Young *et al.* (2005) measured NR activity associated with epiphytes on seagrass leaves (*Posidonia sinuosa* and *A. anartica*) and showed that this was as important as NR in seagrasses as a sink for water column NO_3^-.

4.2. Turnover in plant biomass

Seagrasses have several nutrient conservation strategies that enhance nutrient use efficiency and reduce the demand for uptake of nutrients from the environment. Internal recycling, enhanced leaf longevity, and storage are important mechanisms that reflect a high efficiency for retaining nutrients within plant tissues, and are advantageous in nutrient-poor coastal waters. Nutrient conservation by resorption from senescing leaves and reallocation to young, growing leaves has been studied for several seagrass species (*Z. marina*, *P. oceanica*, *T. hemprichii*; Alcoverro *et al.*, 2000; Borum *et al.*, 1989; Invers *et al.*, 2002; Lepoint *et al.*, 2002b; Pedersen and Borum, 1992; Stapel *et al.*, 2001). It is common for leaf N concentration to decrease with increasing leaf age (Alcoverro *et al.*, 2000; Borum *et al.*, 1989; Kraemer and Mazzella, 1999). This reflects N resorption and recycling as well as leaching from ageing leaves. Invers *et al.* (2002) suggested that N is transported during resorption primarily as free amino acids. Resorption may be most important in temperate seagrasses in the spring-summer when the growth is high and when external nutrient concentrations are often depleted (Alcoverro *et al.*, 1997; Pedersen and Borum, 1993; Pedersen *et al.*, 1997a,b; Stapel and Hemminga, 1997).

　　The methods for calculating nutrient resorption efficiency have included either (1) a mass balance approach to determine the percent reduction of nutrients between mature green and senescent leaves, or (2) ^{15}N tracer studies to follow the reuse of labeled N in plant tissues. The mass balance approach is less precise in that it does not consider potential leaching losses. However, studies on the same species using the two methods agree reasonably well (Romero *et al.*, 2006), suggesting that leaching losses may be small. Estimates for nutrient resorption range from 10 to 50% of annual N requirements for a variety of species (Romero *et al.*, 2006). For example, Pedersen and Borum (1992) showed that internal recycling could contribute up to 12% of the annual N demand of *Z. marina* leaves, Stapel *et al.* (2001) determined N resorption accounted for 28% of the N demand of *T. hemprichii* in Indonesia, and Lepoint *et al.* (2002b) and Alcoverro *et al.* (2000) found that the annual contribution of recycled N for *P. oceanica* was 40%.

Leaf longevity is important for nutrient conservation, and the higher values for *P. oceanica* may be related to the long lifespan of the leaves (as high as 300 days). High leaf longevity increases the time for nutrient resorption and also reduces nutrient demand by decreasing the frequency of leaf formation. In an earlier review of the literature, Hemminga *et al.* (1999) calculated an average resorption efficiency of 20%, which is about half that of perennial terrestrial plants (Duarte and Hemminga, 2000).

Nitrogen can be stored in both rhizomes and leaves; this slows the turnover of N in plant tissues. Nitrogen can be stored on a short time scale of hours to days and on a longer (weekly to seasonal) time scale. Short-term storage usually involves uptake and reduction of NO_3^- when it becomes available as pulses, such as during storms or at night (Invers *et al.*, 2002; Romero *et al.*, 2006; Touchette and Burkholder, 2000). Ammonium would not be expected to accumulate in plant tissues due to its toxicity (McGlathery *et al.*, 1996). Seasonal storage occurs in response to imbalances in the supply and demand of N. Nitrogen accumulates in seagrass tissues during periods when availability is high and growth conditions (light and temperature) are suboptimal (Alcoverra *et al.*, 1997; Kraemer and Mazzella, 1999), and these are used to mobilize growth when conditions improve. Amino acids can be long-term storage pools in seagrasses (Invers *et al.*, 2002; Udy *et al.*, 1999), and soluble proteins also can be important (Murray and Larkum, 1991). Invers *et al.* (2002) found that free amino acids accounted for 50% of the N pools in *P. oceanica*, and were important for N storage in rhizomes over the winter.

5. Fate of Assimilated Nitrogen

The presence of seagrasses slows the overall rate of N cycling compared to algal–dominated systems (Duarte, 1995). Nitrogen that is assimilated by seagrasses is, for the most part, temporarily retained in the system on a time scale of weeks to months. This is longer than the retention time for either bloom-forming macroalgae (days–weeks) or microalgae (days). Seagrass-dominated systems are expected to have higher rates of burial than algal-dominated systems in part because of the inherently greater refractory content of seagrass tissue (and lower nutrient content), and in part because of the presence of belowground material (roots and rhizomes) that is less likely to be exported (Banta *et al.*, 2004; Buchsbaum *et al.*, 1991; Duarte and Cebrián, 1996; Enriquez *et al.*, 1993; Klap *et al.*, 2000).

Most of the N bound in seagrass tissue will ultimately become available through leakage from live tissue, remineralization through decomposition, and grazing and subsequent excretion (Cebrian, 2002; Duarte and Cebrián, 1996). This is shown conceptually in Figure 23.2. The timing of this retention and nutrient release can be important as it can slow the seaward transport of nutrients and reduce nutrient availability for other autotrophs during the growing season. For example, N that was temporarily retained in *Z. marina* leaf tissue in a Danish coastal bay was either nearly completely mineralized (95–98%) in the fall when phytoplankton blooms were less likely to occur, or were lost when the leaves were detached and transported from the system (Risgaard-Petersen and Ottosen, 2000). Some material may be removed from

the system by long-term burial or export as dissolved or particulate organic matter (Figure 23.2). Export of senescent leaf material may be an important loss of N from the system, and this exported material can fuel secondary production in adjacent intertidal and subtidal systems such as marshes, mudflats, and even deep basins (Melville and Connolly, 2005; Suchanek *et al.*, 1985).

5.1. Mineralization and burial

The major fate of seagrass aboveground biomass in modern seagrass systems is decomposition and transfer through the detrital food chain, either *in situ* or after being transported to adjacent regions. However, measured rates of decomposition vary, with studies reporting rates ranging from 15 to 95% of total plant production (Mateo *et al.*, 2006). This amount is greater than that for many terrestrial producers (Cebrian, 1999). Decay of leaf litter *in situ* may contribute as much as 10–46% of the annual N demands for leaf production of several species, including *A. antarctica*, *P. oceanica*, *Cymodocea nodosa* (Romero *et al.*, 2006, and references therein).

Tissue N may play an important role in decomposition and detrital processing of seagrass biomass. Several studies have shown a direct relationship between higher tissue N content in senescent and detrital material and faster decomposition rates (Harrison, 1989; Lopez *et al.*, 1998; Mateo and Romero, 1997; Perez *et al.*, 2001). This would be expected if N is limiting to decomposers. Lopez *et al.* (1998) did find that nutrient fertilization increased bacterial activity and reduced sediment organic matter content by >30% in N-limited *P. oceanica* meadows in the Mediterranean. However, there is some evidence from correlative work using data from studies of six species, including *T. hemprichii*, *T. testudinum*, *P. oceanica*, *Z. marina*, *Zostera noltii*, and *Syringodium filiforme* that detrital N content and decomposition rates were not strongly related (Enriquez *et al.*, 1993). Overall, the effect of tissue N content on decomposition rates of seagrasses appears to be more equivocal than what has been reported for salt marshes (Chapter 22 by Hopkinson and Giblin, this volume), and more research is needed to determine the influence of tissue N content on decomposition.

Some of the difficulty in generalizing among individual studies may be related to the type of material used (e.g. senescent, detrital, fresh), the method used, and the length of the incubation. Decomposition typically follows a 3-phase exponential pattern of decreasing weight loss: (1) a short, rapid phase of leaching of soluble compounds, (2) a slower phase of microbial decomposition and release of soluble compounds, and (3) the slowest phase of breakdown of refractory compounds. The time scale of the different phases of degradation may vary considerably among seagrass species. Different methods used for the same species also may support different conclusions. For example, Banta *et al.* (2004) found that over 86% of *Z. marina* root and rhizome detrital mass (as N) and 14% leaf detrital mass (as N) remained after nearly 2 yr of a litter bag experiment. However, Risgaard-Petersen and Ottosen (2000) modeled *Z. marina* decomposition and suggested that most of the N bound in sloughed plant material was released within one year. Studies have reported different time scales to reach the refractory phase, from several months (*Z. marina*; Banta *et al.*, 2004; Kenworthy and Thayer, 1984) to several years (*P. oceanica*; Mateo *et al.*, 1997; Romero *et al.*, 1994). This decay-resistant refractory

material has a low N content and high lignin content compared to fresh material (Klap *et al.*, 2000; Mateo and Romero, 1997).

Of the potential fates of seagrass biomass, burial is probably the least known. There are few published rates on N burial, and these come from a limited number of species that are know to accumulate large amounts of belowground material (Table 23.2). The presence of a refractory detrital pool is the main determinant of the potential for long-term burial of N in the sediments over the time scale of years to decades, even centuries (Banta *et al.*, 2004; Cebrian, 1999; Duarte and Cebrian, 1996). Refractory material is mostly derived from seagrass belowground biomass; however, allochthonous material imported from nearby terrestrial or intertidal systems may also be important. A few species (*Thallosodendron ciliatum*, *P. oceanica*) accumulate peat-like material similar to salt marshes, but this phenomenon is rare among seagrasses (Romero *et al.*, 2006). Romero *et al.* (1992) found that the buried material in a *P. oceanica* meadow lost 50–80% of its N content within the first 3–5 yr, and that a 10-yr-old detritus had essentially the same composition as a 1000-yr-old material. This buried material represented a long-term sink of 7% of the total plant N (Mateo *et al.*, 1997). Even in this extreme case of peat formation, burial represented a relatively small "loss" of N from the system. Losses of N in other non–peat seagrasses ecosystems would be expected to be even less significant. Nonetheless, some believe that burial of N accumulated in seagrass biomass may provide a natural buffering mechanism to increased nutrient loading during the early stages of eutrophication (de Wit *et al.*, 2001).

5.2. Grazing

Hebivores strongly influence the biomass, productivity, and plant community composition in many marine systems, although we know less about the impacts of grazing on seagrass ecosystems than on macroalgal assemblages (e.g., coral reefs, kelp forests, rocky intertidal). Herbivores consume 15–50%, on average, of seagrass production (Cebrian, 1999; Cebrian and Duarte, 1998), and this is considerably lower than for algal-based systems (Cebrian, 2004). The structure of herbivore communities associated with seagrass ecosystems has changed over time, and this likely has resulted in a reduction in the proportion of seagrass productivity that is directly grazed (Domning, 2001; Valentine and Heck, 1999; Williams and Heck, 2001). Historically, large herbivores including abundant turtles, sirenians (dugongs and manatees), and waterfowl impacted seagrass communities. Today, these large herbivores are reduced in number or are absent (e.g., Jackson *et al.*, 2001), and grazing is dominated by fish, urchins, and invertebrates that feed on seagrass blades and their epiphytes. There are few herbivores that consume seagrass roots and rhizomes directly (Valentine and Heck, 1999). Our current view of seagrasses as detritus-based systems is based on this modern situation, and may well have been different during historical times (Domning, 2001; Jackson *et al.*, 2001).

Leaf N content is an important determinant of food preference and the quantity of seagrass material consumed for some herbivores. Several field and laboratory studies have found a positive relationship between leaf N content and grazing by parrotfish, turtles and dugongs (e.g., Goecker *et al.*, 2005; McGlathery, 1995;

Table 23.2 Comparison of nitrogen (N) mineralization and burial rates in temperate and tropical/subtropical seagrass meadows

[*]Calculated from burial rates of 66.1–657.2 g DW m^{-2} yr^{-1} (Cebrian and Duarte, 2001) and rhizome/root N content of 0.35–0.86% DW (Mateo et al., 1997).

Zieman *et al.*, 1984). However, Valentine and Heck (2001) showed the opposite pattern in cage experiments where the urchin *Lytechinus variegates* consumed more seagrass in low-N treatments than in high-N treatments, presumably to compensate for the lower nutritional value of the food source. More work is needed in this area to determine the controls on food preference and mass consumed for these generalist herbivores. Some believe that herbivores cultivate the nutritional content of their food source by pruning away or removing older lower-N leaves and allowing the younger more N-rich leaves to dominate or another species to persist that is a preferred food source (low fiber, high N) (Bjorndal, 1980; Preen, 1995; Zieman *et al.*, 1984). Also, the epiphyte composition on the leaves (fleshy versus calcareous) will likely influence herbivore choice and consumption rates. Mesograzers (e.g., amphipods and gastropods) can control the abundance of algal epiphytes on seagrasses and can modulate the effects of increased nutrient loading (Hillebrand *et al.*, 2000; Lotze and Worm, 2002; Neckles *et al.*, 1993; Williams and Ruckelshaus, 1993). There are excellent recent reviews on grazing in seagrass ecosystems including Valentine and Duffy (2006) and Williams and Heck (2001).

Given the relatively low assimilation efficiency of most herbivores, little of the ingested leaf and epiphyte material will remain in consumer biomass. Most will be egested as feces or soluble compounds and will be remineralized. This suggests that where grazing is an important fate for seagrass material, most of the N bound in the plant material will be transferred to the decomposers. If the grazers are mobile, a portion of this N may be lost from the system (Preen, 1995).

5.3. Litter export

Plant material that is not decomposed *in situ*, permanently buried, or grazed may be lost from the system via mass transport. Seagrass leaves are transported primarily at the water surface due to their extensive aerenchyma tissue, compared to macroalgal material that moves either as bedload or as floating mats at the water surface. Export of belowground material is likely to occur only during storms (Bach *et al.*, 1996; Mateo *et al.*, 2006). Seagrass leaves may be transported longer distances as they settle to the bottom more slowly than macroalgae, and their surface movements are influenced by wind speed and direction as well as current speed. Water motion related to winds and currents determines the relative importance of export as a fate for seagrass biomass. Large-scale disturbance events such as storms may move large amounts of material to adjacent marsh and subtidal ecosystems and represents a nutrient loss from the seagrass ecosystem.

Transport of plant-bound nutrients is often not included in mass balance calculations of seagrass ecosystems in part because of the difficulty in doing representative sampling. Not including this mass transport can cause significant overestimates of nutrient retention in coastal bays. For example, Flindt *et al.* (2004) determined that for two European systems, Venice Lagoon, Italy and Roskilde Fjord, Denmark, the exclusion of mass transport of plant tissue would lead to an overestimate of N retention by 18–60%. Reports vary from negligible amounts to nearly 100% of aboveground biomass lost due to export (Mateo *et al.*, 2006). The nutritional (N) content of the seagrass may influence export, as higher decomposition rates of

high–N leaf litter may decrease the likelihood of export. Perez *et al.* (2001) estimated that export was 3-fold lower in a N-rich *C. nodosa* meadow than in a nearby N-poor meadow. In many systems, there is a seasonality of high leaf export that coincides with the timing of leaf shedding (Risgaard-Petersen and Ottosen, 2000).

5.4. Exudation

Compared to marine phytoplankton and macroalgae (e.g., Bronk and Steinberg, this volume; Tyler *et al.*, 2003; Ward and Bronk, 2001), we know little about DON leakage from seagrass tissues and the importance of this for N turnover and retention. A study by Jørgensen *et al.* (1981) suggested that leakage of amino acids from seagrass leaves and roots could contribute to standing stock DON pools; however, there has been little work to follow up on this idea. For marine algae, the composition of DON released from living tissue includes dissolved free and combined amino acids, dissolved primary amines, and urea, and release rates are related to light availability and nutrient status (Tyler *et al.*, 2003; Ward and Bronk, 2001). There have been studies of DOC leakage from seagrass leaves (Brylinsky, 1977; Moriarty *et al.*, 1986; Penhale and Smith, 1977), and one would expect this DOC release to be in simple organic compounds that also contain N. This is an area deserving of further investigation, and studies of DON exudation should include leakage from live tissues as well as leaching of soluble compounds during the initial states of decomposition.

6. SEAGRASS INFLUENCES ON BACTERIALLY MEDIATED NITROGEN CYCLING

Seagrasses have a major impact on sediment nutrient cycling by leakage of oxygen and dissolved organic matter (DOM) from the roots (Fig. 23.1). Both processes are largely photosynthetically driven. Oxygen produced by photosynthesis in the leaves is transported to the roots to support aerobic respiration via a well-developed lacunal system, a series of air channels comprising up to 60% of the total plant volume. This process occurs in the light; oxygen that is released to the sediment in the dark originates from the water column and enters the leaves by passive diffusion when the external oxygen concentrations exceed the internal concentrations (Borum *et al.*, 2006). Rates of passive oxygen influx to the leaves can be 10–30% of reported rates of photosynthetic oxygen production in *Z. marina* (Borum *et al.*, 2006). The oxygen that is not respired by the roots is released into the rhizosphere, creating oxidized zones in an otherwise reducing environment. Reported rates of oxygen release to the rhizosphere vary markedly (1–100% of total oxygen release to water column and sediments in light) for a range of marine and freshwater aquatic plants (Sand-Jensen *et al.*, 1982), and are relatively low for *Z. marina* (1–10%; Caffrey and Kemp, 1990; Sand-Jensen *et al.*, 1982). Fredericksen and Glud (2006) recently showed that oxygen release was restricted to the root tips
Figure 23.1 Seagrass influences on N cycling processes. The red line symbolizes the oxic–anoxic interface; oxic microzones around seagrass roots not shown in the figure are also important.

in *Z. marina* and only extended ∼8 mm along the root from the root tip. Oxic microzones of <100 μm extending from the root into the sediment have been shown to occur around roots in the light for *Z. marina* (Greve *et al.*, 2003), *Cymodocea rotundata* (Pedersen *et al.*, 1998), and *Halophila ovalis* (Connell *et al.*, 1999).

The DOM released from seagrass roots is typically in the form of simple organic carbon compounds that are the recent products of photosynthesis (Koepfler *et al.*, 1993; Ziegler and Benner, 1999), and these exudates influence bacterially-mediated N cycling processes. Bacterial productivity in the rhizosphere has been linked to these organic exudates. Moriarty *et al.* (1986) showed that 11% of recent photosynthate was released within 6 hurs into the rhizosphere of the tropical seagrass *Halodule wrightii*, and for *T. hemprichii* and *C. rotundata*, Holmer *et al.* (2001) showed that enough DOC was excreted by belowground tissues to support all anaerobic microbial activity in the rhizosphere. Seasonal and light-induced variation in N fixation and sulfate reduction rates have been associated with these root exudates (e.g., Holmer and Nielsen, 1997; Isaksen and Finster, 1996; McGlathery *et al.*, 1998; Welsh *et al.*, 1996). Also, there is typically a sub-surface peak in bacterial processes in the sediments where root biomass is highest (e.g., Blaabjerg *et al.*, 1998; McGlathery *et al.*, 1998; Welsh *et al.*, 1996).
Figure 23.2 Conceptual model showing the possible fates of seagrass-bound nitrogen. Nitrogen temporarily immobilized in plant tissue can become available through exudation from live tissue, remineralization through decomposition, and grazing and subsequent excretion. Some material may be removed from the system through burial or export as dissolved or particulate organic matter.

6.1. Nitrogen fixation

Nitrogen fixation occurs associated with epiphytes on seagrass leaves, on the surface sediments, and deeper in the sediments in the seagrass rhizosphere (Fig. 23.1). Seagrass leaves provide a three-dimensional substrate in the photic zone that increases the surface area for autotrophic N fixers. The rates of N fixation of heterocystous cyano-bacterial epiphytes on seagrass leaves and on surface sediments tend to be high relative to those in the water column (e.g., Capone and Taylor, 1980; Capone *et al.*, 1992). This is true even in systems where a dense leaf canopy shades the sediment surface. It has been suggested that on an areal basis the activity of autotrophic N fixers is lower than that of heterotrophic bacteria N fixers (e.g., Capone and Taylor, 1980; O'Donohue *et al.*, 1991); however, this may not always be the case. The relative contribution of autotrophic vs. heterotrophic N fixation in seagrass beds likely depends on a number of factors, including the ratio of above- to belowground seagrass biomass, light and N availability, rates of sulfate reduction, and sediment redox conditions. More work is needed to understand how autotrophic and heterotrophic N fixation varies in seagrass meadows inhabiting different nutrient environments.

Heterotrophic N fixation in the sediments is enhanced by the presence of seagrasses relative to unvegetated sediments, both in temperate and tropical environments (e.g., Hansen *et al.*, 2000; McGlathery *et al.*, 1998; O'Donohue *et al.*, 1991; Welsh *et al.*, 1996). Reported rates vary tremendously between systems, although N fixation in general is higher in sediments of tropical seagrass meadows than temperate meadows (Table 23.3). The availability of organic substrate is a major factor

controlling N fixation rates in seagrass sediments. Many studies have shown increases of N fixation by addition of organic compounds, and seasonal and diel variations that are consistent with the role of photosynthetic exudates stimulating N-fixing bacteria (e.g., Hansen *et al.*, 2000; McGlathery *et al.*, 1998; Welsh, 2000). Much of this activity (25–95% of total heterotrophic fixation) has been associated with sulfate

reducers (e.g., McGlathery *et al.*, 1998; Welsh *et al.*, 1996), which also are stimulated by root exudates (Blaabjerg *et al.*, 1998; Hansen *et al.*, 2000). Depth profiles of N fixation activity in *Z. marina* sediments showed a close association with root/rhizome biomass, with seasonal shifts in the magnitude and depth distribution of N fixation matching the shifts in belowground biomass (McGlathery *et al.*, 1998). N-fixing bacteria can colonize roots (Shieh *et al.*, 1989); rates of N fixation directly associated with roots and rhizomes vary from negligible (McGlathery *et al.*, 1998) to over 30% of heterotrophic fixation in the sediments (Nielsen *et al.*, 2001). The higher N fixation rates in seagrass-vegetated sediments in tropical/subtropical systems may in part be due to increased DOM release from the greater root/rhizome biomass of many tropical seagrass species. In tropical/subtropical seagrass meadows, sediment N fixation may provide more than 50% of plant N demand (Hanson *et al.*, 2000; O'Donohue *et al.*, 1991; Welsh, 2000), whereas in temperate systems the contribution to plant N demand is often lower (5–12%; McGlathery *et al.*, 1998; Welsh, 2000).

6.2. Denitrification

Many studies have estimated denitrification rates in seagrass-vegetated sediments, and a broad range of values have been reported (Table 23.4, see Devol, this volume for a review of the denitrification process). The variation appears to be related to the N availability in the sediments, as well as to species-specific characteristics (i.e. root oxygen release). A general pattern is emerging that under N-replete conditions oxygen release from plant roots stimulates coupled nitrification–denitrification, and under N-limiting conditions competition between plants and nitrifying bacteria decreases coupled nitrification–denitrification (see Ward, this volume for a review of the nitrification process). This same regulation of denitrification has also been suggested for sediments in which benthic microalgae are the dominant primary producers (An and Joye, 2001). For example, there is evidence for the temperate species, *Potomogeton perfoliatus* and *Z. marina*, that root oxygen release stimulates coupled nitrification–denitrification (e.g., Cornwell *et al.*, 1999; Flindt, 1994), and variations in rates are linked to the seagrass growth cycle and to variations in oxygen release (Caffrey and Kemp, 1992; Risgaard-Petersen *et al.*, 1998). In other studies, low rates of nitrification and competition between nitrifying bacteria and benthic microalgae in *Z. marina* and *Z. noltii* were believed to be the mechanisms responsible for the low rates of coupled nitrification–denitrification (Ottosen *et al.*, 1999; Risgaard-Petersen and Ottosen, 2000; Rysgaard *et al.*, 1996).

There are fewer reported measurements of denitrification in seagrass-vegetated carbonate sediments in tropical/subtropical environments than in temperate systems (Table 23.4). The available data suggest that denitrification rates are higher in tropical/subtropical seagrass meadows than in temperate seagrass meadows, with one exception (Table 23.4). More work is clearly needed to estimate rates in tropical and/or carbonate sediments. Higher denitrification rates may occur in carbonate sediments dominated by *T. testudinum* because this species allocates more biomass to roots and rhizomes than temperate species, and tends to be P-limited so that competition between bacteria and plants for N is unlikely to occur. Organic matter

concentrations and bacterial oxygen demand also tend to be lower in tropical carbonates sediments, which may make oxygenation of the rhizosphere more efficient in these systems.

Studies on diel and seasonal patterns in denitrification activity in both temperate and tropical/subtropical seagrass meadows suggest that variations in coupled nitrification–denitrification are linked to variations in phytosynthetically-driven oxygen release and plant NH_4^+ uptake (Blackburn et al., 1994; Risgaard-Petersen and Ottosen, 2000; Risgaard-Petersen et al., 1998; Welsh et al., 2000). The relative effect of these two processes on denitrification should depend on whether N is limiting in the system. For example, under N-limiting conditions, NH_4^+ uptake and competition with denitrifiers would depress denitrification most when the plants

are most active photosynthetically during the day and in the summer. If N is not limiting, oxygen release by the seagrass and benthic microalgae in the sediments would stimulate coupled nitrification–denitrification the most in the light and during the summer. Both patterns have been reported. Blackburn et al. (1994) showed diel variation in porewater NH_4^+ and denitrification rates in tropical *Halodule beaudetti* (*wrightii*) meadows, with both being high at daybreak and declining during the day, presumably related to plant uptake of NH_4^+ and competition with nitrifiers. And Welsh et al. (2000) found higher denitrification rates in the dark and attributed this to shorter diffusion distance for NO_3^- to anoxic microzones in the rhizosphere.

Finally, a few studies have measured N fixation and denitrification simultaneously in seagrass meadows to determine if N gains by fixation can compensate for N losses via dentrification, and the results are equivocal (Tables 23.3 and 23.4). In temperate *Z. marina* meadows, one study indicated that denitrification roughly balanced N fixation (comparison in Risgaard-Petersen et. al., 1998, data reported in McGlathery et al., 1998), and another showed that N fixation rates exceeded denitrification rates on a seasonal basis (Welsh et al., 2000). Welsh et al. (2000) calculated that the net N_2 flux (N fixation–denitrification) averaged over the year was 5.4 μmol N m^{-2} h^{-1}. Of the three studies in tropical seagrass beds that have compared these rates, two indicated that gains by N fixation roughly equaled losses by denitrification (Kemp and Cornwell, 2001; Miyajima et al., 2001), and one reported denitrification rates that exceeded N fixation rates (Blackburn et al., 1994). More work is needed to determine what influences the balance between denitrification and N fixation in seagrass meadows and if this can be generalized among systems.

6.3. Mineralization

Nutrient cycling in seagrasses communities appears to be relatively conservative, with much of the nutrients required to support high rates of productivity met by recycling within the sediments in both temperate and tropical systems (Alcoverro et al., 2000; McGlathery et al., 2001b; Miyajima et al., 2001; Risgaard-Petersen and Ottosen, 2000). Mineralization rates appear to be higher in temperate than tropical seagrass sediments (Table 23.2); however, there is some overlap in the rates and there are few studies to compare. Seagrasses influence the production of N as NH_4^+ through mineralization by enhancing organic matter in the sediment. This occurs both through leaching and decay of senescent seagrass biomass and trapping of allochthonous particulate organic matter. Some studies have shown that as with salt marshes, much of the organic matter buried and decomposed in seagrass sediments is imported and that enhanced trapping of seston may be an efficient strategy for acquiring external nutrients (Boschker et al., 2000; Gacia et al., 2002; Pedersen et al., 1997a,b). Fine, organic-rich particles settle out as the water flow is slowed by the seagrass canopy, and the roots and rhizomes also help to stabilize the sediments and prevent resuspension (Gacia and Duarte, 2001; Kenworthy et al., 1982; Koch, 1999). The use of compound-specific stable isotopes has provided new insights into the origin of the organic matter that is decomposed in seagrass beds. Stable isotope ratios of branched polar lipid-derived fatty acids (PFLAs) of bacteria have been used to show that high bacterial production was supported by

benthic microalgae in some temperate systems (Boschker *et al.*, 2000), and by seagrass production (*T. testudinum*) in a tropical system (Jones *et al.*, 2003). Additionally, Barron *et al.* (2006) used ^{15}N-labelled algal material injected into *P. oceanica* sediments to show that seagrass meadows retained 4X more material than unvegetated sediments and that a portion of the material appeared in the seagrass biomass within a few days. The results of these studies indicate that not all microbial production in seagrass ecosystems is based on seagrass detritus as previously thought. More studies are needed to assess differences in mineralization between types of seagrass systems, which may relate to the importance of export and to seagrass community composition (availability of organic matter such as seagrass, microalgae, macroalgae, etc.).

Sulfate reduction is an important mineralization process in seagrass-vegetated sediments, and rates generally are higher than in nearby unvegetated sediments (Blaabjerg and Finster, 1998; Blaabjerg *et al.*, 1998; Holmer *et al.*, 2003). Increased input of allochthonous organic matter, organic exudates from living seagrass roots, and the presence of senescent seagrass material all likely stimulate sulfate reduction in vegetated sediments. A positive correlation between sulfate reduction rates and belowground biomass has been shown for *Z. marina* (Blaabjerg and Finster, 1998; Blaabjerg *et al.*, 1998); however, this was not the case for *P. oceanica* (Holmer *et al.*, 2003).

7. ARE SEAGRASS MEADOWS SOURCES OR SINKS OF NITROGEN?

Whether a seagrass meadow acts a net source or sink of N depends on the balance between processes (1) that contribute N to the system (N fixation, leaf uptake of water column N, root uptake of groundwater N, and import/sedimentation of allochthonous organic matter) and (2) those that contribute to a loss of N from the system (denitrification, leaching, leaf export, grazing and export). The source-sink role of seagrass ecosystems varies over diel, seasonal, and annual (and beyond) time scales.

Nutrient assimilation and temporary retention in plant biomass is an important process regulating the source-sink role of seagrass communities over all time scales. Seagrasses are highly productive (global average: 1012 g DW m^{-2} yr^{-1}; Duarte and Hemminga, 2000), and total annual N incorporation can exceed 2 mol N m^{-2} yr^{-1} (Pedersen *et al.*, 2004). For many systems, this assimilation rate is higher than the fluxes associated with microbial processes (e.g., N fixation, denitrification) by one to several orders of magnitude (Table 23.2–23.4), and is greater than external inputs of N in most systems (Pedersen *et al.*, 2004). Diel and seasonal variation in the source-sink role of seagrass beds depends in part on the growth requirements and N demand of seagrasses. For example, temperate *Z. marina* meadows have been shown to act as strong sinks for N from the beginning of the growing season in the spring to the time of maximum productivity in late summer; in the fall when decomposition rates were relatively high, but plant N demand low, the seagrass community switched to a source of nutrients (Risgaard-Petersen and Ottosen, 2000; Risgaard-Petersen *et al.*, 1998). Averaged over the year, N did not accumulate in above- or belowground

biomass in these seagrass meadows (Pedersen and Borum, 1993; Risgaard-Petersen and Ottosen, 2000). There are often diel patterns in N transfer driven by the seagrasses and algae associated with seagrass beds, with an efflux of nutrients during the dark and uptake from the sediment and water column in the light (Dudley *et al.*, 2001; Eyre and Ferguson, 2002; Larned, 2003; Miyajima *et al.*, 2001). Dudley *et al.* (2001) showed that epiphytes could remove more NH_4^+ and NO_3^- from the water column than the seagrass *Ruppia megacarpa* even though their biomass was only 25% of the seagrass biomass (Dudley *et al.*, 2001).

Several studies have attempted to either construct a mass balances N or follow the fate of seagrass biomass using ^{15}N as a tracer. Risgaard-Petersen *et al.* (1998) determined that over the growing season (April and August) for a *Z. marina* meadow plant uptake was the most important process influencing the role of the meadow, as an N sink, and that 82% of the assimilated N could be returned to the system via leaf shedding. Stapel *et al.* (2001) also found using isotopic tracers that much of the N in shed leaves (44%) in a *T. hemprichii* meadow in Indonesia was mineralized *in situ* and reassimilated by seagrasses. These studies and others (Hansen *et al.*, 2000; McGlathery *et al.*, 2001a) point to efficient sediment N cycling to meet plant demand. In contrast, Cebrian and Duarte (2001) followed the fate of *P. oceanica* leaf material in 16 meadows in the Mediterranean and found that grazing removed only a small percentage (13%), that 85% of the leaves were shed, and that most of these leaves (90%) were exported off the meadows.

When long-term nutrient accumulation occurs in seagrass meadows, it is either as increased biomass or as accumulation of slowly degrading detritus. Nitrogen accumulation in seagrass biomass most likely occurs during meadow development, as biomass accumulates. For example, Pedersen *et al.* (1997a,b) found that colonization and stand development of the N-limited seagrass *C. nodosa* in Mediterranean carbonate sediments resulted in a net accumulation of N (but not P) over a 5-yr period, with about half of the accumulated N accounted for by living and dead plant material. Nitrogen may also accumulate in the "matte" forming species, *P. oceanica*, for which a significant percentage of total seagrass production accumulates as refractory material in belowground detritus (dead roots and rhizomes) (Table 23.4; Mateo and Romero, 1997; Mateo *et al.*, 1997). There is some evidence that nutrient enrichment may cause a switch in mature meadows from being a sink to a source because the accumulation of nutrients in slowly degrading detritus is less likely since allocation to belowground biomass decreases and decay rates of leaves is higher (Perez *et al.*, 2001).

8. SUMMARY AND FUTURE DIRECTIONS

Seagrasses affect the rates and pathways of N cycling in lagoons and estuaries by (1) the temporary retention of N in their tissue and the subsequent fate of this tissue and (2) the release of DOC and oxygen from roots to the sediments that alters bacterial activities. For many systems, N assimilation rates are of the same magnitude as watershed and atmospheric N loading (Pedersen *et al.*, 2004), and thus seagrasses

are a critical part of the estuarine filter. Seagrasses slow the transport of N to the near-coastal zone, and appear to be net sinks of N on daily to seasonal time scales. This sink role is regulated by photosynthesis and nutrient uptake, with meadows acting as a sink during the day and during the active growing season. Whether seagrass meadows are a net sink on annual basis appears to depend on the developmental stage (young vs. old) and on nutrient conditions, with meadows in eutrophic environments possibly becoming a source of nutrients to the water column. At the plant level, we need to know more about exudation of DON from living seagrass tissue and its role in stimulating heterotrophic activity in the water column and sediments.

Bacterial activities associated with N fixation and mineralization are stimulated in seagrass-vegetated sediments relative to "bare" sediments with benthic microalgae. This does not appear to be the case for denitrification, and rates are often similar and low in vegetated and bare sediments. Although there is some evidence of enhanced coupled nitrification–denitrification in seagrass-vegetated sediments, seagrasses more often inhibit nitrification–denitrification due to low rates of nitrification in the oxic microzones surrounding the roots and to competition for ammonium with nitrifying bacteria. Methods still need to be improved to directly link plant metabolism with nitrification and denitrification rates in the rhizosphere over diurnal and seasonal time scales.

Over the last two decades we have developed a good understanding of N controls on the production, morphology and dynamics of seagrass ecosystems, and on the feedbacks of seagrass metabolism on N cycling processes. However, we lack sufficient empirical information to predict the changes in N cycling in seagrass-vegetated systems that will result from eutrophication. Responses of specific N processes (i.e., denitrification, mineralization, N fixation) to excess N loading will likely be nonlinear, as seagrasses are replaced by benthic algae and phytoplankton. There is also uncertainty about the role of consumer control in modulating the response of seagrass ecosystems to nutrient over-enrichment, and their influence on the resilience of these systems. Given the accelerating pace of seagrass degradation worldwide (Orth *et al.*, 2006), understanding the feedbacks of seagrasses on N cycling and the relative role of consumer interactions as systems become eutrophied is important for the conservation and management of these ecologically and economically important systems. These issues are also important for predicting the impacts of seagrass restoration on the transformations and fate of N on its trajectory from land to sea.

Aspects of Marine Cyanobacterial Nitrogen Physiology and Connection to the Nitrogen Cycle

David J. Scanlan *and* Anton F. Post

Contents

1. Introduction

Nitrogen (N) is an essential nutrient for photosynthetic organisms for which the cellular demand is higher than that for phosphorus, iron, or trace metals. N sources that are commonly found in aquatic ecosystems include reduced and oxidized inorganic species, like ammonium and nitrate alongside organic N–compounds such as urea, amino acids etc. For decades N–availability has been considered the limiting factor for primary productivity by marine phytoplankton. This concept has recently been subjected to evaluation based on oceanographic findings showing that other nutrients, like phosphate and iron, limit primary production in large ocean provinces. Moreover, improved analytical methods have provided more detailed information on the spatial and temporal distribution of the various N–species. Furthermore, an increased understanding of the flow of matter via the microbial food web has resulted in an appreciation of high N–regeneration rates within the photic layer. Nevertheless, large oceanic regions, mostly in the (sub)tropics are characterized by N–deplete surface waters, from the surface down to below the 1% isolume. Such waters are more often than not populated with cyanobacteria as the

major phytoplankton group. These cyanobacteria may be either the microscopically small *Synechococcus, Prochlorococcus, Cyanothece*, and *Chrocosphaera* unicells or the large colonies of N_2-fixing *Trichodesmium* filaments. This chapter will largely focus on the N-metabolism, N-stress response and niche adaptation of these three major phytoplankton groups, as they impact significantly on the N-cycle in marine water bodies. Much emphasis will be put on the molecular ecology and phylogeny of these groups, which have seen a rapid development over the last decade. More rare planktonic species such as the filamentous N_2-fixing cyanobacteria *Richelia* and *Katagnymene* as well as those found in benthic ecosystems will not be considered here. Likewise we will not discuss the cyanobacteria found in atypical marine environments, like e.g., *Nodularia* populations in the Baltic Sea.

2. General Aspects of Cyanobacterial Nitrogen Metabolism

Cyanobacteria are key components of marine microbial communities contributing up to two-thirds of carbon dioxide fixed in oceanic systems. Although it is with C cycling that cyanobacteria are most notably associated, their contribution to the transformation of nitrogenous compounds is equally important, and indeed with roles in both regenerated and new N production and utilisation, they are also inextricably linked to the global N-cycle.

In nutrient-depleted surface layers of the ocean cyanobacteria often experience sudden pulses of N either by physical mechanisms such as up-wellings that provide nitrate to the euphotic zone or by biological mechanisms such as animal excretion that add regenerated N forms such as ammonia and urea. We thus consider here examples of N-metabolism and N-acquisition that encompasses the range of N substrates encountered by these organisms *in situ* (see Fig. 24.1) and including problems of aerobic N_2 fixation. For the latter we focus on the use of specialised regions, diazocytes, that provide a reduced oxygen microenvironment in *Trichodesmium* spp. as well as the temporal separation of nitrogen fixation and photosynthesis as found in *Cyanothece* and *Crocosphaera* spp. We will highlight where appropriate, and this is especially obvious in the unicellular picocyanobacterial genera *Prochlorococcus* and *Synechococcus*, the genotypic variation that can exist within a genus with respect to N resource utilisation and the concomitant N regulatory network, a feature that we can see no reason should be confined to these genera, but which we consider to be inextricably linked to the specific environmental niches occupied by particular genetic lineages. The importance of these picocyanobacteria to N-cycling should not be overlooked given their typical cell concentrations of between 10^6 and 10^8 cells l^{-1} and compared to *Trichodesmium* which is found at concentrations around 1 colony l^{-1} as a function of the integrated mixed-layer water column.

Of specific interest are issues that relate to the fine interplay between cellular processes and nitrogen scavenging from the environment. Studies of such interactions have shown much progress for some cyanobacteria (e.g., for *Trichodesmium*, see Section 2.1) but others still pose a challenge e.g., very little is known to date as to

1 - preferred nitrogen source
2 - alternative nitrogen sources
3 - N deprivation, internal stores e.g. phycobiliproteins
Figure 24.1 Cyanobacterial nitrogen incorporation as depicted at the level of (1) preferred N sources, (2) alternative N sources, and (3) the response to N starvation.

whether marine cyanobacteria have a cellular hierarchy with which they determine the presence of certain N compounds in the environment and establish the order for acquisition of these compounds. Based on purely theoretical considerations of energy requirements it would be logical to utilize ammonium preferentially, followed by nitrite, nitrate, and lastly the fixation of molecular nitrogen, provided that these sources are all available. A deeply mixed water column may contain such mixes and marine *Synechococcus* thrives in such environments with the capability of rapidly adapting to the differential utilization of the combined N sources (Lindell and Post, 1995, 2001; Lindell *et al.*, 1998, 1999). However, a ''pecking order'' for the use of these compounds (with the addition of organic N sources) has as yet not been determined with the exception of a preference for ammonium utilization over all other N sources, a property derived from the molecular regulation of N–stress responses (see Section 3). Once N has been acquired nitrogen assimilation by all (marine) cyanobacteria studied proceeds via the glutamine synthetase/glutamate synthase (GS/GOGAT) pathway. GS is required for ammonium assimilation irrespective of the primary source of N. Elevated GS activity is characteristic of cells that are N limited or using N_2 as their N source although this is not true for all genera (e.g., *Prochlorococcus* see Section 2.3). Lastly, cellular processes need to be tuned to the presence and activity of nitrogenase. Nitrogenase, catalysing the reduction of atmospheric nitrogen to ammonium is irreversibly inhibited by exposure to molecular

oxygen, a major problem for oxygen-evolving photosynthetic organisms. As a result various adaptations have evolved that either involve (1) a spatial segregation of the process in specialised cells, heterocysts and diazocytes, in which photosystem II activity is strongly reduced or even lacking, or (2) a temporal separation, where N_2 fixation takes place in the dark.

2.1. Filamentous cyanobacterial N_2 fixers

In oligotrophic tropical and subtropical oceans planktonic marine cyanobacteria of the genus *Trichodesmium* are responsible for the bulk of nitrogen fixation providing more than half of the new nitrogen used for primary production (Capone *et al.*, 1997; Karl *et al.*, 1997). To put this into perspective, current estimates of global N_2 fixation are $\sim$240 Tg N year^{-1} with a marine contribution of 100–190 Tg N year^{-1}. Of this $\sim$100 Tg N year^{-1} are now considered contributed by *Trichodesmium* (Berman-Frank and Falkowski, 2003). The well documented surface accumulation of colonies (blooms) of this organism (Capone *et al.*, 1998) testifies to its importance as a major player in marine N_2 fixation dynamics and have led to much study of its ecology and biology (see e.g., Capone *et al.*, 1997; Carpenter *et al.*, 1992; Mulholland and Capone, 2000). We consider here then, only those more recent advances in its biology with specific respect to aspects of N metabolism that directly impinge on its wider role in the N cycle.

As a filamentous N_2 fixing cyanobacterium, *Trichodesmium* is unusual in being both non-heterocystous, but also in carrying out N_2-fixation maximally during the day (see Capone *et al.*, 1990, 1997; Karl *et al.*, 2002). This ''diel'' cycle of nitrogenase activity, found in both cultured (Chen *et al.*, 1996) and natural (Capone *et al.*, 1990; Zehr *et al.*, 1993) populations, is manifest as activity only during the light period and with maximal activities around midday. Such a cycle is consistent with protein data for nitrogenase with enzyme modification and inactivation during the late afternoon (Zehr *et al.*, 1993), prior to its degradation at night and with new nitrogenase being synthesized again each morning (Capone *et al.*, 1990; Wyman *et al.*, 1996). Similarly, in natural *Trichodesmium* populations, *nifH* (encoding one of the multi-subunit metalloproteins of nitrogenase) transcripts show a maximum between mid-morning and midday, decline during the afternoon and are largely undetectable at dusk. Such a cycle of gene expression has recently been shown, in cultures, to be due to a circadian rhythm, with cyclic nitrogenase gene expression persisting under constant conditions, the rhythms being trainable to daily light–dark (L–D) cycles by L–D cues; the rhythms are also temperature compensated (Chen *et al.*, 1998). Interestingly, *nifH* gene expression shows a pattern out of phase to the photosynthetic core polypeptide genes of photosystem II and I, *psbA* and *psaA*, respectively, the latter also being regulated in a circadian manner (Chen *et al.*, 1999). Circadian oscillation of gene expression seems then to underlie part of the mechanism allowing simultaneous photosynthesis and nitrogen fixation in *Trichodesmium* filaments. However, such transcriptional studies give data only on gene expression of ''bulk'' filaments and need to be put into the context that not all cells appear to be capable of N_2 fixation i.e., that spatial as well as temporal segregation of N_2 fixation and photosynthesis occurs within the photoperiod. Thus, immunological evidence has shown that

nitrogenase is localized to a subset of cells, now called diazocytes, clustered along regions of the filament in several *Trichodesmium* strains (El-Shehawy *et al.*, 2003; Fredriksson and Bergman, 1997; Janson *et al.*, 1994; Lin *et al.*, 1998). These diazocytes do not show the thickened cell wall typical of heterocysts, but appear to contain more cytochrome oxidase than surrounding cells (Bergman *et al.*, 1993), a denser thylakoid network dividing vacuole-like spaces into smaller units, less extensive gas vacuoles and smaller cyanophycin granules (Lin *et al.*, 1998). There is also an indication that these diazocytes may be shorter than adjacent cells (Janson *et al.*, 1994). However, this spatial segregation is not in itself sufficient to protect nitrogenase against oxygen evolution since active photosynthetic components (PSII and PSI complexes, RuBisCO and carboxysomes) are present in all cells. Instead, *Trichodesmium* has evolved the ability to rapidly switch on and off photosynthesis, within 10 or 15 min (Berman-Frank *et al.*, 2001a), with this modulation of oxygen consumption and production during the photoperiod being restricted to parts of the filament, often at their centres, a feature consistent with the presence of specialized cells for nitrogen fixation. Thus, a consensus mechanism is now emerging for this enigmatic simultaneous N_2 fixation and photosynthesis capacity in *Trichodesmium*—that the underlying circadian control of gene expression, and subsequent translational modification of nitrogenase which allows for high nitrogen fixation during the day is mirrored by a decline in photosynthetic production and increased light dependent oxygen consumption via the Mehler reaction which results in a net removal of oxygen, and particularly in specific cells clustered along a filament (Berman-Frank *et al.*, 2001a).

It seems then that nitrogen fixation in *Trichodesmium* appears to be a complicated interplay between both temporal and spatial controls of photosynthesis, respiration and nitrogen fixation. What is unclear though is how the circadian regulation of gene expression manifest in all cells is then overlaid with a more cell-specific regulatory network that allows for a window of opportunity for increased nitrogenase activity in specialized cells. The presence/absence or ''switching-on'' of a developmental cycle in some cells, and the role of global N regulators e.g., *ntcA* (see Section 3) will shed further light on this fascinating process.

The fact that nitrogen fixation does not occur in all cells of a *Trichodesmium* filament simultaneously implies some mechanism of N cycling between cells, and/or the concurrent uptake of other nitrogenous substrates, so as to maintain the intracellular N levels of individual cells. Indeed, *Trichodesmium* sp. strains NIBB1067 and IMS101 are capable of simultaneous N_2 fixation and utilization of combined N sources (Mulholland and Capone, 1999; Mulholland *et al.*, 1999). Furthermore, in these strains N_2 fixation accounts for ~15%, whereas the uptake of ammonium + glutamate accounts for around 85%, of total N uptake. Work with natural populations which demonstrates high rates of amino acid, DON, and ammonium release together with simultaneous uptake of amino acids (largely glutamate and glutamine) and ammonium suggests a cycle of release of fixed N by N_2 fixing cells and uptake by non N_2 fixing cells (Mulholland and Capone, 2000). While this release may fuel gross productivity of *Trichodesmium* spp. it likely also benefits the microbiota attached to *Trichodesmium* filaments, which may themselves be involved in the regeneration of dissolved inorganic and organic N.

2.2. Unicellular cyanobacterial N$_2$ fixers

Several unicellular cyanobacterial N$_2$ fixers have been described from the marine environment. All seem to share the common property of being aerobic diazotrophs and of being slightly larger (2.5–10 µm) in size to corresponding non N$_2$-fixing unicells (León *et al.*, 1986; Montoya *et al.*, 2004; Reddy *et al.*, 1993; Waterbury *et al.*, 1988; Zehr *et al.*, 2001). They have been described in the literature as belonging to the *Synechococcus*, *Synechocystis*, *Cyanothece*, and *Crocosphaera* genera, but there is some level of phylogenetic coherence among several of these cultured organisms (Mazard *et al.*, 2004; Turner *et al.*, 2001—see boxed area within Fig. 24.2) suggesting they should be unified into a single taxon. As well as free-living isolates, 16S rDNA sequences closely related to these organisms have been obtained from symbionts associated with the diatom *Climacodium frauenfeldianum* suggesting the potential of these types of organisms for nitrogen fixation within symbiotic relationships also (Carpenter and Janson, 2000; Falcón *et al.*, 2002, 2004a,b). Although the contribution of these unicellular cyanobacterial strains to global nitrogen fixation rates is not yet clear, indirect estimates from size-fractionated (10–0.2 µm) seawater samples (which include any nitrogen–fixing heterotrophs) suggests they can reach 2–100% of the rates of *Trichodesmium* at the same location (Falcón *et al.*, 2004a; Montoya *et al.*, 2004; Zehr *et al.*, 2001). Since there appear to be large differences in these rates between the Pacific and Atlantic Oceans (Falcón *et al.*, 2004a), and indeed even over small spatial scales within the same ocean basin (Montoya *et al.*, 2004) it would appear that, depending on location, these are major diazotrophs in oligotrophic marine ecosystems. The spatial heterogeneity in fixation rates and abundance of these coccoid cyanobacterial diazotrophs might reflect differences in aeolian Fe input or Fe:P ratios (Falcón *et al.*, 2004a) or may be a result of changes in water column temperature (Mazard *et al.*, 2004). Certainly, temperature appears important in dictating the distribution of heterocystous versus non-heterocystous cyanobacteria in oceanic systems (Staal *et al.*, 2003). Thus, differences in the temperature dependence of oxygen flux, respiration, and N$_2$ fixation activity were shown to be critical in explaining how *Trichodesmium* performs better than heterocystous species at higher temperatures, and it may be that some of these factors are important for unicellular nitrogen–fixing species too.

The N physiology of these marine unicellular N$_2$ fixers has been restricted to only a few strains (Falcón *et al.*, 2004b; León *et al.*, 1986; Mitsui *et al.*, 1986, 1987; Waterbury *et al.*, 1988) and with most data from a single isolate, *Cyanothece* sp. ATCC 51142 (= strain BH68; e.g., see Colón-López and Sherman, 1997; Li *et al.*, 2001; Reddy *et al.*, 1993; Schneegurt *et al.*, 1994; Sherman *et al.*, 1998). A consistent feature is the full temporal separation of photosynthesis and N$_2$ fixation, a process which is likely controlled by an endogenous circadian rhythm (see Sherman *et al.*, 1998). N$_2$ fixation, respiration and photosynthesis all show peaks with a periodicity of 24 h, with photosynthesis 12 h out of phase relative to N$_2$ fixation. In *Cyanothece* sp. ATCC 51142 such rhythms can occur under continuous light (LL), light–dark (L–D) or continuous dark (DD) conditions, the latter via heterotrophic growth on glycerol. Under L–D growth N$_2$ fixation is restricted to dark periods. The establishment and maintenance of these rhythms appears complex but includes tight regulation of expression of the *nifHDK* operon, with net
Figure 24.2 Phylogenetic tree showing the relationships of marine and freshwater cyanobacteria, including diazotrophs and non-diazotrophs, inferred from 16S rRNA gene sequences. The tree was constructed by the neighbour joining method with Jukes-Cantor correction. The region highlighted encompasses a lineage that only includes unicellular nitrogen-fixing isolates. The scale bar represents 0.1 nucleotide substitutions per position.

accumulation of *nifHDK* transcripts only during a small percentage of the diurnal cycle irrespective of culture growth conditions (i.e., L–D, LL, or DD). L–D growth conditions do demonstrate, however, the most highly synchronised regulatory behaviour of the *nifHDK* operon, with transcription confined to the first four hours of the dark period during which a peak of transcription occurs and

followed by a rapid disappearance (Colón-López and Sherman, 1997). This peak of transcriptional activity coincides with the peak of nitrogenase activity. This relatively simple pattern of nitrogenase activity contrasts with a complicated pattern of regulation of photosynthetic activity (reviewed by Sherman *et al.*, 1998). Photosynthetic changes appear to favour PSII and noncyclic electron flow during the light period, whilst PSI and cyclic flow (ATP synthesis) are favoured early in the dark period. Interestingly, these temporal patterns of photo-synthesis and N_2 fixation are mirrored by circadian oscillation of C and N storage products. Thus, glycogen granules formed during the light period remain at high levels 4 h into the dark period before rapidly disappearing (presumably as a result of respiratory utilisation—see Falcón *et al.*, 2004b). Conversely, cyanophycin gran-ules only begin to appear 4 h into the dark period, accumulate during the later stages of the dark period and gradually disappear during the light period as the cyanophycin is utilised. Cyanophycin polymerisation/depolymerisation appears then to be an important mechanism for storage and utilisation of nitrogen in *Cyanothece* sp. ATCC 51142 at least, and contrasts with what appears to be the more typical degradation of phycobilisomes as a N store in unicellular non-N_2 fixers (Li *et al.*, 2001).

2.3. Unicellular non-N$_2$-fixers

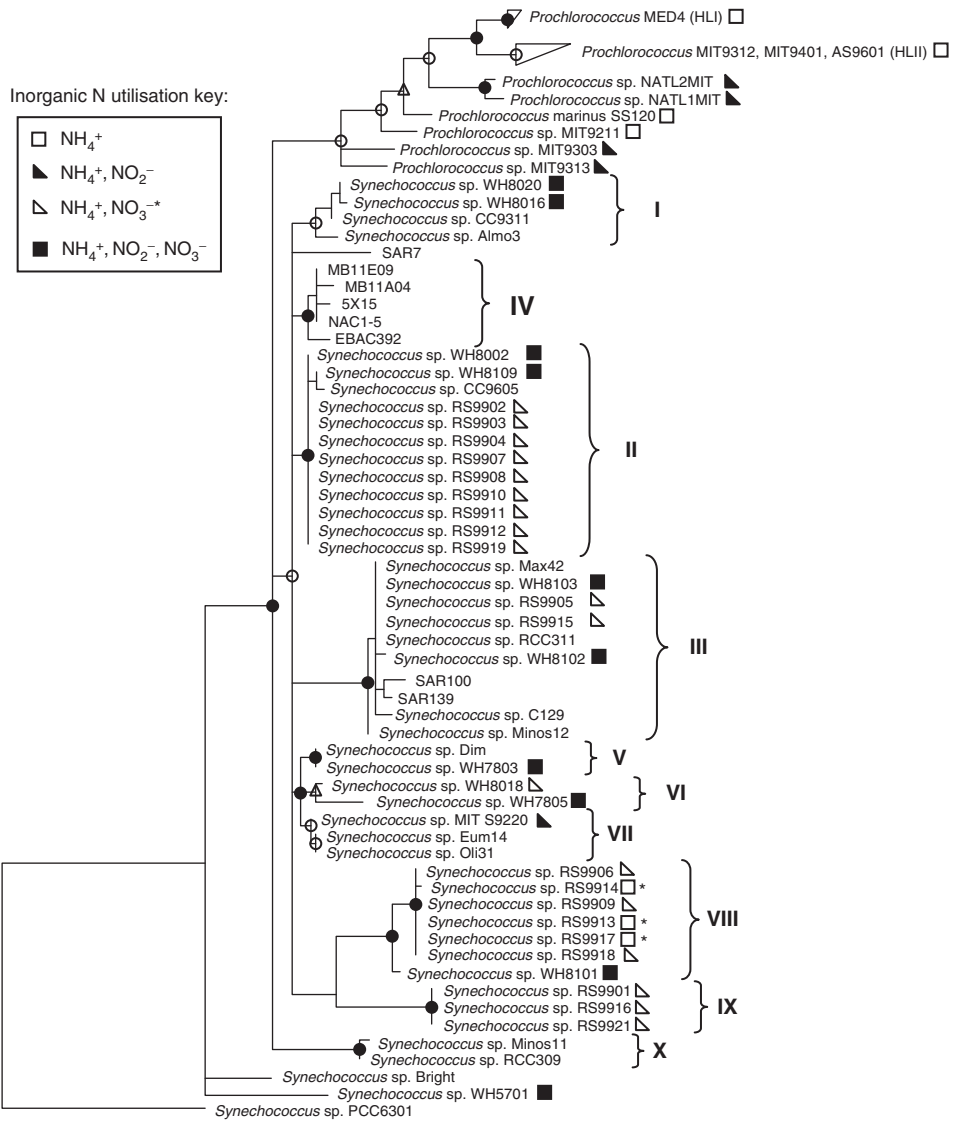
The vast equatorial open ocean gyres are typified by oligotrophic conditions low in available N, but it is in these waters that picocyanobacteria <2 μm dominate. This picocyanobacterial component encompasses the genera *Synechococcus* (Scanlan, 2003; Waterbury *et al.*, 1986) and *Prochlorococcus*, the latter genus comprising probably the most abundant photosynthetic organism on Earth (Partensky *et al.*, 1999). The high numerical abundance of these unicellular cyanobacteria make them potentially important players in N recycling, and as contributors to new and regenerated production. Predicting the precise role that these organisms play in N cycling requires knowledge not just of the physical (e.g., stratified vs mixed) and chemical (e.g., nutrient concentrations that equate to oligotrophic, mesotrophic, or eutrophic conditions) nature of the water column though. It also requires an understanding of the genetic composition of the *in situ* population, and knowledge of the N resource capacity of these populations (see Fig. 24.3). Indeed, *Synechococcus* and *Prochlorococcus* populations can occupy a variety of environmental niches that are not entirely consistent with what is known with respect to N resource utilisation. Thus, in stratified oligotrophic areas *Synechococcus* generally establishes a population maxima in surface waters, where nitrate concentrations are low or undetectable, though nearly all cultured strains, but with a few exceptions (Fuller *et al.*, 2003; Moore *et al.*, 2002), can utilise nitrate for growth. Conversely, *Prochlorococcus* usually possesses a sub-surface maxima and may be the dominant phytoplankter at the base of the euphotic zone close to the nitracline. However, surprisingly all *Prochlorococcus* strains so far studied lack the ability to grow on nitrate (García-Fernández *et al.*, 2004; Moore *et al.*, 2002).


Figure 24.3 Evolutionary relationships of the 16S rRNA gene in *Prochlorococcus* and *Synechococcus* isolates (based on Fuller *et al.*, 2003). Symbols to the right of each strain show N resource utilisation capacity i.e., the ability of each strain to utilise nitrate, nitrite, or ammonium as sole N source. *Nitrite not tested. The scale indicates 0.1 substitutions per position.

For *Synechococcus* this apparent contradiction can be reconciled with the need of members of that genus to fuel phycobilisome synthesis. The capacity to utilise all available N sources, including episodic pulses of up-welled nitrate, would then be critical for construction of such a N-rich light–harvesting macromolecular structure. A low cell density at depth would then be consistent with the incident light levels at depth not providing sufficient energy to reduce nitrite to ammonium (Moore *et al.*, 2002). Overlying obvious differences in N resource utilisation amongst different *Synechococcus* strains, are more subtle differences in N physiology (see Scanlan, 2003) that are also likely an adaptation to the specific environmental niche occupied by individual genotypes.

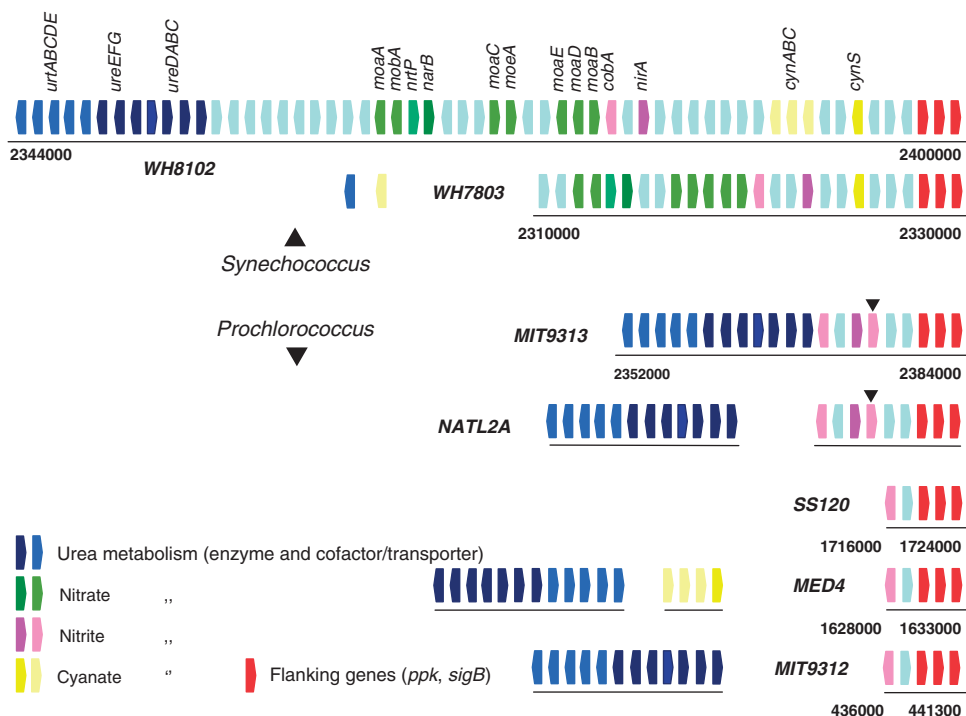
For *Prochlorococcus* the lack of nitrate utilisation amongst isolates is mirrored by utilisation of ammonium and nitrite N sources which is partitioned amongst closely related, but distinct ecotypes, a feature correlating well to the environmental niche where these resources are available and the known niche of these ecotypes (Moore *et al.*, 2002; Fig. 24.4). Indeed, the lack of utilisation of nitrite, nitrate and urea in specific strains is correlated with actual gene loss e.g., of the nitrite and nitrate reductase structural genes or the nitrate transporter (Rocap *et al.*, 2003; see Fig. 24.5 and Section 5). Interestingly, natural populations of *Prochlorococcus* can take up significant amounts of dissolved organic nitrogen in the form of amino acids (Zubkov *et al.*, 2003). Thus, at an oligotrophic site in the Arabian Sea *Prochlorococcus* was responsible for 33% of the methionine turnover by all bacterioplankton. This data suggests significant competition for reduced N compounds in the form of
Figure 24.4 Schematic diagram of potential N substrate profiles in a stratified water column, mapped against the known 'partitioned' distribution of specific *Prochlorococcus* genotypes/ecotypes from molecular ecological studies (e.g., see Moore *et al.*, 1998; Steglich *et al.*, 2003; West and Scanlan 1999).


Figure 24.5 Evolution of N acquisition capacity in marine cyanobacteria. *Synechococcus* sp. WH8102 has a wide capacity for N utilisation including nitrate, nitrite, ammonium, and urea. *Prochlorococcus* sp. MIT9313 can utilise ammonium, urea, and nitrite, MED4 ammonium and urea whilst *Prochlorococcus* sp. SS120 only uses ammonium as a N source—consistent with genomic information (Dufresne *et al.*, 2003; Palenik *et al.*, 2003; Rocap *et al.*, 2003). Additional information on the *Synechococcus* sp. WH7803, *Prochlorococcus* sp. MIT9312 and NATL2A genomes are courtesy of Dufresne and Partensky; Steglich and Chisholm resp.

amino acids exists between these autotrophs and heterotrophs in natural populations, particularly in oligotrophic areas. High rates of *Prochlorococcus* methionine uptake were also observed along a transect across the Southern Atlantic gyre, and with high red fluorescing *Prochlorococcus* populations showing a fourfold higher cellular uptake rate than low red fluorescing populations (Zubkov *et al.*, 2004). Thus, within-genus differences also appear important in this aspect of the N nutrition of these organisms.

3. REGULATION OF NITROGEN METABOLISM

Much of the N-metabolism of marine cyanobacteria observes the same basic scheme as that known for widely studied freshwater species (see Flores and Herrero 1994; Herrero *et al.*, 2001 for reviews). Nitrogen acquisition and metabolism in marine cyanobacteria are finely tuned to photosynthetic activity, the availability of additional nutrients, and other environmental factors. Most, if not all, of N-metabolism is funnelled through the GS–GOGAT pathway which—on balance—links ammonium

to oxoglutarate to yield glutamate. This glutamate forms the building block for the synthesis of other amino acids and essential cell components. Alternative N–sources like dinitrogen, nitrate, nitrite, urea, and cyanate are converted into ammonium following their uptake and they subsequently enter cell metabolism via the same route. However, compounds like amino acids and oligopeptides should also be considered as N-sources (see Section 2.3). Although very little is known about their utilization, genome sequences of *Prochlorococcus*, *Synechococcus*, and *Trichodesmium* carry genes with good similarity to those known to encode amino acid and oligopeptide transporters.

The acquisition and metabolism of N is encoded by a vast array of genes, often deposited in operons, the transcription of which is controlled by a single transcriptional activator *ntcA*, a 24 kD DNA binding protein. The *ntcA* sequence is highly conserved among cyanobacteria and it acts specifically in N stress responses (Lindell and Post, 2001). *ntcA* has been identified in all marine cyanobacteria, including both culture isolates as well as in natural samples, whilst its expression has been characterized in *Synechococcus* sp. WH7803 (Lindell and Post, 2001; Lindell *et al.*, 1998), *Synechococcus* sp. WH8103 (Bird and Wyman, 2003), *Prochlorococcus* sp. MED4 (Lindell *et al.*, 2002), *Cyanothece* sp. BK68K (Bradley and Reddy, 1997) and *Trichodesmium* sp. IMS101 (Wang and Post, unpublished results). Interestingly, *ntcA* expression patterns differ considerably, both between organisms but also during different growth conditions within the same organism. Thus, *Synechococcus* sp. WH7803 expresses *ntcA* at three distinct levels, minimal expression when ammonium is sufficient, intermediate expression when ambient ammonium is <1 µM, and maximal expression when cells are N-deprived (Lindell and Post, 2001).

In *Prochlorococcus* sp. PCC9511, a surface-adapted strain (Rippka *et al.*, 2000), *amt1*, encoding a high affinity ammonium transporter, is expressed at high levels both in the presence of ammonium as well as during all but the severe stages of N-deprivation. This constitutive *amt1* expression, and the absence of a typical *ntcA* binding site upstream of *amt1*, has led to the proposal that *amt1* is not regulated by *ntcA* in this *Prochlorococcus* strain (Lindell *et al.*, 2002). Whether constitutive *amt1* expression occurs in *Synechococcus* sp. WH7803 and other marine *Synechococcus* strains awaits further investigation, but interestingly there is a recent report of constitutive expression of *nirA*, encoding nitrite reductase, in the marine *Synechococcus* sp. strain WH 8103 (clade III), i.e., with little effect of ammonium on *nirA* transcription (Bird and Wyman, 2003). Such regulation contrasts with the enhanced expression of *nirA* and *amt1* in the absence of ammonium in freshwater *Synechococcus* strains (see for example Vazquez-Bermudez *et al.*, 2002) and highlights the regulatory constraints placed on these organisms in the N-poor marine ecosystem, a feature though that may well differ subtly between coastal and open-ocean strains.

4. ASSESSMENT OF *IN SITU* NITROGEN-STATUS

One of the outstanding challenges in biological oceanography is the determination of the limiting step in marine primary productivity. Both abiotic (nutrients, light, temperature etc.) and biotic factors (grazing, viruses, allelochemicals) are of

significance, but it is generally believed that productivity is ultimately controlled by nutrient supply. Determining the limiting step in marine productivity is not only important for basin-scale carbon and nutrient flux estimates, but also affects our understanding of ecosystem structure and functioning. Over the last decade it has become increasingly clear that nutrient limitation changes dynamically over space and time, e.g., distinct provinces of the Pacific Ocean are controlled by either N (see e.g., Tyrrell and Law, 1997), P (Karl, 1999), or Fe supply (Coale *et al.*, 1996). A comparable situation occurs at different sites in the Atlantic Ocean (Graziano *et al.*, 1996; Mills *et al.*, 2004). Moreover, invasion by diazotrophic cyanobacteria may drive an N-controlled phytoplankton community into one limited by P-supply. Furthermore, the main taxonomic groups within the phytoplankton community may be controlled by different nutrients, e.g., diatom blooms are controlled by silicate as opposed to P-controlled blooms of diazotrophic cyanobacteria. Nevertheless, it is fair to state that nitrogen is likely the main nutrient that limits phytoplankton productivity as N-requirements of each phytoplankton group are 1 to 2 orders of magnitude greater than those for P and Fe, respectively. As cyanobacteria are reportedly the most abundant phytoplankton fraction in nutrient-deplete oligotrophic waters they routinely meet and adapt to limited N-supplies.

As mentioned above, the *ntcA* gene is commonly found in cyanobacteria and it is the sole gene controlling N-stress responses in cyanobacteria, non nitrogen-fixing and nitrogen-fixing species alike. In the marine unicellular cyanobacteria *Synechococcus* and *Prochlorococcus*, transcription of the *ntcA* gene is up-regulated when ammonium is lacking (Lindell and Post, 2001; Lindell *et al.*, 1998). The threshold ammonium concentration below which *ntcA* expression is up-regulated was determined to be <1 μM in *Synechococcus* sp. WH7803 cultures (Lindell and Post, 2001). *ntcA* is thus expressed over an ecologically relevant concentration range. Moreover, *ntcA* expression was shown to be specific to N-stress responses and to derive from a single gene copy (Lindell and Post, 2001). It is also specific for marine cyanobacteria (Post, 2005). The enhanced expression is required for both nitrite and nitrate utilization in *Synechococcus* sp. WH7803 (Lindell *et al.*, 1998, 1999) and *ntcA* expression may thus have the potential for differentiating between regenerated and new primary production by cyanobacterial phytoplankton. In order to use *ntcA* probing as a means to assess the N-status of marine cyanobacteria, a protocol was developed which studies *ntcA* expression of natural populations relative to their basal and maximal transcript levels (Lindell and Post, 2001). The latter were obtained from the rapid response of *ntcA* expression to additions of 1 mM ammonium and 100 μM methionine-sulfoximine (MSX)—a GS inhibitor—respectively (Lindell and Post, 2001). Based on this protocol it was shown that *Synechococcus* populations in the northern Gulf of Aqaba were not N-deprived over the 1999 annual cycle (Post, 2005). A consecutive study during 2000 established that such *Synechococcus* populations express *ntcA* at an intermediate level shortly after a deep mixing event which injected micromolar concentrations of nitrate into the photic zone (Lindell *et al.*, 2005). *Synechococcus* populations were found to be ammonium sufficient in all other periods even though ammonium concentrations did not exceed 60 nM (Lindell *et al.*, 2005). It would appear then that *ntcA* expression by *Synechococcus* in nature responds to the ammonium flux rather than to ammonium concentration, the latter

being the case for cultures. Although *ntcA* probing allows for unequivocal assessment of the N-status of marine cyanobacteria, the applicability of the protocol may not be universal. On the one hand, not all cyanobacteria express *ntcA* at distinct levels consistent with their N-nutrition. For example, the diazotrophic cyanobacterium *Trichodesmium* sp. IMS101 (see Section 2.1) does not down-regulate *ntcA* transcript to basal levels in the presence of ammonium (Wang and Post, unpublished results). On the other hand, assessment of maximal levels of *ntcA* expression requires the uptake of added MSX via an amino acid transporter. Absence of such a transport system in e.g., *Prochlorococcus* spp. requires that different GS inhibitors, like glufosinate (Aflalo *et al.*, 1999), are used for N-status assessment in such organisms.

5. Genomics

A recent development in the biology of cyanobacteria concerns the sequencing of whole genomes. The first cyanobacterial genome to be sequenced was that of *Synechocystis* sp. PCC6803, a model organism in photosynthesis studies (Kaneko *et al.*, 1996). The sequencing of marine cyanobacterial genomes followed on the heels of this breakthrough. The interest in these genomes was triggered by the significant contribution of marine cyanobacteria to the "biological pump," i.e., the exploration of the genetic potential required to withdraw CO_2 from the surface ocean (and thus atmosphere) and deposit particulate organic matter in the deep ocean. Currently, several marine cyanobacterial genomes are at various stages of sequencing, annotation, and publication, whilst others have either been published or are at an advanced stage. Fully annotated genome sequences are available for *Prochlorococcus* sp. strains MED4, MIT9313, and SS120 (Dufresne *et al.*, 2003; Rocap *et al.*, 2003) along with that of *Synechococcus* sp. strain WH8102 (Palenik *et al.*, 2003). Further genome sequences are in advanced stages of annotation. *Prochlorococcus* sp. strains MIT9312 and NATL2A along with *Synechococcus* sp. strains WH7803, RCC307, and CC9311 are expected to provide much complementary information regarding the evolution of this group of unicellular picocyanobacteria, their physiological traits and their genetic potential to address environmental conditions encountered in distinct ocean niches. In addition, a number of other *Synechococcus* genomes have been selected for sequencing (http://www.moore.org/microgenome/strain-list.aspx). As well as those of *Prochlorococcus* and *Synechococcus*, genomes of the nitrogen-fixing marine cyanobacteria *Cyanothece* sp. *Trichodesmium erythraeum* strain IMS101 and *Crocosphaera watsonii* are currently being analyzed (http://www.jgi.doe.gov). Together these genomes are expected to yield a wealth of information on nitrogen acquisition capabilities, nitrogen metabolism, and nitrogen stress responses in these species.

Based on the genomes available at the time this chapter was written, we can make the following statements. Both *Prochlorococcus* and *Synechococcus* have relatively small genomes ranging in size from roughly 1.6 to 2.5×10^6 nucleotides (Dufresne *et al.*, 2003; Palenik *et al.*, 2003; Rocap *et al.*, 2003). They appear to share a common gene pool of some 1300 genes, with the remainder of the genes mostly encoding

functions that define adaptation to their respective (micro) niches. The genes required for basic nitrogen metabolism are scattered over the genome of *Synechococcus* sp. WH8102, the species thought to be most closely related to the ancestor of the unicellular marine *Synechococcus–Prochlorococcus* clade. The ammonium transporter *amt*, *glnA*, and *glts* encoding GS–GOGAT, *glnB* encoding the regulatory protein P_{II} and the N-stress response gene *ntcA* are all found at different locations on the genome (Palenik *et al.*, 2003). On the other hand, genes required for the uptake of alternative nitrogen sources, e.g., nitrite, nitrate, urea, cyanate are found as a large cluster of tightly grouped genes (Fig. 24.5).

The 11 genes required for the urea transporter and the urease enzyme are organized in three adjacent clusters. Likewise the ∼17 gene cluster for nitrate utilization includes the nitrate permease gene *nrtP*, the nitrate reductase gene *narB* and genes involved in molybdopterin synthesis, supplying the nitrate reductase cofactor. Finally, the four genes required for cyanate uptake and hydrolysis are located in this genome region. Whereas nitrite and nitrate are widely available in the environment, and marine *Synechococcus* can utilize either of these as its sole source of nitrogen, cyanate is a poorly known compound both in terms of cyanobacterial nitrogen metabolism and as a nitrogen source in the marine environment.

This large cluster of genes can be identified in the other marine *Synechococcus* and *Prochlorococcus* genomes currently available by use of the flanking genes *ppk–sigB* (polyphosphate kinase, sigma factor B) on one side and the *pyrG* (glutamine amidotransferase) gene on the other. Comparison of this genome section among the various closely related strains indicates a dynamic plasticity in its make-up (Fig. 24.5), possibly relating to nitrogen sources available in different ocean niches (Fig. 24.4). *Synechococcus* sp. WH7803, known for its inability to grow on urea, lacks the genes for urea utilization. All the *Prochlorococcus* strains known are incapable of nitrate utilization (Moore *et al.*, 2002) and the genes encoding this function are all missing supposedly due to a single deletion event (Rocap *et al.*, 2003). The low-light adapted *Prochlorococcus* strains MIT9313 and NATL2A retained the genes for nitrite utilization and indeed grow on nitrite as the sole nitrogen source (Moore *et al.*, 2002; Rocap *et al.*, 2003). This phenotype is consistent with the depth distribution of low-light adapted *Prochlorococcus* which centers around depths where the primary nitrite maximum is found. As cyanate has not been identified as a nitrogen source in surface waters, it is as yet unclear what the significance is of the presence of the cyanate utilization genes. However, key genes in this genome region, required for the utilization of the various nitrogen sources, are characterized by the presence of an *ntcA* binding site in the promoter region suggesting they are controlled by *ntcA*. Likewise the nitrogen metabolism genes *glnA* and *glnB* have putative *ntcA*-binding sequences in their promoter regions and are likely controlled by *ntcA*. The situation is less obvious for the utilization of other nitrogen sources, like amino acids, oligopeptides etc. for which open reading frames with high similarity to genes encoding transporters for these compounds are found on the genomes. Such open reading frames more often than not lack putative *ntcA* binding sites and thus their function in the nitrogen stress response remains as yet unresolved.

Interestingly, the nitrogen stress regulon of the unicellular marine picocyanobacteria appears much simpler than that of their freshwater counterparts such as

Synechocystis sp. PCC6803 and *Synechococcus* sp. PCC7942. These freshwater strains can carry secondary transcriptional activators like *ntcB*, encoding a *lysR*-type transcriptional activator required for optimal utilization of nitrate (Aichi and Omata, 1997; Aichi *et al.*, 2001), *gifA*, *gifB*, encoding inhibitory factors for GS activity (Garcia-Dominguez *et al.*, 2000), and *nblA* required for the timely degradation of the phycobilisome under environmental stress including nitrogen deprivation (Collier and Grossman 1994; Grossman *et al*, 1994; Luque *et al.*, 2001; Schwarz and Grossman, 1998) all of which appear absent in marine strains. The lack of the *ntcB* gene in the marine *Synechococcus* genomes so far analysed is perhaps surprising given the often massive surface blooms of these organisms in waters freshly enriched with nitrate. In addition, these genomes lack genes required for the synthesis and degradation of cyanophycin, an N-storage polypeptide commonly found in other cyanobacteria and including some marine phycoerythrin-containing *Synechococcus* (Wingard *et al.*, 2002) suggesting marine *Synechococcus* is mostly incapable of exploiting ambient nitrogen levels beyond its cellular requirements.

   Although the genomes of the nitrogen fixing *Cyanothece* sp. *Trichodesmium eythraeum* strain IMS101 and *C. watsonii* are at an advanced stage of analysis, no complete annotation file has yet been made public. However, these genomes are much larger than those of *Synechococcus* and *Prochlorococcus* ranging in size from ~5.5 to 7.8 × 10^6 nucleotides. This is slightly surprising as e.g., *Cyanothece* and *Crocosphaera* are unicellular and with a cell diameter of <8 μm are of the same size class as *Synechococcus*. The larger genome sizes likely reflects the inclusion of the extensive family of *nif* genes as well as genes required for the spatial segregation of the carbon and nitrogen fixation processes along the filaments of *Trichodesmium* (Berman-Frank *et al.*, 2001a; Janson *et al.*, 1994; Lin *et al.*, 1998) or the temporal segregation of these processes in the unicells (Bradley and Reddy, 1997; Reddy *et al.*, 1993). Although they are often considered as obligate nitrogen fixers, the genomes of these cyanobacteria are likely to have further common features given that they can utilize a wide variety of nitrogen sources, very much like their non nitrogen-fixing counterparts.

6. CYANOBACTERIA AND THE NITROGEN-CYCLE

   The marine cyanobacteria are mainly found in the (sub)tropical ocean and sometimes extend into waters at more temperate latitudes. They thus thrive in waters which are either "permanently" stratified or ones that are subject to seasonal stratification. Such waters are preconditioned to become nitrogen-deplete, so that selective pressure favours nitrogen fixing cyanobacteria that inject new nitrogen into the photic zone. They also favour the abundance of picocyanobacteria with their extremely low sinking rates and their surface-to-volume ratios that supports life near the diffusion limit for dissolved nutrients. It is interesting to note that cyanobacterial species are mostly found in the strongly illuminated surface layers. *Trichodesmium*, *Synechococcus* and *Prochlorococcus* have all been described as populating surface layers in dense communities. Of these, *Trichodesmium* is considered as an

obligate nitrogen fixer and thus to be engaged in new primary production only. Likewise, *Synechococcus* may be characterized as contributing to new primary production. It is most abundant in recently mixed water columns and up-welling areas, water bodies that are enriched in nitrate. Natural populations have been shown to adapt to utilize this nitrogen source (Lindell *et al.*, in press; Post, 2005). Low light adapted *Prochlorococcus* are found at depths that coincide with the primary nitrite maximum and such types can utilize nitrite but not nitrate (Moore *et al.*, 2002; Rocap *et al.*, 2003). They may thus also contribute to new primary production, although it is estimated to be quantitatively less significant. Low light adapted *Prochlorococcus* populations are less abundant than those of high light adapted *Prochlorococcus* and light may become a limiting factor as these populations experience ambient light of <5% of surface intensities. Species that are involved in regenerated production—traditionally considered the main contribution of cyanobacteria—belong both to *Synechococcus*, which maintains a sizable population in nitrogen deplete surface water over extended periods, as well as high light adapted *Prochlorococcus*. These latter organisms, which contribute significantly to regenerated production, rely solely on urea and ammonium and they are most abundant in layers deplete of oxidized nitrogen sources like nitrate. Much less is known on the spatial and temporal distribution of the diazotrophs *Cyanothece* and *Crocosphaera* though Fe levels and water column temperature appear important determinants (Falcón *et al.*, 2004a; Mazard *et al.*, 2004; see Section 2.2).

Cellular N-quota and thus N-requirements of phytoplankton in general, and their cyanobacterial component in particular, exceed those of other inorganic nutrients. Hence one would intuitively expect nitrogen to be the factor limiting marine phytoplankton biomass and its productivity. However, cyanobacteria also have the capacity to upset the canonical Redfield ratio, the "natural" balance relating N:P both as dissolved nutrients and plankton mass. Thus, *Trichodesmium* forms a source of nitrogen input in the surface ocean, but it constitutes a sink for phosphate. Hence, the very process of N_2-fixation may inject significant amounts of new nitrogen into the photic layer. This nitrogen can become immediately available via ammonium excretion or follow a more convoluted route via the marine food web. Whereas little is known about all other N_2-fixers, *Trichodesmium* is known for its potential for ammonium release (see Section 2.1). Grazing pressure on *Trichodesmium* is considered not extensive, with the copepod *Macrosetella* as the main grazer, although *Trichodesmium* specific fatty acids have been identified in other marine zooplankters including larger tunicates (Post *et al.*, 2002). Water bodies known to carry *Trichodesmium* populations have been shown to exhibit properties consistent with P-stress (Sanudo-Wilhelmy *et al.*, 2001). Thus, in the nutrient deplete waters of the Gulf of Aqaba, one may find occasional blooms of *Trichodesmium* (Post *et al.*, 2002). During such periods phytoplankton typically shows enhanced alkaline phosphatase activities (Li *et al.*, 1998) and the cyanobacterial P-stress protein PstS is highly expressed during this period (Fuller *et al.*, 2005). *Trichodesmium* populations are themselves P-stressed with high levels of alkaline phosphatase activity (Dyhrman *et al.*, 2002; Stihl *et al.*, 2001) and enhanced PstS (Scanlan, unpublished results). Alternatively, one should consider that *Trichodesmium* populations may become Fe-limited. Both a low Fe supply in certain ocean provinces and the high

Fe-requirements of *Trichodesmium* as compared to other phytoplankters (Berman-Frank *et al.*, 2001b) contribute to this notion. Whether Fe limits N_2-fixation in free-living cyanobacteria like *Crocosphaera*, *Cyanothece*, and possibly even in endosymbionts like *Richelia* needs to be established. Certainly, the two former cyanobacteria do have the capacity to respond to Fe-limiting conditions (Webb *et al.*, 2001).

7. FUTURE PERSPECTIVES

Over the last two decades developments in flow cytometry, molecular biology, microbial genomics, N-isotope studies etc have propelled cyanobacteria into a role as key players in the field of biological oceanography. On the other hand such studies have raised many more questions that need to be addressed. Firstly, genome information indicates that N-stress responses may differ substantially with different cyanobacteria carrying different gene pools for the acquisition of alternative N compounds. Some of these N compounds have not been recognized as ''common'' N sources in the marine environment. The fact that many cyanobacteria have genes with a high degree of similarity to amino acid, cyanate, nitrite, oligopeptide transporters and to enzymes required for the incorporation of these N compounds into the cell's metabolism attest to the fact that these compounds may have some significance. Especially interesting in this respect is the fact that diazotrophic cyanobacteria considered to be obligate N_2-fixers have the capacity to address a wide suite of inorganic and organic N species.

Other, unicellular, N_2-fixers have only recently been shown to be significant contributors to the marine phytoplankton communities (Falcón *et al.*, 2004a; Montoya *et al.*, 2004; Zehr *et al.*, 2001). Many aspects of their spatial and temporal distribution as well as the environmental factors determining the niche they occupy, are still unresolved.

Lastly, recent studies have shown an unexpected genetic diversity among, the morphologically uniform, marine *Synechococcus* with at least 10 distinct clades identified (Fuller *et al.*, 2003; Rocap *et al.*, 2003). It needs to be established whether such *Synechococcus* clades represent different ecotypes adapted to different niches in the ocean environment. Moreover, little is known whether certain clades represent stable populations over seasonal cycles and/or multi-annual time periods.

In the near future we anticipate further progress in ocean acidification as a result of increased atmospheric CO_2 concentrations (Caldeira and Wickett, 2003) with sea surface pH potentially reaching as low as 7.8, a decrease of ~0.5 pH units since the middle of the 20th century. More extensive periods of stratification and a spreading of oxygen-minimum zones in the world's oceans are also expected. Each of these processes is likely to impact on the oceanic N-cycle and the role cyanobacteria play within these systems. Specifically, these climate induced changes are likely to have significant effects on the composition of marine cyanobacterial communities and hence on the N dynamics they carry out.

VIRUSES, BACTERIA, AND THE MICROBIAL LOOP

Ian Hewson *and* Jed A. Fuhrman

Contents

1. INTRODUCTION

Study of the role of microorganisms in the marine environment has led to the concept of amicrobial loop in the oceans, which cycles nutrients through organisms smaller than 10 um. Our concept of the marine microbial loop has undergone

considerable change since formalization over 20 years ago because newly recognized metabolic capabilities, types of organisms, revised rates of metabolic processes as well as a greater understanding of the genetic diversity of microorganisms have been observed. Here we review developments in our understanding of the microbial loop as it relates generally to all marine microorganisms as well as to the marine N cycle, focusing specifically upon prokaryotes (bacteria and archaea) and the role of viruses in the emerging microbial loop paradigm.

The microbial loop is a critical component of the marine nitrogen cycle in which viruses, prokaryotes, and unicellular eukaryotes play distinct roles. Nitrogen transformations e.g., nitrogen fixation, ammonification, nitrification, ammonium oxidation, and denitrification are mediated by prokaryotes, and the formation of autochthonous dissolved organic nitrogen is a direct result of either intracellular component leakage into surrounding waters by grazing, apoptosis or viral lysis, or by direct excretion from phytoplankton. Thus, the microbial loop plays a key role in both the generation and uptake of both organic and inorganic nitrogen in the ocean. Understanding of the dynamics of marine microbial communities has undergone substantial revision in the past three decades since initial descriptions of the microbial food web in the 1970s (Pomeroy, 1974) and formalization of the microbial loop by (Azam *et al.*, 1983) (Fig. 25.1). Classical ideas that bacteria were responsible solely for remineralisation of zooplankton and fish wastes (Steele, 1974) and unable to derive nutrition from the pool of dissolved organic C (Krogh, 1934; Sverdrup *et al.*, 1942), were then challenged by studies rejecting ideas of tightly-closed grazing food chains with little flow of organic matter to microheterotrophs (le B. Williams, 1981), and later by studies demonstrating that 10–50% of primary production and about 40% of reduced inorganic N is consumed directly by prokaryotic nanoplankton (Andrews *et al.*, 1971; Fuhrman and Azam, 1980, 1982; Hagstrom *et al.*, 1979; le B. Williams, 1981; Pomeroy, 1974; Sieburth *et al.*, 1977; Suttle *et al.*, 1990a) (Fig. 25.2). The definition of ''bacteria'' in original models has been revised to include not only bacteria (''heterotrophic'' bacteria including photoheterotrophic genera) and cyanobacteria, but also an entirely new domain, the Archaea. Until 1992, Archaea were originally believed to occur only in ''extreme'' environments, but since have been found in mesopelagic (100–500 m), pelagic (Fuhrman *et al.*, 1992) and later in surface coastal (DeLong *et al.*, 1992) waters, but also in large abundance in the deep ocean (Fuhrman and Ouverney, 1998; Karner *et al.*, 2001), where they may play a significant role as dominant nitrifiers (Ward Chapter 5, this volume). Observation of a ubiquitous, abundant, and diverse viral assemblage in the marine environment further challenged understanding of the microbial carbon transfer (Bergh *et al.*, 1989; Proctor and Fuhrman, 1990; Wommack and Colwell, 2000). Even the lifestyles of the protozoan component of microbial communities has undergone revision to include not only heterotrophic and autotrophic, but also mixotrophic eukaryotes (Caron, 2000).

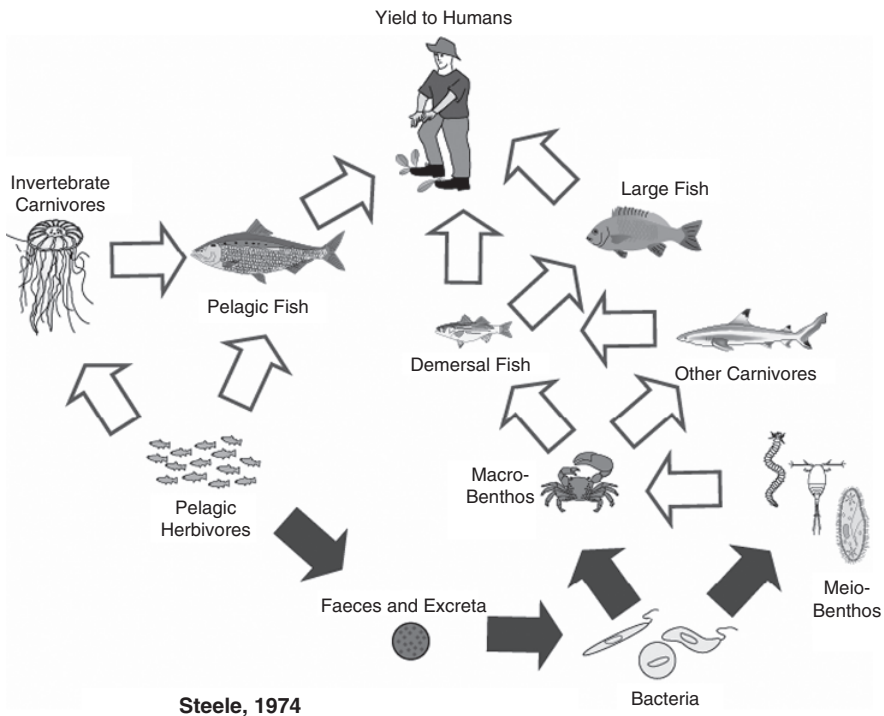
The purpose of this chapter is to emphasise the role of the microbial loop in the oceanic nitrogen cycle. It begins by briefly introducing classical concepts of microbial loop function, then shifts to the increase in our knowledge that has occurred in the past three decades. It then introduces the components of the microbial loop that


Figure 25.1 Two classical marine food webs adapted from Steele (1974) and Pomeroy (1974), where microbial loop cycling is indicated by red arrows. "Net" phytoplankton and zooplankton were defined as those collected in 20 μm plankton nets; "nannoplankton" were those cells passing through plankton nets. One significant step in the Pomeroy (1974) model was the inclusion of dissolved organic matter (DOM) which is remineralised by bacteria and thereby made available to higher trophic levels.
Figure 25.2 Contemporary microbial loop with nitrogen fluxes under homogenous N supply, redrawn from Suttle *et al.* (1990b). The numbers next to each arrow indicate the relative partitioning of inorganic N into different functional groups of bacteria, protists and metazoa, and the numbers beneath groups of organisms indicates the biomass of C in each size class. Under pulsed N supply, a greater proportion of NO_3^- and NO_4^+ is transferred to larger organisms than to smaller organisms.

exist in contemporary conceptualizations and models, including viruses as the new members of the microbial loop paradigm.

1.1. Historical context for the microbial loop

Observations of submicron-sized living particles in aquatic environments can be attributed originally to Antonie van Leeuwenhoek (van Leewenhoek, 1677) who examined lake water samples through a microscope, and observed protozoa, metazoa, and bacteria. Early and continuing attempts to isolate bacteria from the marine environment (Gran, 1901; Russel, 1892, 1893) were later found to be inconsistent with reports of large abundances of bacteria-like organisms in seawater, and were interpreted to mean that the majority of bacteria in the marine environment were not active (i.e., "the great plate count anomaly" (Jannasch and Jones, 1959; Staley

and Konopka, 1985)). Accurate counts of bacteria were not obtained until the advent of epifluorescence microscopy and DNA stains in the late 1970s (Ferguson and Rublee, 1976; Hobbie et al., 1977; Watson et al., 1977), and measurements of their activity have since confirmed that most bacteria show at least some measureable activity (Fuhrman and Azam, 1982; Tabor and Neihof, 1982b).

Initial concepts of the role of microbes in the marine ecosystem suggested that they were mostly decomposers of macro-organism faeces in sediments (Steele, 1974), before the observation of high bacterial abundance in the oceans. But a forward thinking microbiologist (Pomeroy, 1974) recognised bacteria as reminer-alising dissolved organic matter (DOM) and feeding higher trophic levels. A few years earlier, higher levels of chlorophyll–a associated with ''nanophytoplankton'' (i.e., passing through phytoplankton nets) than to ''net'' phytoplankton (i.e., trapped within a net) were found, which suggested that photosynthesis may be dominated by smaller phototrophs (Malone, 1971). With the discovery of unicellular cyanobac-teria (which account for most chlorophyll–a in the ocean) (Chisholm et al., 1988; Johnson and Sieburth, 1979; Waterbury et al., 1979) it became clear that bacteria played far more complicated roles in marine ecosystems than originally thought, and caused a re-think of the role of prokaryotes in material and energy cycling in the ocean. Subsequent models of the marine food webs contain shunts of DOM from zooplankton and higher organisms (secondary production) and phytoplankton exu-dation (primary production) into bacteria (Azam et al., 1983).

Until the late 1980s it was thought that the bacteria in the ocean comprised only a few different species due to low morphological diversity observed in culture (Giovannoni et al., 1990). A greater understanding of the diversity of bacteria was gained when advances in molecular biology allowed universal, evolutionarily-conserved regions (particularly 16S ribosomal RNA) within the bacterial genome to be sequenced (Pace et al., 1986). This indicated a wide richness of marine bacteria, many of which were not culturable by classical enrichment techniques (Giovannoni and Rappe, 2000; Jannasch and Jones, 1959). Further developments in molecular techniques allowed discrimination of bacteria involved in different aspects of nutrient cycling based upon functional gene sequences (Zehr et al., 2000).

More recently, sequencing of large segments of microbial genomes from nature has elucidated new energy-assimilating pathways, for example that involving the retinal–containing pigment bacteriorhodopsin (Beja et al., 2000). With discoveries of phylogenetically diverse previously unrecognised prokaryotic ecophysiological pro-cesses (Beja et al., 2000; Rocap et al., 2003; Venter et al., 2004; DeLong et al., 2006; Rusch et al., 2007), and a greater understanding of the size-spectra and metabolic plasticity of protists (Caron, 2000; Sherr and Sherr, 2000), the conceptual microbial loop has become vastly more complicated than originally conceived.

1.2. Components of the microbial loop

In its simplest form, the microbial loop comprises autotrophs, heterotrophs and an abiotic pool of DOM. These organisms are <100 μm and in basic models comprised bacteria, flagellates, ciliates, zooplankton, phytoplankton, and cyanobacteria (Azam

et al., 1983). The microbial loop described in recent years has been expanded to include viruses, heterotrophic bacteria, pico- and nano-cyanobacteria, anoxygenic aerobic/anaerobic phototrophic bacteria, heterotrophic flagellates, heterotrophic diatoms, and microzooplankton (a catchall term which refers to all hetero- and mixotrophic protists which phagocytise particles and are <200 μm in length). Bacteria in the early microbial loop models included all cells <1 μm and hence encompassed Bacteria and Archaea, the latter of which can comprise up to 60% of bacterioplankton in deep sea environments (DeLong *et al.*, 1999; Fuhrman and Ouverney, 1998; Karner *et al.*, 2001). The composition of the DOM pool has also received considerable study in the past 20 years. DOM is comprised of a spectrum of compounds of variable refractability ranging from low molecular weight (i.e., <2 kDa) monomers, lipids, fatty acids, complex condensates, and amino acids, to high molecular weight (>100 kDa) aliphatic algaenans, proteins, nucleic acids, and polymers (Gelin *et al.*, 1999; Ogawa and Tanoue, 2003). Of these compounds, those with high molecular weight are taken up more rapidly and consequently are younger, while low molecular weight compounds are less utilised by bacterioplankton and therefore turn over slowly (Amon and Benner, 1996; Loh *et al.*, 2004). DOM may form complex aquatic gels (Azam, 1998) which result in ''hotspots'' of microbial activity and possibly diversity (Long and Azam, 2001; Seymour *et al.*, 2004). The net result of research in the past two decades is a more complete understanding that the seemingly homogeneous environment of surface waters is in fact heterogeneous on the micrometer scale, and encompasses a wide variety of metabolic pathways and capabilities.

1.3. Viruses as a member of the microbial loop

Isolation of bacteriophage directly from coastal and pelagic seawater (Moebus, 1980) and observation of high viral abundances in marine plankton (Bergh *et al.*, 1989; Proctor and Fuhrman, 1990) and sediments (Danovaro and Serresi, 2000; Hewson *et al.*, 2001a,b,c; Paul *et al.*, 1993), raised interest in their biogeochemical and ecological roles in the marine environment (Fuhrman, 1999; Wommack and Colwell, 2000). While some reviews of bacterivory indicated close coupling between bacterial production and loss via grazing in some environments (Strom, 2000), others suggested that grazing was insufficient to account for all production (Hamels *et al.*, 2001; McManus and Fuhrman, 1988). Data showing high rates of viral mortality in both the water column (Proctor and Fuhrman, 1990) and sediments (Hewson and Fuhrman, 2003) have shown that viruses must be included in contemporary models of the microbial loop. In some cases, viruses may be the dominant form of bacterial mortality and consequent organic N release (Bratbak *et al.*, 1993; Hewson and Fuhrman, 2003).

   This review focuses on four key research areas directly related to the microbial loop which are critical to the oceanic N cycle and for which the picture is slowly evolving. First, the opening of the black box of marine bacterial taxonomy and physiology is reviewed, which provides context for later sections addressing bacterial ecology and physiology. The distribution of secondary production in the oceans is then reviewed since a global- and ecosystem-scale biogeochemical view of bacterial

activities in seawater is warranted in the context of the marine N cycle. A review of viral lysis as a newly recognised shunt of N through the microbial loop follows, since this source of mortality has important consequences for the cycling of organic N in marine plankton. This work will also review key differences between pelagic and sediment microbial food webs, since sediments are sites of important N cycling processes. Finally, it concludes with a discussion of several promising future directions for research on the role of the microbial loop in the oceanic N cycle, as well as a new view of the microbial loop.

2. BACTERIAL DIVERSITY AND PHYSIOLOGY

Early studies of marine bacteria via culture-based methods indicated a low abundance in seawater (Sverdrup *et al.*, 1942; ZoBell, 1941), and that their assemblages were not diverse (Waksman, 1934). Reliable enumeration techniques developed in the late 1970s indicated that typical bacterial abundances in marine surface waters exceeded colony-forming unit (cfu) estimates by over two orders of magnitude (Hobbie *et al.*, 1977), with abundances of typically 10^9 cells l^{-1} in surface waters. Employment of microautoradiographical and molecular techniques has since indicated that bacterioplankton and sediment bacteria have a spectrum of activities (Fuhrman and Azam, 1982; Tabor and Neihof, 1982b; Ouverney and Fuhrman, 1999a,b). The percentage of "actively growing" bacteria (i.e., those growing at a rate that makes them detectable above thresholds of these techniques) can range from below 20% to greater than 90% (Karner and Fuhrman, 1997; Luna *et al.*, 2004; Smith and del Giorgio, 2003). The advent of flow cytometry has allowed observation of cellular DNA content and has indicated that bacterioplankton contain a range of DNA concentrations, which has been argued to be an indicator of physiological state (Button and Robertson, 1989; Gasol *et al.*, 1999). Rates of bacterial production measured by "bulk" techniques (i.e., radioactive thymidine or leucine incorporation (Fuhrman and Azam, 1982; Simon and Azam, 1989)) represent averages among the entire prokaryotic community. Reportedly "live" and "dead" bacteria in marine systems can be observed by use of vital stains (i.e., those reporting metabolite formation within cells or associated with cell wall permeability), however, these may be somewhat misleading since there are likely cells within assemblages that fall below the detection threshold of such stains (which are described incorrectly as "dead") (Sherr *et al.*, 1999) or which can rise above detection thresholds when favorable conditions occur (Choi *et al.*, 1999).

2.1. Broad phylogenetic affiliation of bacteria

The term "bacteria" in the ocean is commonly used to describe prokaryotes (Archaea and Bacteria). In the last 20 years, there has been an explosion in the understanding of the phylogeny of bacteria that is based primarily upon culture-independent sequencing of the universally conserved genes (i.e., those on which there is strong evolutionary selection) involved in ribosome function (Giovannoni and Rappe, 2000; Olsen *et al.*,

1986; Pace *et al.*, 1986). Early molecular studies utilised length heterogeneity in electrophoresis of extracted 5S rRNA (Fox and Woese, 1975; Stahl *et al.*, 1981) from mixed, low-diversity lake communities to examine assemblage structure (Hofle, 1988). A second approach, in which mixed community DNA was sheared and ligated into lambda phage DNA was proposed, but not widely adopted, probably due to the difficulty in obtaining universally conserved fragments in lambda libraries (Schmidt *et al.*, 1991). Later studies sequenced part of the 16S rRNA gene amplified with PCR primers designed from cyanobacterial sequences (Giovannoni *et al.*, 1990), and by amplification using universal primers (Fuhrman *et al.*, 1992, 1993) from DNA extracted from natural mixed communities. 16S rRNA is larger than 5S rRNA (*ca.* 1492 bp *cf.* 126 bp). The 16S rRNA gene contains both conserved and variable regions and provides greater phylogenetic resolution than 5S rRNA. Further studies examining the intergenic spacer region (lying between the 16S and 23S rRNA genes) have indicated even more phylogenetic microdiversity among closely related taxa (Brown and Fuhrman, 2005, Garcia–Martinez *et al.*, 1999; Garcia–Martinez and Rodriguez–Valera, 2000; Orcutt *et al.*, 2002). Very recently, whole metagenome (i.e., the combination of all genomes of all organisms present at a single location) shotgun sequencing has been applied to marine bacterioplankton communities and has indirectly provided further appreciation of the depth of microdiversity in communities (Rusch *et al.,* 2007; Venter *et al.,* 2004). Interesting, in the first such marine metagenomics study, the genomes of the most common marine taxa (SAR–11) could not be closed (i.e., assembled computationally into a continuous chromosome) due to high microdiversity (Giovannoni, 2004).

PCR amplification biases are a concern in studies examining bacterial diversity. Biases investigated include uneven operon copy number (Crosby and Criddle, 2003), bias in template annealing temperatures (Suzuki and Giovannoni, 1996; Suzuki *et al.*, 1998) and differential extractability of bacterial cells (Polz and Cavanaugh, 1998; Polz *et al.*, 1999). However there has been at least one report of few net PCR biases, with proportional amplification of genes in mixed-culture conditions (Leuders and Friedrich, 2003). Most marine bacteria are oligotrophic and thus are slow growing, hence they probably contain only single or a small number of operon copies (Klappenbach *et al.*, 2000). It is interesting as well to note that clone libraries constructed using PCR based techniques (Fuhrman *et al.*, 1993; Giovannoni *et al.*, 1990) have very similar proportions of phylogenetic groups to those estimated with PCR-independent approaches (e.g., metagenomics and lambda phage libraries) (Schmidt *et al.*, 1991; Venter *et al.*, 2004).

Prokaryotic communities in the marine environment are comprised primarily of eleven broad groups of organisms, many of which have relatively unknown physiology due to their low culturability on enriched media (Giovannoni and Rappe, 2000). For example, the family Proteobacteria includes a cluster of phylotypes, described as the SAR–11 group (in the α-Proteobacteria), named for their original sequence recovery in the Sargasso Sea (Giovannoni *et al.*, 1990). These are abundant (making up ∼30% of total counts (Morris *et al.*, 2002)) and ubiquitous in the world's oceans (Morris *et al.*, 2002), yet are only recently culturable and therefore have almost completely unknown physiology (Rappé *et al.*, 2002; Simu and Hagstrom, 2004). Aside from the α-Proteobacteria (SAR–11, SAR–116, *Roseobacter*), marine plankton contains diverse and abundant γ-Proteobacteria

and cyanobacteria. Cytophaga–Flavobacteria–Bacteroides (CFB) group bacteria, Actinobacteria, Planctomycetales, and Cren- and Euryarchaeota round out the total but typically each make up a relatively small proportion of clone libraries in most pelagic waters (Giovannoni and Rappe, 2000). In marine sediments, the δ- and ε- Proteobacteria comprise a greater proportion of communities than in the water column, along with CFB and Actinobacteria (Cifuentes et al., 2000; Madrid et al., 2001; Todorov et al., 2000). β-Proteobacteria are relatively uncommon in marine clone libraries, but typically dominate freshwater systems (Fuhrman and Ouverney, 1998; Fuhrman et al., 1993; Giovannoni and Rappe, 2000; Methe et al., 1998; Venter et al., 2004). Whole-metagenome shotgun sequencing and bacterial artificial chromosome (BAC) library studies provide a future direction to overcome some culture limitations (De Long, 2002; Schmidt et al., 1991; Venter et al., 2004; Rusch et al., 2007, DeLong et al., 2006) and may elucidate unexpected physiological capabilities that can be investigated in studies of field samples or pure cultures (Fuhrman, 2003). Among nitrogen cycling bacterial guilds (bacteria here referring to both Bacteria and Archaea) there is a spectrum of diversity associated with each function.

2.2. Common features of bacterial physiology

Bacteria and Archaea, as prokaryotes, are the simplest and oldest life-forms on earth, having evolved early in the Achaean era 3.4–3.8 Ga (Schopf, 1993). Prokaryotic DNA is not contained within a nucleus and prokaryotic cells contain no membrane-bound organelles. All bacteria contain a cell wall composed of membrane and peptidoglycan. Bacteria contain generally smaller genomes than eukaryotes, however they have a higher percentage of biomass in nucleic acids than most protists. Marine heterotrophic bacterioplankton contain on average 2 fg DNA cell^{-1} (Fuhrman and Azam, 1982). The average C biomass of heterotrophic and autotrophic bacteria ranges from 12 to 280 fg C cell^{-1} but most studies of heterotrophic bacteria converge on 10–20 fg C cell^{-1} (Carlson et al., 1999; Caron et al., 1995; Christian and Karl, 1994; Ducklow, 2000; Fagerbakke et al., 1996; Fukuda et al., 1998; Heldal et al., 2003; Lee and Fuhrman, 1987). The C content of cells depends primarily upon growth rate (Heldal et al., 1996) and on the size of cells (Troussellier et al., 1997). Volumetric conversion factors based upon cultures range from 65 to 290 fg C μm^{-1} (Ducklow et al., 1992; Fagerbakke et al., 1996; Heldal et al., 2003; Troussellier et al., 1997), however in natural bacterioplankton samples they range from 32 to 400 fg C μm^{-3} (Fagerbakke et al., 1996; Lee and Fuhrman, 1987; Simon and Azam, 1989; Vrede et al., 2002). Marine bacteria (autotrophs and heterotrophs) range in diameter from 0.2 to 3 μm, however most heterotrophs are small (0.2–1 μm) encompassing volumes of $<$0.004–0.524 μm^3 (Caron et al., 1995; Carlson et al., 1999; Christian and Karl, 1994; Lee and Fuhrman, 1987).

Bacteria may live aerobic, anaerobic or microaerophilic lifestyles, and do not necessarily utilise O_2 as a terminal electron acceptor; many can use a suite of organic and inorganic compounds. Bacteria may have autotrophic (cyanobacteria and nitrifying bacteria), heterotrophic (supposedly most planktonic bacteria) or chemoautotrophic (utilising energy from reduced inorganic compounds) physiologies. Additionally, some prokaryotes have been observed to contain plastic metabolism and mixotrophic physiologies, however it is unclear whether these provide

significant energy for metabolism, or if they may have unknown ecological advantages (Beja *et al.*, 2000; de la Torre *et al.*, 2003; Schwalbach *et al.*, submitted for publication). Recent metagenomic studies of bacterioplankton has suggested that mixotrophy may be very common (Venter *et al.*, 2004; Rusch *et al.*, 2007). Observation of variable physiology and its implications for biogeochemical cycling complicates our view of the microbial loop, and in part requires opening the bacterial "black box" in biogeochemical models including unicellular prokaryotes.

2.3. Carbon:nitrogen ratios in bacteria

The atom ratio of C:N in marine bacterial biomass depends upon the type of bacteria, as well as their growth rate (Heldal *et al.*, 1996). The first descriptions of elemental ratios in marine plankton can be attributed to Vinogradov (Vinogradov, 1935) who described C:N:P ratios in large phytoplankton (diatoms and "Peridinians" i.e., dinoflagellates) of 100:18:3 (Sverdrup *et al.*, 1942). Later descriptions of plankton >20 μm, predominantly phytoplankton, found C:N:P ratios of 106:16:1, referred to as the Redfield ratio (Redfield, 1958). Difficulty in separating elemental analysis signatures of bacteria from detritus inhibited estimates of their elemental ratios until the advent of X-ray microanalysis which allowed the composition of single cells to be determined. These studies have revealed a range of ratios for both cultured and natural marine bacteria (Fagerbakke *et al.*, 1996; Heldal *et al.*, 2003; Vrede *et al.*, 2002). The source of variation has remained unclear, however environmental conditions and the physiology of bacteria may explain some of the variability (Table 25.1).

Table 25.1 Size and elemental composition of example eubacterial taxa based upon X-ray microanalysis. The natural bacterioplankton includes values from the oligotrophic subtropical gyres to highly productive coastal embayments

Physiology	Taxa	C content (fg cell^{-1})	Cell Vol. (μm^3)	Atom C:N	Ref.
Heterotroph	*Vibrio natriegens* culture	62–350	0.93–3.5	3.8	Fagerbakke *et al.*, (1996)
Phototroph	*Prochlorococcus* culture	17–34	0.08–0.22	8.8–9.9	Heldal *et al.*, (2003)
	Synechococcus culture	120–250	0.62–1.60	8.2–10.0	
Anaerobe	*Haloanaerobium praevalens*	137–756	5.01–20.30	2.9–3.3	Oren *et al.*, (1997)
Natural bacterioplankton		6–48	0.11–0.41	2.0–8.3	Fagerbakke *et al.*, (1996), Goldman *et al.*, (1987), Fukuda *et al.*, (1998)

The ratio of C:N decreases with increasing growth rate, presumably due to greater synthesis of N–rich nucleic acids and protein (Norland *et al.*, 1995). This is consistent with reports of high C:N ratios in the oligotrophic subtropical gyres, and lower ratios in productive coastal embayments (Fukuda *et al.*, 1998). The higher C:N ratios in photosynthetic bacterioplankton than in heterotrophs reportedly reflects their inclusion of carbon-rich thylakoid membranes and other photosynthetic apparati (Heldal *et al.*, 2003).

The ratio of N:P is frequently used to determine growth limitation in marine ecosystems when the water column concentrations of inorganic N and P species is known. Heterotrophic bacterial N:P ratios are between 3.5 and 9.0 (Goldman *et al.*, 1987; Fagerbakke *et al.*, 1996), while cultures of *Prochlorococcus* sp. and *Synechococcus* sp. are higher at 8.0–43.0 depending upon strain and growth conditions (Heldal *et al.*, 2003). Interestingly, the N:P ratios in heterotrophic bacteria are substantially less than in larger phytoplankton, which typically follow Redfield stoichiometry (16:1 (Redfield, 1958)). This could be due to larger nucleic acid:protein ratios and lack of chloroplasts in heterotrophic bacteria when compared to eukaryotic phytoplankton (Fagerbakke *et al.*, 1996; Heldal *et al.*, 2003).

3. DISTRIBUTION OF BACTERIAL SECONDARY PRODUCTION IN THE MARINE ENVIRONMENT

Bacterial secondary production, the synthesis of new bacterial cellular components from organic molecules taken up from the surrounding environment, has long been of interest to marine biogeochemists since it provides estimates for elemental flow through the submicron size fraction. Until the advent of molecular techniques, it was assumed by some marine scientists that most bacteria, including those observed by recently-developed epifluorescent techniques, were inactive or moribund because estimates of colony-forming units in enrichment culture from seawater samples fell well short of observed cell abundances (Hobbie *et al.*, 1977; ZoBell, 1941). However, development of enrichment culture-independent techniques has indicated a spectrum of bacterial activities, ranging from undetectably to highly active cells (Cottrell and Kirchman, 2004; Fuhrman and Azam, 1982; Gasol *et al.*, 1999; Karner and Fuhrman, 1997; Ouverney and Fuhrman, 1999a,b; Tabor and Neihof, 1982b). In this section, we review methods of measurement currently used to assess bacterioplankton production, as well as summarise current knowledge about secondary production rates in a range of environments.

3.1. Methods of measurement

The biogeochemical activities of microbes in the oceans was of interest since initial reports of elemental cycles in the oceans (Redfield, 1958). Initial attempts to determine rates of heterotrophic synthesis focused upon dark respiration rates of

bulk water samples, however these were confounded by the presence of algae (Sorokin, 1964). Demand for bacterioplankton-specific growth rate estimates resulted in several methods of estimating turnover of planktonic bacterial communities. The frequency of dividing bacterial cells, as observed by epifluorescence microscopy, provided among the first, though not widely adopted, estimates of bacterial growth rate in marine environments, and was based upon the assumption that the relative number of visibly dividing cells was proportional to growth rate (Hagstrom et al., 1979). Incorporation of labeled amino acid substrates into DNA or protein provided another way of estimating activity, since the incorporation rate is putatively proportional to bacterial growth rate, and has been used in virtually all studies of bacterioplankton production since 1982. Incorporation of ^{3}H-thymidine directly into DNA was the first widely used approach in studies of bacterioplankton growth and production rates in the marine environment (Fuhrman and Azam, 1982), and more recently ^{3}H-leucine has been used to determine the rate of protein synthesis and growth or production in marine bacteria (Kirchman et al., 1985; Simon and Azam, 1989). As these are ''bulk'' analyses, they represent averages of bacterial activity across the entire community based upon conversion factors of cells per amount of labeled compound incorporated (Fuhrman and Azam, 1982). There have since been several estimates of these conversion factors which in most studies converge on $1.1–1.8 \times 10^{18}$ cells mol^{-1} of total thymidine and $100–150 \times 10^{18}$ cells mol^{-1} leucine (Coveney and Wetzel, 1988; Ducklow et al., 1992; Fuhrman and Azam, 1982; Kirchman, 1992; Kirchman and Ducklow, 1993; Kirchman et al., 1982; Pulido-Villena and Reche, 2003; Simon and Azam, 1989), with similar estimates of bacterial production using both approaches (Fuhrman and Azam, 1982; Fuhrman and Noble, 1995; Kirchman, 1992; Simon and Azam, 1989), which have been extensively reviewed elsewhere (Ducklow, 2000).

3.2. Distribution of bacterial secondary production

Bacterial secondary production is dependent upon supply of dissolved organic carbon (Carlson and Ducklow, 1996) or inorganic nutrients (Kirchman, 1994; Kirchman and Rich, 1997) and is controlled in part by temperature (Shiah and Ducklow, 1994). It is not surprising therefore that the most productive bacterioplankton communities occur in subtropical and temperate estuaries, where warm temperatures and high allochthonous DOC inputs sustain high bacterial growth rates (Table 25.2). However, temporal changes in bacterioplankton production are tightly correlated to primary productivity such as in the Ross Sea and Southern Ocean, which are highly seasonal (Ducklow et al., 2001) and where consistently low temperature is not an overwhelming controlling factor. Other ''hotspots'' of bacterioplankton activity occur in oxic/anoxic boundaries and hydrothermal vents. Oxic/anoxic boundaries occur in only a few locations in the water column (e.g., Black Sea, Cariaco Trench, Arabian Sea, Eastern Tropical Pacific), but are biogeochemically critical regions for water column denitrification and processes such as anammox (Dalsgaard et al., 2003; Devol, 2003), and also occur within virtually all sediments. Within hydrothermal vent fluid, most frequently found in the bathyl ocean,

Table 25.2 Examples of bacterioplankton production and growth rates in surface waters of various environments ranging in temperature and nutrient concentrations. Production rates were converted using published data and conversion factors of 2×10^{18} cells mol^{-1} TdR (Fuhrman and Azam, 1982), 1.5×10^{17} cells mol^{-1} leu (Simon and Azam, 1989), and 20 fg C cell^{-1} (Lee and Fuhrman, 1987; Troussellier et al., 1997)

Habitat	Location	Bact. abund. ($\times 10^8$ cells l^{-1})	Bact. prod. ($\times 10^5$ cells l^{-1} day^{-1})	Ref.

[c] Measured by both ^{3}H-TdR and ^{3}H-leu
[d] Assuming euphotic zone depth of 20 m.

prokaryotic abundances are enhanced 2–3-fold over surrounding bathypelagic waters (Juniper et al., 1998) and importantly, prokaryotes dominate food web processes in this habitat type.

Deep (meso-, bathy-, and abyssopelagic) bacterioplankton communities turn over more slowly than epipelagic communities, dramatically demonstrated during accidental sinkings of the submersible *Alvin* and cruise liner *Titanic*. In these cases, strong preservation of food materials (Jannasch et al., 1970), and structural materials (Holden, 1985), respectively, suggested that bacteria in deep water environments are slow to metabolise. Recent study of bathypelagic assemblages in the Northwest Pacific showed turnover of bacterial C every 1–30 years, compared to bacteria in surface waters which turned over every 10–20 days (Nagata et al., 2000). Similar

deep-water results have been demonstrated in the North Atlantic Ocean (Hansell and Ducklow, 2003). Deep water bacterioplankton communities rely upon a patchy rain of POC from overlying waters for growth requirements (Cho and Azam, 1988; Hansell and Ducklow, 2003).

4. Viral Infection and Mortality

Viral activities in the marine environment have been observed for decades, primarily by isolation of lytic bacteriophage (Arloing and Sempe, 1926; Asheshova, 1926; Fejgin, 1926; Kakimoto and Nagatomi, 1971; Kriss and Rukina, 1947; Kriss et al., 1967; Spencer, 1955, 1960) and by observation of virus particles internalized within phytoplankton cells (Pienaar, 1976). However viruses were not considered important in marine ecosystems because of their low observed abundance by plaque titer (Moebus, 1980), which was partially due to low culturability of host bacteria (Giovannoni et al., 1990). The first attempt to directly observe the assemblage of viruses in marine plankton noted $<10^4$ particles ml^{-1}, and apparently greatly under-estimated their abundance because most viruses passed through the 0.2 μm filters used in that study (Torella and Morita, 1979). Further development of staining methods and protocols for concentrating viruses from seawater onto electron microscope grids enabled researchers to view an astonishing abundance of viruses in seawater samples from both open-ocean locations (Proctor and Fuhrman, 1990; Proctor et al., 1988) and coastal (Bergh et al., 1989; Borsheim et al., 1990) waters. It became clear that not only were viruses abundant in marine ecosystems, but they may cause significant mortality of marine microorganisms (Proctor and Fuhrman, 1990, 1992; Suttle et al., 1990a,b) and therefore may play significant roles in biogeochemical cycles. Key aspects of marine viral ecology are reviewed here, however readers are also pointed to recent reviews (Fuhrman, 1999; Fuhrman and Suttle, 1993; Weinbauer, 2004; Wommack and Colwell, 2000) for more comprehensive information.

4.1. Virus abundance in marine waters and sediments

The abundance of viruses in the marine environment has been investigated using multiple approaches, initially by plaque-titer on specific hosts (Spencer, 1960), by electron microscopy (Bergh et al., 1989; Borsheim et al., 1990; Proctor and Fuhrman, 1990; Proctor et al., 1988; Torella and Morita, 1979), nucleic acid staining (e.g., DAPI (Hara et al., 1991), YoPro (Xenopoulos and Bird, 1997), SYBR Green I (Noble and Fuhrman, 1998), and SYBR Gold (Chen et al., 2001)) and epifluorescence microscopy, and by flow-cytometry (Chen et al., 2001; Marie et al., 1999). There have been numerous studies inter-calibrating different staining and microscopic techniques (Hennes and Suttle, 1995; Noble and Fuhrman, 1998; Proctor, 1997; Suttle, 1993; Weinbauer and Suttle, 1997). Virus-sized particle concentrations range from 10^5 to 10^8 VLP ml^{-1} in surface waters (reviewed in Wommack and Colwell, 2000)

however are typically 1–2 orders of magnitude less abundant in sub-euphotic zone (Hara *et al.*, 1991, 1996; Noble and Fuhrman, 1998) and hydrothermal vent plume waters (Juniper *et al.*, 1998). In estuaries, virus abundance can exceed 10^8 VLP ml^{-1} (Hewson *et al.*, 2001b; Wommack *et al.*, 1999a), representing an intermediate of abundance in completely fresh (10^8–10^9 VLP ml^{-1}) (Leff *et al.*, 1999; Maranger and Bird, 1995) and completely marine waters (10^6–10^7 VLP ml^{-1}) (Bergh *et al.*, 1989; Proctor *et al.*, 1988; Wommack and Colwell, 2000). The ratio of virus to bacteria abundance in marine waters ranges from 1 to 100, however is typically 10–30 in most pelagic and deep environments (Fuhrman, 2000; Weinbauer, 2004; Wommack and Colwell, 2000). These ratios are similar to the number of viruses produced per marine bacterium upon lysis (the ''burst size'') which ranges from 5 to 200, but is more commonly reported within the range of 10–50 (Wommack and Colwell, 2000). It is important to note that TEM and epifluorescence counts of viruses may underestimate viral abundances due to fast viral decay within preserved samples (Wen *et al.*, 2004), which may in turn affect the ratios of viruses to bacteria, since preserved bacteria decay less rapidly (Gundersen *et al.*, 1996).

By contrast, the observation of high abundance of viruses in sediments has received considerably less attention than the water column, possibly due to the difficulty of separating viruses from other particulate matter (Fig. 25.3). Initial reports of very high virus abundance in benthos, up to 10^9–10^{10} VLP cm^{-3} (Maranger and Bird, 1996; Paul *et al.*, 1993) suggested that viruses could be important components in sediment microbial food webs, however their origin was unknown. Empirical studies in a range of environments including high suspended matter–containing harbour waters demonstrated that the arrival of adsorbed viruses on sinking particles could only account for a tiny fraction of observed abundance, and that most viruses are produced autochthonously (Hewson and Fuhrman, 2003). The ratio of viruses to bacteria in marine sediments is highly variable depending on study location. Surface sediments in estuarine and coastal sediments have been
Figure 25.3 Viruses, bacteria, and other microorganisms in plankton (left) from Southern California and from sediments (right) from Florida Bay. Note bacterial morphological diversity is greater in sediments than in the water column but viruses and bacteria are harder to distinguish from detritus.

reported to contain a wide range of virus to bacteria ratios (0.2–71). Some studies have found that the virus-to-bacteria ratios in sediments are significantly higher than in overlying waters (Hewson and Fuhrman, 2003; Hewson et al., 2001a,b,c), while others have found lower benthic virus:bacteria ratios than in overlying waters (Danovaro and Serresi, 2000; Danovaro et al., 2001, 2002), but most studies converge on ratios of 1–7 in sandy marine environments (Danovaro et al., 2001; Drake et al., 1998; Hewson and Fuhrman, 2003; Hewson et al., 2001a,b,c, 2003; Mei and Danovaro, 2004; Middelboe et al., 2003). Similarly, bathyl and abyssal sediments also contain a range of virus-to-bacteria ratios (0.1–5; most reports 0.8–2 (Danovaro and Serresi, 2000; Danovaro et al., 2002; Hewson and Fuhrman, 2003)). The great variability in virus-to-bacterium ratios in marine sediments suggests that local geochemical features (i.e., sediment type) or biological fluxes (e.g., sedimentation) and processes (e.g., bacterial production) may have a strong impact upon the persistence of viruses in different regions.

The geochemical composition of viruses in marine environments is most similar to bacteria hosts, however there are important differences. Viruses are composed of protein and nucleic acids (DNA or RNA) in an approximate 1:1 ratio (Ackermann and DuBow, 1987). Viruses contain C, N, and P in the calculated ratio 10:4.5:1 (Hewson and Fuhrman, 2003). Since viruses are extremely small (size range ca. 15–300 nm but typical diameter of 40–50 nm (Steward et al., 1996b; Suttle et al., 1991)) and contain only small amounts of nucleic acids (15–300 kbp (Fuhrman et al., 2002; Wommack et al., 1999a,b)), they are not believed to comprise a large fraction of DOM in the ocean (Fuhrman, 1999). Using a bacterial conversion factor of 350 fg C μm^{-3} (Lee and Fuhrman, 1987), and average diameter of virus of 50 nm, each virus particle probably only contains 0.2 fg C, hence with an average abundance of 10^9 VLP l^{-1} (Wommack and Colwell, 2000) they only comprise approximately 15 nM DOC and 6 nM DON out of typical DOC concentrations of 40–60 μM (le and Williams, 2000) and DON concentrations of 3–20 μM (Capone, 2000). Although they are not a large component of DOC themselves, their effects on bacterial communities by killing bacteria and thereby releasing their dissolved and particulate intracellular components is potentially a significant component of marine elemental cycling.

4.2. Rates of viral mortality and nitrogen release

Viruses have three potential lifestyles, two of which have been observed in the marine environment (Fuhrman and Suttle, 1993): (1) Lytic viruses cause cell lysis shortly after successful infection, typically about one generation after infection (Proctor et al., 1993); (2) Lysogeny results when temperate phage successfully infect cells, but the viral DNA becomes incorporated into the genome as a ''prophage'' and does not enter the lytic cycle until stimulated to do so by either internal or external factors (discussed in later section) (Jiang and Paul, 1994, 1996; Weinbauer and Suttle, 1996). The third lifestyle, chronic infection, is like lysogeny except live cells extrude viruses over many generations and virus release is sub-lethal (Fuhrman and Suttle, 1993).

Lytic viral mortality of bacteria in marine systems has been studied with 3 basic approaches; (1) by examining the percentage of visually infected bacterial cells,

(2) by examining rates of viral decay, or (3) by examining rates of viral production. The percentage of visually infected bacteria is determined by staining bacteria with a heavy metal stain (typically uranyl sulfate) (Proctor and Fuhrman, 1990, 1991; Proctor et al., 1993; Weinbauer and Suttle, 1996), then observation of virus particles within cells by transmission electron microscopy. Using assumptions about the relative percentage of time during which infected bacteria can be recognized (by the presence of electron–dense shading within bacterial cells), it is possible to calculate the percentage of infected cells (Proctor and Fuhrman, 1990). Since viral abundance in pelagic marine waters is presumably stable over long time scales, viral decay must approximate production and can therefore be used to estimate it. Viral decay is measured primarily by three approaches. By treating samples with compounds that kill bacteria, but do not effect enzyme activities (e.g., KCN), production of viruses is stopped; The rate of decrease in virus abundance over time is equivalent to the production rate (Heldal and Bratbak, 1991; Suttle and Chen, 1992). In the second approach, in which a subset of virioplankton is stained with the nucleic acid fluorochrome SYBR Green I, the disappearance of fluorescently labeled virus (FLV) can be used to estimate viral decay in an approach similar to isotope dilution (Noble and Fuhrman, 2000). A third approach to assess viral decay in natural waters is to add a large titer of cultured bacteriophage to seawater, then to determine abundances of these over time (Wommack et al., 1996). To directly estimate the production of viruses, two approaches are used. The first method is to determine the accumulation rate of radiolabeled (with ^{3}H or ^{33}P), DNAse resistant particles into the 0.02–0.2 μm size fraction (Steward et al., 1992, 1996a,b). More recently, production has been determined by a dilution technique where virioplankton is mostly removed from bacteria by dia- or tangential–flow filtration and virus abundance increase monitored by microscopy (Hewson et al., 2001b; Wilhelm and Suttle, 1999, 2000; Wilhelm et al., 2002). In production estimates, mortality is calculated with a conversion factor which includes estimates of burst size to estimate the number of bacteria that need to be lysed to maintain the observed production rate.

Reports of lytic viral mortality in surface waters of the ocean average near 20–25% (range 4–74%) of mortality (reviewed in Weinbauer, 2004; Wommack and Colwell, 2000), which in some environments is similar to the proportion of mortality attributed to protists (Fuhrman and Noble, 1995). The large range in viral mortality is due mainly to the range of environmental conditions in which virus infection has been measured, but also due to variability in estimates of host burst size, which can effect mortality rate calculations by over an order of magnitude (Wommack and Colwell, 2000). Viral lysis results in the release of intracellular compounds and, of course, viruses into surrounding waters. Assuming a generous burst size for a small marine bacterium of approximately 50 VLP cell^{-1}, then most cellular C and N is released into surrounding waters upon lysis. Assuming viral lysis results in 2–20% of bacterioplankton mortality per day (Proctor and Fuhrman, 1990), viral lysis could release 4–40 nM N day^{-1} into DOM (calculated). It is interesting to note that lytic virus infection may have diel variability (Winter et al., 2004a,b), with most initial virus infection occurring at night and lysis at noon or afternoon.

Cyanophage of filamentous cyanobacteria (Hewson et al., 2001a, 2004; Ohki, 1999; Ohki and Fujita, 1996) and marine representatives of the unicellular

phytoplankton genera *Prochlorococcus* and *Synechococcus* (Sullivan *et al.*, 2003; Suttle, 2000; Suttle and Chan, 1993, 1994; Waterbury and Valois, 1993; Wilson *et al.*, 1993) have been isolated and observed for some time. Both are of particular interest due to their role in primary production and global carbon sequestration. Lytic cyanophage are believed to cause only modest mortality of *Synechococcus* ($5–10\%$ d^{-1}) in oligotrophic waters, less in temperate waters (Fuhrman, 1999; Suttle and Chan, 1994; Waterbury and Valois, 1993) and most culturable strains of this genus have been reported to be resistant to co-occurring cyanophage (Sullivan *et al.*, 2003; Waterbury and Valois, 1993). This suggests minimal impact of viruses upon total abundance of *Synechococcus*. Recent study has demonstrated that cyanophage infecting *Prochlorococcus* have a range in host specificities, with some cyanophage infecting only a single strain of cyanobacterium, while others infect both *Prochlorococcus* (both high- and low-light adapted strains) and *Synechococcus* (Sullivan *et al.*, 2003). Lysogeny in marine *Synechococcus* may be an important source of mortality (McDaniel *et al.*, 2002; Williamson *et al.*, 2002), but the stimuli causing prophage to enter the lytic cycle remain unclear.

Viral pathogens of eukaryotic phytoplankton have been observed for some time (Pienaar, 1976), and now almost every group of phytoplankton in marine waters has been demonstrated to be affected by viral lysis (Brussaard, 2004; Brussaard *et al.*, 1999; Nagasaki *et al.*, 1994, 2004; O'Kelly *et al.*, 2003; Suttle *et al.*, 1990a,b, 1991; Tarutani *et al.*, 2000; VanEtten *et al.*, 1991). Despite this, there is little information on the rate of viral mortality that can be attributed to "phycoviruses" under ambient conditions, because it is difficult to distinguish eukaryotic viruses from bacteriophages in indirect observation techniques. Direct observation of cells of *Micromonas pusilla* indicate that 2–10% of cells lyse per day under ambient conditions (Cottrell and Suttle, 1995), while observation of *Emiliana huxleyii*, *Ostreococcus taurii*, and *Aureococcus anophagefferens* indicate that viral mortality upon bloom decline could be up to 80–100% (Bratbak *et al.*, 1993; Milligan and Cosper, 1994; O'Kelly *et al.*, 2003). Clearly, viruses have significant impacts upon eukaryotic phytoplankton, which may cause substantial N release upon lysis.

To date, the only study attempting to examine viral mortality of metazoan zooplankton found no strong effects of concentrated viral communities upon copepod physiology or fecundity (Drake and Dobbs, 2005), but viruses of prawns (Decapoda) have been known for some time (Bonami *et al.*, 1990; Tsai *et al.*, 2000). Recent discovery of a diverse array of RNA Picorna virus-like sequences in surface waters of the Georgia Strait and north of Oahu suggests that zooplankton viruses may proliferate in marine waters (Culley *et al.*, 2003; Culley and Steward, 2007). Picorna-like viruses, which are within the same family as those infecting prawns could conceivably also infect dominant microcrustacean zooplankton in the ocean (e.g., Copepods, Amphipods). Clearly this area remains a potentially significant research direction for future studies.

4.3. Lysogeny and horizontal gene transfer

Lysogeny, the process by which temperate viral DNA becomes integrated into host genomes could be a major source of mortality for marine microorganisms if induction of lysogens is significant. However, the stimuli causing induction are not well understood. There have been detailed studies of natural factors impacting lysogens in

single-species cultures. Bioegeochemically, it is difficult to assess the potential impact of lysogens on nutrient cycling, since methods of detection (e.g., addition of strong mutagens or UV irradiation to induce lytic activity) are unrealistic of natural marine stimuli (Jiang and Paul, 1994; Weinbauer and Suttle, 1996). Addition of mitomycin C, which is the only inducing agent among cultures of prokaryotes consistently causing increases in virus abundance in incubations (Wommack and Colwell, 2000), has revealed a variable percentage of lysogens, from 0 to 27% (most studies fall within the range of 3–10%) of all bacterioplankton in oceanic surface waters (Jiang and Paul, 1994, 1996; Ortman *et al.*, 2002; Weinbauer and Suttle, 1996, 1999; Weinbauer *et al.*, 2002, 2003), 0–79% (most studies 2–38%) in estuarine waters (Cochran and Paul, 1998; Jiang and Paul, 1996; McDaniel *et al.*, 2002; Weinbauer *et al.*, 2003) and 16–84% in sub-euphotic waters (Weinbauer *et al.*, 2003). The abundance of lysogens has been demonstrated to have a seasonal cycle, with greatest occurrence in months of lowest bacterial and phytoplankton production, suggesting that this lifestyle was selected for when host densities were low and least active (Cochran and Paul, 1998; McDaniel *et al.*, 2002; Williamson *et al.*, 2002).

Another aspect of lysogeny of interest to biogeochemists is the role of viruses in gene transfer (i.e., transduction). Lysogeny is believed to cause significant exchange of host materials and introduce new genes into hosts (Chiura, 1997; Jiang and Paul, 1998; Paul *et al.*, 2002). For example, lysogenic conversion of *Vibrio cholerae* and possibly the cyanobacterium *Microcystis aeruginosa* cause hosts to produce toxins (Vance, 1977; Waldor and Mekalanos, 1996). Recent observations of genes encoding for phosphate metabolism (*pho*) and for the production of proteins essential for photosynthetic apparatus (D1 proteins) have been observed in phage infecting *Roseobacter* SI01 (Ritalic,*et al.* 2000) and *Prochlorococcus* (Lindell *et al.*, 2004), respectively (reviewed in Paul *et al.*, 2002). Observation of environmental viral metagenomes has indicated that the a large numbers of viral DNA open reading frames (ORFs) that were affiliated with phage encode for unknown functions (Breitbart *et al.*, 2002, 2004), however roughly half of ORFs were similar to Bacterial, Archaeal, and eukaryotic sequences in GenBank (National Center for Biotechnology Information's sequence database). While to date no sequences similar to key nitrogen cycling genes have been recovered, it is likely that within the unknown fraction of viral ORFs there are genes that are involved in nitrogen processing.

5. Marine Sediments Compared to the Water Column

Marine sediments are an important compartment for N cycling. Shelf sediments in particular are sites of active denitrification (Codispoti *et al.*, 2001), and estuarine, coastal, and coral reef sediments can be important sites of nitrogen fixation (Burns *et al.*, 2002; Capone, 1983; Capone *et al.*, 1992). Despite extensive study of biogeochemical processes in sediments, the study of the microbial loop in this compartment has had considerably less attention, possibly due to difficulty in studying sediment microorganisms. There are two primary differences between water column and sediment microbial processes. The first of these is the presence

of an abiotic matrix of sediment material which limits diffusion and onto which charged particles and solutes may absorb. The second primary difference is that sediments are the sink for both autochthonous and allochthonous organic matter from overlying waters (especially within estuaries), and thus, unlike the water column, are extremely rich environments. In this section, we review current knowledge of the sediment microbial loop, and compare rates of loop processes with the water column.

5.1. Bacterial production in sediments

Sediments are often extremely nutrient rich environments, hence it is not surprising that bacterial abundances there are typically an order of magnitude more than in overlying waters per unit volume of porewater (Bird et al., 2001; Danovaro and Serresi, 2000; Drake et al., 1998; Hewson et al., 2001a,b,c; McDaniel and Capone, 1985), nor is it surprising that benthic microalgal biomass exceeds phytoplankton biomass in shallow-water benthic environments (e.g., coral reefs) by over an order of magnitude (Heil et al., 2004; MacIntyre et al., 1996). The method used to measure bacterial production in sediments is similar to that in the water column, that is, by incorporation of radiolabeled thymidine or leucine (Fuhrman and Azam, 1982; Simon and Azam, 1989), then extraction of sediment macromolecules and determination of radioactivity (van Duyl and Kop, 1994).

Benthic bacterial production rates cover a wide range of activity from 0.1 to 600 mg C m^{-2} day^{-1}, representing approximate growth rates of 0.1–5.1 day^{-1} (Alongi, 1994; Dixon and Turley, 2001; Epstein, 1997; Findlay, 1995; Hamels et al., 2001; Hietanen et al., 1999; Hondeveld et al., 1995; Mei and Danovaro, 2004; Nodder et al., 2003; Poremba and Hoppe, 1995; Sander and Kalff, 1993; Sinsabaugh and vanDuyl et al., 1997; Turley and Dixon, 2002; Vanduyl et al., 1993). Bacterial production is related to sediment grain size, with coarser sediments being less productive than silty or muddy sediments (Hamels et al., 2001). The supply of organic matter from overlying waters is also related to sediment bacterial production, with significant correlations between suspended particulate organic carbon and production rates in deep sea sediments (Hietanen et al., 1999; Nodder et al., 2003; Suits and Arthur, 2000; Turley and Dixon, 2002), however lag times between inputs and stimulation of bacterial production have been noted under algal blooms (vanDuyl et al., 1997). Through multiple correlation analysis, temperature and sediment chlorophyll-a levels have also been demonstrated to explain variability in sediment bacterial production rates (Sander and Kalff, 1993). Since sediments also contain large quantities of dissolved and particulate organic N (Guldberg et al., 2002; Middelboe et al., 2003), bacterial hydrolysis of these compounds probably plays a large role in their decomposition in marine systems.

5.2. Grazing, bacterivory, and viral lysis in marine sediments

Bacterial production in planktonic marine environments is believed to be tightly controlled by a combination of bacterivory and viral lysis (Proctor and Fuhrman, 1990; Sherr and Sherr, 1994). While it is tempting to apply these loss factors to

models of benthic marine food webs (Epstein, 1997), several studies have demonstrated that protozoan grazing in sediments is insufficient to account for benthic bacterial production (reviewed in Hamels *et al.*, 2001; Kemp, 1990). However, meiofaunal grazing has been demonstrated to remove significant proportions of daily bacterial and benthic microalgal production (Epstein, 1997; Montagna, 1995), and grazing by protozoa has been observed to remove roughly half of bacterial production per day in intertidal sand flats (Epstein, 1997; Hamels *et al.*, 2001; Hondeveld *et al.*, 1995). Grazing by larger fauna, such as deposit feeding Holothurians has been demonstrated to significantly increase sediment bacterial productivity (Moriarty *et al.*, 1985).

In shallow water environments, benthic microalgae make up a large component of sediment autotrophic production (Heil *et al.*, 2004; Kendrick *et al.*, 1998; Thornton *et al.*, 2002). Their high biomass overlying anoxic sediments has profound impacts upon denitrification efficiency in benthic compartments, since photosynthesis deepens the oxic layer depth, while depleting NO_3^- (Dong *et al.*, 2000). Removal of benthic microalgae has been demonstrated to result from meiofaunal and macrofaunal grazing (Epstein, 1997; Moriarty *et al.*, 1985), although attempts to simulate enhanced viral lysis of benthic microalgae *in situ* resulted in only modest effects on bacterial assemblage composition and protistan photosynthetic rate (Hewson *et al.*, 2001c).

Viral lysis in sediments has received only recent attention as a source of mortality of bacteria (Hewson and Fuhrman, 2002, 2003; Mei and Danovaro, 2004; Middelboe *et al.*, 2003) and has been shown to kill up to 14% of bacterial biomass per hour in highly productive sediments, accounting for 9–57% of total sediment bacterial mortality (Mei and Danovaro, 2004). Lysogeny investigated by mitomycin C addition has been reported to account for only 0.1–1.8% of all bacteria (Mei and Danovaro, 2004) across a range of sediment types. This is despite reports of a high number of ORFs from sediment metagenomes belonging to the *Siphophage* family, many members of which are temperate (i.e., causing lysogeny (Breitbart *et al.*, 2004)). The limited data suggest that unlike in the water column, lysogeny may be of only limited importance in this compartment. An alternative explanation is that it is difficult to induce sediment lysogens with mitomycin C.

A combination of bacterivory and lytic viral activity appears to account for roughly similar amounts of bacterial biomass loss in marine sediments, which is comparable to the dynamics in overlying waters (Strom, 2000). However, rates of bacterivory and viral lysis are strongly influenced by sediment type and organic matter loading (Hamels *et al.*, 2001; Hewson and Fuhrman, 2003), which is ultimately linked to local geography and productivity of overlying waters.

6. FUTURE DIRECTIONS OF MICROBIAL LOOP RESEARCH

This chapter has reviewed several key aspects of the marine microbial loop that have become clearer in the past 20 years. Many of the developments in our understanding have come about thanks to novel molecular techniques and advances in microscopy. While conceptualised models of the microbial loop have changed dramatically since first conceived (Ducklow, 1983; le and Williams, 1981; Pomeroy,

1974) and formalised (Azam *et al.*, 1983), to include new pathways and processes, there is still a large "black box" of information yet to be fully understood. In the following section we briefly preview four promising areas of future research on microbial loop processes, however we note that there are undoubtedly many others to come.

6.1. Metagenomics and metatranscriptomics

The desire to discover novel genes in the marine environment has given rise to whole genome shotgun sequencing of viral and prokaryotic communities, whereby entire, mixed community genomic DNA is fractured into millions of small fragments, then sequenced and attempts made to reconstruct individual genomes. This has already begun to provide interesting information on the organisms intrinsic to the microbial loop (Breitbart *et al.*, 2002, 2004; Venter *et al.*, 2004; Rusch *et al.*, 2007 and DeLong *et al.*, 2006). This approach is an extension of early work (Olsen *et al.*, 1986; Pace *et al.*, 1986; Schmidt *et al.*, 1991) which sheared whole community DNA, then used bacteriophage λ, containing small pieces of this sheared extract, as a library. The technique was the precursor for the approach known today as BAC library analysis (De Long, 2002, DeLong *et al.*, 2006), and was the first entire-metagenome attempt to understand diversity in marine bacterioplankton. The sequencing of entire environmental metagenomes is related to complete sequencing of cultivated marine viral (Rohwer *et al.*, 2000), bacterial (Heidelberg *et al.*, 2000), cyanobacterial (Palenik *et al.*, 2003; Rocap *et al.*, 2003), and eukaryotic genomes (Armbrust *et al.*, 2004). Annotation of single genomes and metagenomes has provided information on unexpected and previously unknown metabolic pathways (Fuhrman, 2003), such as phosphonate utilisation in *Synechococcus* (Palenik *et al.*, 2003). One of the most exciting discoveries made using BAC or metagenomic approaches has been observation of genes encoding for bacterial rhodopsins, a suite of retinal-containing pigments which serve a variety of potential functions (Fuhrman *et al.*, 2008), including the generation of energy from sun energy (i.e., phototrophy) (Beja *et al.*, 2000), or regulatory (i.e., sensory) functions (Wang *et al.*, 2003). Discovery of these genes, and observation of a small percentage of bacteria bearing the photosynthetic pigment bacteriochlorophyll-*a* (Kolber *et al.*, 2001) have suggested that phototrophy may be more widespread and not as restricted to chlorophyll-*a* than previously thought. Flow cytometric sorting, whole genome amplification, and pyrosequencing technologies promise to provide complete genome sequences from uncultivated microorganisms important in the N cycle. Metatranscriptomics, the study of community gene expression, also promises to highlight dominant metabolic processes which may be under-represented in genomic surveys (Poretsky et al., 2005). The recognition of genes from cultured organisms within environmental metagenomes will potentially elucidate new N–cycling pathways which have not been considered in previous models of biogeochemical cycling, however recognition of the function of such genes is only possible if metagenomic studies are coupled with culture studies.

6.2. Culturing previously unculturable microorganisms

Study of metabolic capabilities of numerically dominant components of marine ecosystems have been hampered by low culturability of these taxa. Early work showed that bacteria could be serially diluted and grown in filtered seawater in lab

(Ammerman *et al.*, 1984; Fuhrman and Azam, 1980). Recent extensions of this culturing theory have enabled labs to develop nontraditional approaches to isolating marine microorganisms, for example extinction—dilution (Button *et al.*, 1993; Connon and Giovannoni, 2002; Rappé *et al.*, 2002), and isolation of single cells away from colonies on enriched media (Simu and Hagstrom, 2004). These methods have allowed culture of the ubiquitous and highly abundant SAR-11 clade of marine bacterioplankton (Rappé *et al.*, 2002; Simu and Hagstrom, 2004), however it should be noted that these cultures are not easy to grow or study. The isolation of such organisms, and studies of cultured organism genomics, will open doors on both physiological studies and interactions with other marine microbes in the microbial loop. The axiom that >90% of bacterioplankton taxa are not culturable may be partially a consequence of dependence upon enrichment for isolation (Giovannoni and Rappe, 2000), and ultimately understanding of dominant prokaryotes in the environment may progress when novel techniques such as those applied to SAR-11 cultures are applied on a massive scale.

6.3. Viral and autocatalysed mortality of key nitrogen-processing organisms

Virus infection of bacteria involved in nitrogen processing has been observed for decades (Adolph and Haselkorn, 1973; Khudyakov, 1977; Mendzhul *et al.*, 1991; Safferman *et al.*, 1972), however it is only recently that the implicated in releasing fixed nitrogen (Hewson *et al.*, 2004; Ohki, 1999; Ohki and Fujita, 1996; Suttle, 2000). Programmed cell death, a form of autocatalysed mortality, has also received little study in marine microbial ecology, probably due to difficulty in distinguishing this process from induction of lysogens (Bidle and Falkowski, 2004), and is believed to be restricted to colonial prokaryotes or eukaryotes. Recent observation of viral and autocatalytic lysis of *Trichodesmium* cultures (Berman-Frank *et al.*, 2004; Ohki, 1999) and large estimates of viral mortality under *in situ* conditions (Hewson *et al.*, 2004), suggest that viruses play underappreciated roles in controlling abundance and N fluxes from important N-cycling microorganisms. Observation of high rates of viral lysis within sediments (reviewed in Mei and Danovaro, 2004), for example, raises interesting questions about the role of viral lysis in regulating processes mostly carried out in the benthic domain (e.g., denitrification, nitrification). Moreover, viral activities have been hypothesized to be important in determining the taxonomic and clonal composition of marine bacterial assemblages (Thingstad, 2000; Thingstad and Lignell, 1997), by killing the winner of resource competition and thereby maintaining diversity. Experimental approaches to addressing this interaction have provided important results on the effects of viruses on total bacterial and eukaryotic assemblage composition and diversity (Hewson *et al.*, 2001c, 2003; Schwalbach *et al.*, 2004; Winter *et al.*, 2004b), but there have been no reports to date of virus effects on composition of nitrogen cycling guilds of bacteria. Since apoptotic cell death is unlikely to occur in unicellular bacterioplankton or sediment bacteria, it is unlikely that this process affects greatly nitrogen cycling in the microbial loop.

6.4. Nitrogen fixing heterotrophic bacteria

Nitrogen fixation was until recently believed to be dominated by large, filamentous cyanobacteria, such as *Trichodesmium* and *Kategynemenae* (reviewed in Capone *et al.*, 1997). It was not until DNA and RNA-based PCR techniques were applied to the <20 μm size fraction in oligotrophic seawater that nitrogenase activity by unicellular cyanobacteria was detected (Zehr *et al.*, 1998, 2001). Since initial descriptions, these cyanobacteria have been found to be highly active and have nitrogenase activity rates similar to larger diazotrophs per unit sea surface area (Falcon *et al.*, 2004; Zehr *et al.*, 2001; Montoya *et al.,* 2004). In addition to autotrophic cyanobacteria, heterotroph nitrogenase sequences have also been recovered as genes and gene transcripts from bacterioplankton in both Atlantic and Pacific oceans (Falcon *et al.*, 2002; Zehr *et al.*, 1998, 2001; Church *et al.,* 2005a,b), suggesting that heterotrophic bacteria may also contribute to nitrogen fixation in open ocean pelagic environments (Fuhrman and Capone, 2001; Zehr *et al.*, 2001). Extensive study of the distribution of nitrogenase genes in the Chesapeake Bay has demonstrated that heterotrophic diazotrophs have variable distribution throughout the estuary and with season (Short *et al.*, 2004) and at least 2 phylotypes actively express their nitrogenase genes (Short and Zehr, 2007). Future studies using microarray technology promise to elucidate the diversity of non-cyanobacterial diazotrophs in open-ocean conditions (Taroncher-Oldenburg *et al.*, 2003; Hewson *et al.,* 2007). Combined with quantitative molecular tools (e.g., quantitative PCR) (Short *et al.*, 2004) and stable isotope incorporation (Montoya *et al.*, 2004; Zehr *et al.*, 2001) they should elucidate the role of this previously underappreciated source of N in the microbial loop.

7. CONCLUSION: A NEW MICROBIAL VIEW—THE GENE LOOP

Our understanding of the microbial loop has changed dramatically since formalisation (Azam *et al.*, 1983; Ducklow, 1983). Elucidation of new metabolic pathways, incorporation of viruses (Fuhrman, 1999; Fuhrman and Suttle, 1993; Fuhrman *et al.*, 1992), and a further unfolding of the "black boxes" of both biotic components (i.e., bacteria, viruses, and protists) through molecular tools, and abiotic components (i.e., DOM composition) through advances in chemistry, have made our view of the microbial loop more complex. It has been argued that since genes freely exchange between prokaryotes in the marine environment by transduction and viral infection, the bacteria in the ocean represent a supergenome where diversity among communities has evolved as a consequence of random recombination (Sonea and Panisset, 1983). Recent observation of high levels of microdiversity (Acinas *et al.*, 2004; Brown and Fuhrman, 2005) has demonstrated that evolution of bacterial taxa is not random, but rather individuals within communities undergo selection to enable them to exist within tightly-defined niches (Giovannoni, 2004; Kimura, 1968). Ultimately, the types of organisms existing within communities hypothetically depend upon the physical conditions present, which in turn is a consequence of biological activity. Incorporation of all metabolic pathways into current conceptualisations of the microbial loop results in extremely complicated webs of interactions. This complexity is exacerbated by discovery of metabolic plasticity in a large number of microorganisms (Caron, 2000),

and observations of microdiversity in some closely related bacteria occupying similar, but not exactly the same niche (e.g., ecotypes) (Garcia-Martinez and Rodriguez-Valera, 2000; Rocap *et al.*, 2002). Since the lines between metabolisms, and between different interactions becomes blurred, we must move towards a more continuous idea of the microbial loop in affecting biogeochemistry and ecology in the marine environment.

Nitrogen Consumption and Metabolism in Marine Zooplankton

Deborah K. Steinberg *and* Grace K. Saba

Contents

1. Introduction

Zooplankton play a pivotal, multi-faceted role in the ocean nitrogen cycle. They consume organic nitrogen and thus exert control on primary production, as well as sustain the growth of phytoplankton via N excretion, thus enhancing primary production (Miller and Landry, 1984). Release of dissolved organic nitrogen (DON) by sloppy feeding or excretion by zooplankton can also support heterotrophic bacterial growth and may be the principal pathway of dissolved organic matter from phytoplankton to bacteria (Carlson, 2002; Jumars *et al.*, 1989). Zooplankton transport particulate organic nitrogen (PON) to depth via production of sinking fecal pellets (Altabet and Small, 1990; Small *et al.*, 1989). Diel vertically migrating zooplankton contribute to vertical export of N by

consuming organic particles in the surface waters at night and metabolizing the ingested food as ammonia, DON, or via production of fecal pellets below the mixed layer during the day (Longhurst and Harrison, 1988; Schnetzer and Steinberg, 2002; Steinberg *et al.*, 2002).

   This chapter will focus on the important role that zooplankton play in nitrogen cycling by ''following the path of the food'' from ingestion to all aspects and stages of metabolism (Fig. 26.1). We begin with a discussion of N consumption, including the nitrogenous composition of available food types, rates of N consumption, and effects of food quality. We then discuss the various aspects of N metabolism, emphasizing the importance to biogeochemical cycling and coupling with other major elements (carbon, phosphorus). The contribution of zooplankton N regeneration to the N budget and requirements for phytoplankton growth will be covered in Bronk and Steinberg (in this volume). Recent methods for measuring zooplankton consumption and metabolism can be found in the *International Council for the Exploration of the Sea (ICES) Zooplankton Methodology Manual* (Harris *et al.*, 2000), thus we do not cover methodology herein. In addition, the analytical procedures for
Figure 26.1 Pathways of nitrogen consumption and metabolism by zooplankton discussed in this chapter. Prey (other zooplankton such as the ciliates shown here, or phytoplankton) PON of differing quality and quantity are ingested by zooplankton. Some of the DON in the prey is lost to the surrounding water due to sloppy feeding, while the rest is ingested. A portion of the PON that is ingested is assimilated, or taken up into the organism's tissues, and the rest is egested as fecal pellets which may subsequently leach DON. Of the N that is assimilated, a portion is excreted as ammonia (NH_4) or DON, and the rest goes into the animal's growth and reproduction (= secondary production) (Adapted from Møller *et al.*, 2003).

measuring the products of N metabolism (i.e., various forms of particulate and dissolved N) are described in McCarthy and Bronk (in this volume). There are several helpful prior reviews on N nutrition (Roman, 1983) and metabolism (Bidigare, 1983; Caron and Goldman, 1990; LeBorgne, 1986; Regnault, 1987) which this chapter builds upon. As most previous reviews have focused on crustacean mesozooplankton (>200 μm), we have made an effort to include information on both gelatinous zooplankton and microzooplankton (<200 μm, most of which are protozoans) herein.

2. Consumption of Nitrogen

2.1. Biochemical (nitrogenous) composition of food for zooplankton

2.1.1. Phytoplankton

A significant proportion of ocean primary production is grazed by zooplankton. A recent synthesis of microzooplankton grazing rate estimates indicate microzooplankton graze an average of 60–75% of the daily primary production across a wide range of open-ocean to coastal environments (Calbet and Landry, 2004; Landry and Calbet, 2004), and mesozooplankton are responsible for removing 10–40% of the daily primary production (Calbet, 2001). Phytoplankton N content consists mostly of protein (65–85% of cell N) and amino acids (6–12% of cell N); however, nucleic acids, pigments, and inorganic N also contribute to phytoplankton N content (Geider and La Roche, 2002; Lohrenz and Taylor, 1987; Lourenco et al., 1998). Phytoplankton have a heavy N requirement due to their photosynthetic apparatus protein complexes such as the enzyme ribulose 1,5-biphosphate carboxylase (RUBISCO), and reaction center II protein D1 (Falkowski et al., 1989; Geider et al., 1993). The elemental composition of phytoplankton reflects the changes in these protein macromolecules relative to high carbon carbohydrates and lipids such as those found in the cell wall (Beardall et al., 2001; Goldman et al., 1979). While the Redfield ratio is consistent for non-nutrient limited marine phytoplankton at high growth rates (Geider and La Roche, 2002), phytoplankton C:N, N:P, and C:P ratios can deviate greatly from Redfield due to differences in nutritional and growth conditions. Thus, differences in the N content and chemical composition of phytoplankton depends on the species, as well as a number of factors including growth rate, nutrient limitation, cell size, temperature, and irradiance levels (Hecky et al., 1993; Perry, 1976).

Differences in the nitrogen content between phytoplankton taxa can be due to differential growth rate (Goldman et al., 1979), as well as cell size, shape, structure (e.g., presence of a vacuole), and composition (e.g., amino acid requirements) (Beardall et al., 2001; DeYoe and Suttle, 1994; Quigg et al., 2003). For example, Moal et al. (1987) found that in exponential growth phase, diatoms with vacuoles had the lowest levels of protein, protein:chlorophyll a, and total N content (24–141 fg protein μm^{-3}, prot:chl a = 30–172, 5–26 fg N μm^{-3}, respectively) compared to dinoflagellates absent of vacuoles (43–434 fg protein μm^{-3}, prot:chl a = 222–740, 7–45 fg N μm^{-3}, respectively). Nutrient limitation and the resulting

decrease in growth rate (Fernandez *et al.*, 1996; Sterner and Hessen, 1994) can affect phytoplankton N content via a decrease in internal pools of amino acids, inorganic N storage, and protein—including photosynthetic proteins RUBISCO and D1, and an increase in carbohydrate and lipid storage, thus increasing the C: N (Beardall *et al.*, 2001; Dortch, 1982; Dortch *et al.*, 1985; Falkowski *et al.*, 1989; Geider *et al.*, 1993; Goldman *et al.*, 1979; Harrison *et al.*, 1990; Moal *et al.*, 1987). Moal *et al.* (1987) found that C, N, and protein density in many species of diatoms, dinoflagellates, cryptophytes, and haptophytes can decrease as much as 50% from exponential to stationary phase. The N content of a common brown tide alga, *Aureococcus anophagefferens*, off Texas, USA, varies with different inorganic N sources (DeYoe and Suttle, 1994). *A. anophagefferens* grown on ammonium (NH_4), their preferred N source, had higher N (1.3 pg cell^{-1}), chlorophyll *a* content, and a C:N near Redfield, whereas those grown on nitrate (NO_3) had low N (0.88 pg cell^{-1}) and chlorophyll *a* content, and a high C:N (25:1). Cell size may also decrease with increasing nutrient limitation and effect cellular N content. Verity *et al.* (1992) and Menden-Deuer and Lessard (2000) compared cellular C and N in a variety of phytoplankton taxa and found that in general, small cells have higher C and N densities (per cubic micrometer) than larger cells. For example, among the prymnesiophytes, *Emiliana huxleyi* with a biovolume of 70 μm^3 has a N density of 47 fg μm^{-3} whereas the larger *Pleurochrysis carterae* with a biovolume of 648 μm^3 has a N density of 17 fg μm^{-3} (Verity *et al.*, 1992). Irradiance and temperature may also affect cell N content. At low light more photosynthetic apparatus protein complexes (RUBISCO and D1) are needed, which decreases the C:N and increases the N:P ratios (Beardall *et al.*, 2001; Dortch *et al.*, 1985). At photoinhibitory levels of irradiance, however, proteins decrease (Geider *et al.*, 1996; Geider and La Roche, 2002; Raven, 1984). Berges *et al.* (2002) found that as temperature increases, diatom *Thalassiosira pseudonana* protein, total cellular N, and biovolume remain constant, but cell C and chl increase, which causes an increase in C:N.

Despite their dominance and important ecological role in large open ocean habitats, there are few data on the chemical composition of photosynthetic, nitrogen fixing cyanobacteria. *Prochlorococcus* spp. have N contents ranging from 2.2 to 9.4 fg N cell^{-1} and a C:N ranging from 5.0 to 9.9 in nutrient replete conditions (Bertilsson *et al.*, 2003; Heldal *et al.*, 2003). As with most other phytoplankton species, the C:N increases with increasing nutrient limitation (Bertilsson *et al.*, 2003). *Synechococcus* spp. have higher N contents ranging from 17 to 50 fg N cell^{-1}; however, they have similar C:N and N cell density as *Prochlorococcus* spp. (Bertilsson *et al.*, 2003; Heldal *et al.*, 2003). Nitrogen fixing species have high N:P stoichiometry due to the need for more light harvesting machinery for energy to power the fixation process (Klausmeier *et al.*, 2004). For example, *Trichodesmium* spp. have an N:P of 42–125 (Letelier and Karl, 1996). Only a few studies have determined protein content of cyanobacteria. Vargas *et al.* (1998) found protein makes up 37–52% of the dry weight of 12 strains of filamentous cyanobacteria, and Cuhel and Waterbury (1984) determined the average cellular protein content (96 fg protein cell^{-1}) and C:protein (3.1) of *Synechococcus* Clone 7803.

2.1.2. Bacteria

Heterotrophic bacteria (and autotrophic cyanobacteria, described above) are consumed directly by protozoan microflagellates and ciliates (Azam et al., 1983; Strom, 2000). Although too small to be consumed directly by most mesozooplankton except for the mucous-web feeders (e.g., larvaceans, Deibel and Lee, 1992), bacteria colonizing fecal pellets, marine snow, or other such detritus are indirectly consumed by detritivores (Steinberg, 1995). Heterotrophic bacteria utilize a wide range of dissolved organic N substrates (e.g., amino acids, proteins, urea, nucleic acids) with highly variable biochemical compositions, and can compete with phytoplankton and utilize inorganic N (e.g., ammonium) to meet their N requirements when organic N is limited (Kirchman, 2000). Despite the variable C:N stoichiometry of the substrates they catabolize, bacteria maintain a strict, nutrient-rich stoichiometry with C:N between 4 and 7 (Bratbak, 1985; Fukuda et al., 1998; Goldman et al., 1987; Lee and Fuhrman, 1987; Makino and Cotner, 2004; Nagata, 1986). Natural marine bacteria contain 1.6–35 fg N cell^{-1}, with coastal bacteria having higher C and N contents relative to oceanic bacteria (Fagerbakke et al., 1996; Fukuda et al., 1998; Vrede et al., 2002). Additionally, small cells have higher N densities relative to larger cells in similar environmental conditions (Kroer, 1994). Bacteria are N rich mainly due to their peptidoglycan cell membrane and high growth rates, which reflect high nucleic acid (14.5% N) and high protein (17% N) contents (Simon and Azam, 1989). Bacteria contain between 60 and 330 fg protein cell^{-1} (Zubkov et al., 1999), which can be nearly 63% of a bacteria cell's dry weight (Simon and Azam, 1989). Although bacteria typically maintain a narrow range of C:N, changes in growth rates and available nutrients can alter the C:N. For example, C:N ratio increased from exponential to stationary growth phases in Vibrio natriegens (Fagerbakke et al., 1996; Vadstein and Olsen, 1989) due to a decrease in RNA and protein cell content (Maaloe and Kjeldgaard, 1966). Additionally, the C:N reached 12 in nutrient-limited isolate marine bacteria in a study by Vrede et al. (2002). Finally, as bacteria become starved, water is lost from the cell (Kerkhof and Ward, 1987), which decreases cell volume, increases C:volume ratio, and increases the cellular C:N (Simon and Azam, 1989; Troussellier et al., 1997).

2.1.3. Zooplankton

Many zooplankton feed omnivorously or carnivorously, thus they are both the consumer and the consumed. Marine zooplankton have a rigid stoichiometry, similar to heterotrophic bacteria. The biochemical composition of a variety of marine crustacean and gelatinous zooplankton is shown in Table 26.1, and is averaged by major taxa in Fig. 26.2. For crustacean zooplankton as a group, the average body N content is 10% of dry weight and C:N ratio (by weight) is 5 (Fig. 26.2A; see also Ventura, 2006). Nitrogen content in marine copepods ranges from 4.6 to 23.5% of body dry weight and C:N ratio ranges from 1.7 to 16.6 (Table 26.1, the majority of which listed are calanoids), but on average are also 10% and 5, respectively (Fig. 26.2B). On average, body N content and C:N is similar across all the major crustacean taxa, as well as the polycheates (Fig. 26.2B). Proteins are the most abundant organic compound in copepods, and are found mainly in

For some species, data were compiled using multiple references. Polychaetes are included as a separate grouping.

— = Not determined, or not reported in cited reference. When C:N (by weight or atoms) was not available in the reference, it was calculated using body C and N values provided.

[a] AFDW, ash-free dry weight.

[b] Species listed in the reference were sampled from the following environments: Gismervik (1997)—Oslofjord, Norway; Cataletto and Fonda Umani (1994)—Gulf of Trieste, N. Adriatic Sea; Ambler (1985)—East Lagoon, Galveston, TX; Libourel Houde and Roman (1987)—Chesapeake Bay; Walve and Larsson (1999)—Baltic Sea; Gorsky *et al.* (1988)—Ligurian Sea, NW Mediterranean; Omori (1969)—N Pacific; Ikeda (1972)—Bering Sea, N Pacific Ocean; Mayzaud and Martin (1975)—St. Margaret's Bay, N Atlantic; Tande (1982)—Balsfjorden, Norway; Båmstedt and Ervik (1984)—west coast of Norway; Ikeda and Skjoldal (1989)—Barents Sea, Arctic; Ikeda and Mitchell (1982)— Antarctica (epipelagic); Ikeda and Hing Fay (1981)—Antarctica; Båmstedt (1978)—Korsfjorden, Norway; Dagg and Littlepage (1972)—Haro Strait and Saanich Inlet, British Columbia; Walve and Larsson (1999)—Baltic Sea; Ikeda and Hirakawa (1998)—S Japan Sea; Lindsay (2003)—Sagami Bay, Japan; Kosobokova *et al.* (2002)—Arctic Ocean; Thibault *et al.* (1999)—Chukchi Sea, Arctic Ocean; Morris and Hopkins (1983)—Gulf of Mexico; Beers (1966)—Sargasso Sea; Ikeda (1988)—Prydz Bay, Antarctica (mesopelagic); Ikeda (1990)—Japan Sea; Kaeriyama and Ikeda (2004)—W North Pacific Ocean; Mauchline (1980)—various (review); Ishii *et al.* (1987)—Antarctica; Childress and Nygaard (1974)—S California; Giese (1966)—Antarctica; Clarke *et al.* (1992)—Southern Ocean; Curl (1962)—New York (continental shelf); Anninsky *et al.* (2005)—Black Sea; Kremer *et al.* (1986)—Bahamas; Larson (1986)—Saanich Inlet, BC; Schneider (1988)—Kiel Bight, Baltic Sea; Arai (1997)—various (review); Lutcavage and Lutz (1986)—Biscayne Bay, FL; Bailey *et al.* (1995)—Cape Hatteras, North Carolina; Morand *et al.* (1987)—Ligurian Sea, NW Mediterranean; Malej (1989)—Gulf of Trieste, N. Adriatic Sea; Malej (1991)—Gulf of Trieste, N. Adriatic Sea; Ikeda (1974)—various; Madin *et al.* (1981)—N Atlantic; Le Borgne (1982)— E tropical Atlantic Ocean; Iguchi and Ikeda (2004)—Antarctica; Skjoldal (1981)—Great Barrier Reef, Australia.

[c] Original C:N, N:P converted from molar to weight according to formulas: C:N (weight) = (atomic C:N) × (12/14); N:P (weight) = (atomic N:P) × (14/31).

[d] Determined assuming dry weight = carbon content × 2.5.

[e] Calculated from Clarke *et al.* (1992; tables).

[f] Determined assuming dry weight = 2.4% wet weight (Finenko *et al.*, 2001).

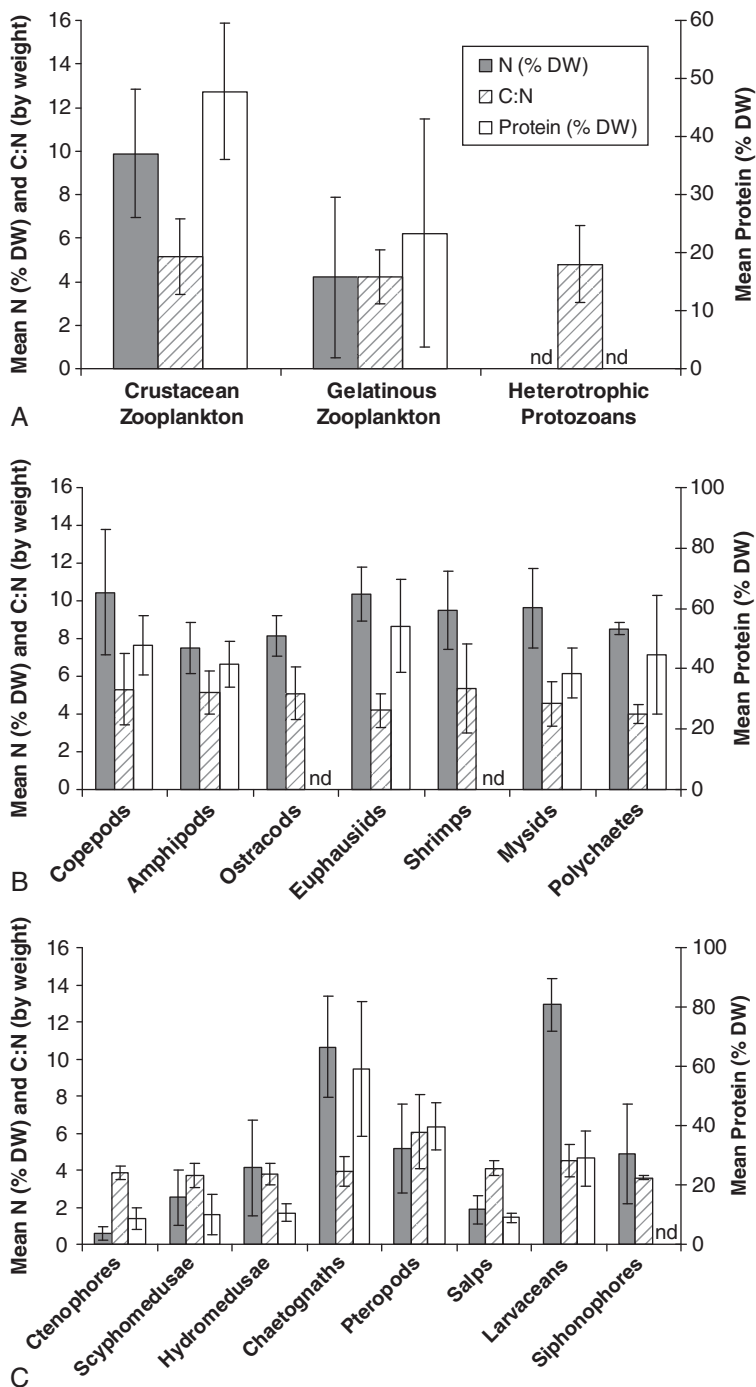
[g] Dry weight calculated from ash-free dry weights using carbon content ranges of 50–5000 μg for *P. confoederata* and 100–30,000 μg for *S. maxima* (Madin *et al.*, 1981).


Figure 26.2 Summary of literature data on nitrogen and protein content, and C:N ratio of major zooplankton taxa, from Tables 26.1 and 26.2. (A) Major zooplankton groups, (B) Crustacean taxa and polychaetes, (C) Gelatinous taxa. Bars represent mean ±1 standard deviation. nd indicates not determined.

muscle tissue (Båmstedt, 1986). Proteins and free amino acids together have been shown to account for most of copepod body N content (67 and 7%, respectively, for *Calanus finmarchicus*, Ventura, 2006). Protein content in marine copepods ranges from 27.7 to 67.7% of body dry weight (Table 26.1), and on average 48% for copepods overall and for crustacea as a group (Fig. 26.2B; see also Ventura, 2006). Crustacean zooplankton contain a large diversity of amino acids, with highest concentrations of glutamic acid, aspartic acid, lysine, leucine, and glycine (Cowey and Corner, 1963; Parsons *et al.*, 1984). Free amino acids contribute less to body dry weight (e.g., on average 5–11% of body dry weight in mysiids, euphausiids, and marine calanoid copepods, Ventura, 2006) than proteins in the crustacean zooplankton.

Gelatinous zooplankton have lower body N and protein content compared to crustacean zooplankton, but a similar C:N (Fig. 26.2A–C). Table 26.1 shows the range of body N as a proportion of dry weight in a variety of gelatinous zooplankton which, for example, includes: ctenophores (0.2–1.1%), schyphomedusae (0.1–6.3%), hydromedusae (0.8–8.2%), pteropods (1.5–8.5%), and salps (0.5–2.8%), and on average is 4% for all gelatinous taxa (Fig. 26.2A). Gelatinous zooplankton protein content ranges from 0.1% of body dry weight in the scyphozoan medusa *Poralia rufescens* (Bailey *et al.*, 1995) to 2.1–28.6% in *Aurelia aurita* (Lucas, 1994) (Table 26.1) and is generally higher than both lipid and carbohydrate content in scyphomedusae (Arai, 1997). Overall mean protein content for gelatinous zooplankton is 23% of dry weight (Fig. 26.2A), and for some groups, such as the medusae and ctenophores, is noticeably lower than this overall mean (Fig. 26.2C). However, isolated tissues in medusae, such as gonads and tentacles, can contain higher carbon, nitrogen, protein, carbohydrate, and lipid content (as proportion of dry weight) relative to the whole organism (Larson, 1986; Lucas, 1994). Interestingly, Pacific leatherback sea turtles, which primarily depend on gelatinous zooplankton for food, have been observed consuming only tentacle and gonadal tissue, presumably targeting these higher nutritional parts of the medusae (Benson, unpublished).

Studies of the biochemical composition of marine protozoa are extremely limited, and are summarized in Table 26.2. Nitrogen content in marine ciliates and heterotrophic dinoflagellates ranges from 60 to 131,000 pg N cell^{-1} (mean = 1274 pg N cell^{-1}—excluding the large dinoflagellate *Noctiluca scintillans*), and C:N ratio (by weight) ranges from 3 to 13 (mean = 4.4). Ohman and Snyder (1991) determined the protein content of the ciliate *Uronema* sp. to be 310 pg cell^{-1}. Marine flagellates have lower cellular N contents (0.3–19 pg N) compared to ciliates and heterotrophic dinoflagellates, but higher N density (0.1–0.2 pg N μm^{-3} for flagellates vs. 0.04 pg N μm^{-3} for ciliates and heterotrophic dinoflagellates— excluding *N. scintillans*) and similar C:N (4.1–5.5, by weight for flagellates).

Although zooplankton tend to maintain a rather rigid biochemistry, intra- and interspecific differences may arise due to physical characteristics (e.g., water content, body size), developmental stage, as well as location (e.g., latitude) and season. Increased water content, and thus decreased muscle tissue, leads to a decrease in protein and N content in zooplankton (Childress and Nygaard, 1974; Morris and Hopkins, 1983). This may explain the lower N and protein content in gelatinous zooplankton relative to crustaceans as described above. The effect of water content on proteins can also be seen within taxonomic groups. For example, *Calanus pacificus*

[h] N cell content calculated from equation in Goldman *et al.* (1985) for exponential growth.

Deborah K. Steinberg and Grace K. Saba

copepods have 42.7–54.5% body dry weight as protein (Willason *et al.*, 1986), and some *Eucalanus* spp., with higher water content, have 4–5.5% body dry weight as protein (Flint *et al.*, 1991; Mauchline, 1998). Relationships between body length and N content for marine copepods have been made using linear regression models and generally show an increase in N content with body length (Cataletto and Fonda Umani, 1994; Uye, 1982). Additionally, there are likely small compositional differences between juvenile and adult developmental stages (Sterner and Hessen, 1994), and copepods that are reproducing and utilizing their lipid storage have lower C:N compared to non-reproducing copepods (Ventura and Catalan, 2005).

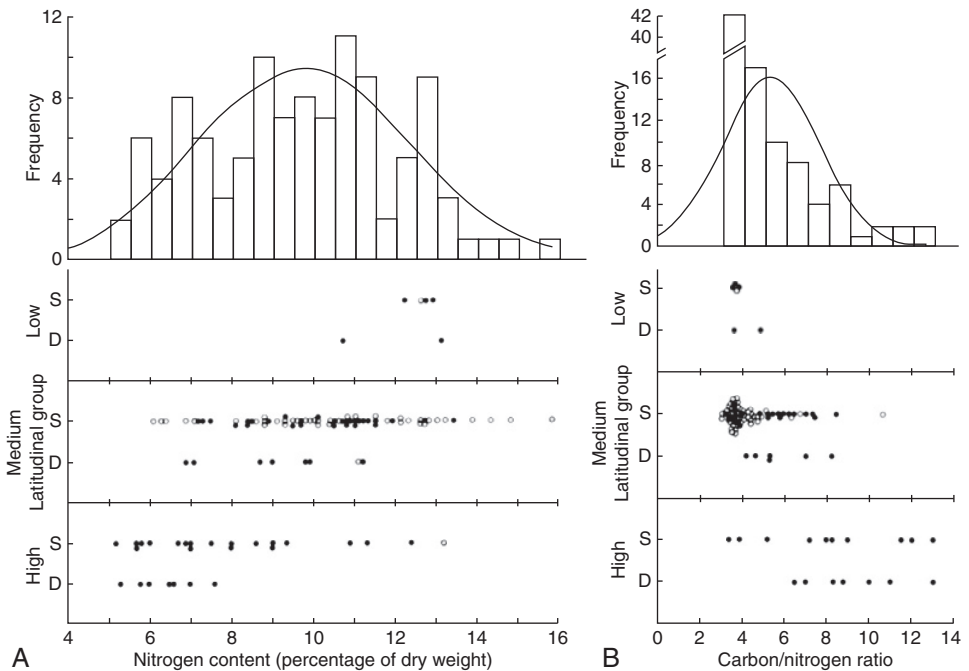
A general regional trend in copepod biochemical composition is an increase in N content and a decrease in C:N from high to low latitudes (Fig. 26.3; Båmstedt, 1986); thus, eastern tropical Atlantic copepods have a lower C:N (4.5–5.4; Le Borgne, 1982A) than polar copepod species (6.8; Conover and Huntley, 1991). Interestingly, the same overall mean N content (7% of dry weight, calculated from Madin *et al.*, 2001 and Landry *et al.*, 2001) and C:N (5.1) for mixed zooplankton is found at two long-term mesozooplankton time series in the N. Atlantic (Bermuda Atlantic Time-series Study, BATS) and N. Pacific (Hawaii Ocean Time-series, HOT) oligotrophic central gyres (Landry *et al.*, 2001; Madin *et al.*, 2001). In addition, chemical composition among different zooplankton taxa in the Sargasso Sea and N. Pacific (at similar latitudes) are nearly indistinguishable. Beers (1966) determined the range of percent N as dry weight for a variety of Sargasso Sea


Figure 26.3 Nitrogen contents (A) and C:N ratio (B) of copepod species from low, medium, and high latitudes. S, shallow-water species; D, deep-water species. (Adapted from Båmstedt, 1986).

zooplankton to be 8.2–11.2% for copepods, 9.4–10.5% for euphausiids and mysids, and 6.2–9.4% for chaetognaths. Similarly, N as % dry weight for North Pacific copepods, euphausiids, and chaetognaths is 5.1–13.1%, 10.0–10.7%, and 10.7–11.1%, respectively (Omori, 1969). Seasonal differences in zooplankton biochemical composition are also predictable, especially for copepods in temperate and high latitudes, which experience high seasonality (Costa *et al.*, 2006; Sterner and Hessen, 1994; Tande, 1982). *C. finmarchicus*, for example, displayed a decreasing C:N (from 13.0 to 7.9 in copepodite stages IV and V, males and females) and an increase in protein from late winter until the spring spawning period. C:N then increased throughout the summer until early winter for female copepods due to increasing lipid content in preparation for the overwintering period (Tande, 1982). During overwintering, copepod body lipid (primarily wax esters) declines as reserves are metabolized (Campbell *et al.*, 2004; Costa *et al.*, 2006; Jónasdóttir, 1999; Tande, 1982). In another example, *Acartia tonsa* seasonal N content ranged from 8.7 to 16.4% of body dry weight and C:N ranged from 3.0 to 4.9, with the highest N content and lowest C:N in spring, and the opposite in summer (Ambler, 1985).

2.1.4. Detritus

Detritus can be an important food and N source for zooplankton (Dilling *et al.*, 1998; Hessen *et al.*, 1990; Mayzaud *et al.*, 1998; Roman, 1977, 1984, 1980; Steinberg, 1995). A majority of the particulate matter in marine systems is composed of detritus (Volkman and Tanoe, 2002), which consists of non-living biogenic material such as senescent phytoplankton, zooplankton fecal pellets, and abandoned larvacean houses (e.g., Alldredge and Silver, 1988). In coastal regions, allochthonous organic matter input (Cai *et al.*, 1988; Goñi *et al.*, 2003) as well as non-living macrophyte organic matter (Mann, 1972) are also important components of detritus. The nutrient content of detritus depends on the detrital source (plankton community composition), age, depth, particle size, and bacterial remineralization activities (Tenore *et al.*, 1982). Copin-Montegut and Copin-Montegut (1983) conducted a study comparing particulate organic matter in the Atlantic, Indian, and Antarctic oceans and the Mediterranean Sea. The average surface C:N among these sites was 5.6 (by atoms) and varied less than 20% between sites, while N:P was more variable ranging from 18 to 23. Although the concentrations of particulate matter decreased with depth, the C:N and the percent of refractory carbon in the particles slightly increased. Caron *et al.* (1995) found Sargasso Sea detrital C:N (by weight) is 7.3–7.4. However, detrital C:N may be much higher when derived from N-limited algae (Tezuka, 1989). Detrital N consists of protein as well as amino sugars (chitin), humic acids and inorganic clay particles bound with N, and mucopolysaccharides released by bacteria (Roman, 1983). In a study conducted by Mayzaud *et al.* (1998), protein content in *Thalassiosira weissflogii* detritus was 32 pg cell^{-1}, equal to only about half of protein content in live *T. weissflogii* cells. Similarly, Roman (1984) found live *T. weissflogii* cells contained 6 × more N, 12 × more protein, 9 × more fatty acid, a low near Redfield C:N, and more types and higher concentration of amino acids compared to detritus from *Thalassia testudinum*. Detrital particles also serve as a hotspot of microbial activity and are colonized by N-rich bacteria (Kiørboe, 2003; Kiørboe *et al.*, 2002), which increase bulk N content and decrease

C:N of detrital particles (Tenore *et al.*, 1982). However, detritus with low nitrogen and phosphorus content (high C:N, C:P) will be decomposed much slower than nutrient-rich detritus, as the gross growth efficiency of bacteria decreases with increasing C:N of detritus (Goldman *et al.*, 1987).

2.2. Nitrogen requirements: Effects of food quantity and quality

Feeding and growth rates, egg production and hatching success, and fecal pellet production are affected by both quantity and quality of food supply (Abou Debs, 1984; Besiktepe and Dam, 2002; Frost, 1972; Tang and Taal, 2005). Changes in food quality can create a mismatch in stoichiometry between predator and prey (Sterner and Hessen, 1994) and effect all of the above parameters, as well as body N content, and ultimately zooplankton production and biomass. In fact the nutritional status of phytoplankton (N cell quotas), not the phytoplankton biomass, may be the major bottom-up determinant of zooplankton biomass (Hessen, 1992; Sterner and Hessen, 1994) except in periods of low food availability (Jónasdóttir *et al.*, 2002).

Food quality may be based on prey size, shape, mobility, and chemical and physical properties (Stoecker *et al.*, 1986). The C:N of food reflects its protein: lipid ratio (Omori and Ikeda, 1984; Urabe and Watanabe, 1993); thus, an organism may be protein limited, but not necessarily N-limited. In addition, phytoplankton with lower C:N are not always nutritionally high-quality food because they may be deficient in some essential organic compounds, such as polyunsaturated fatty acids and specific amino acids (Ahlgren *et al.*, 1990; Anderson and Pond, 2000; Urabe and Watanabe, 1993). This is evident in trophic upgrading studies, which have focused on the importance of microzooplankton in mediating the transfer of essential nutrients from phytoplankton to zooplankton greater than 200 μm (Klein Breteler *et al.*, 1999; Tang and Taal, 2005; Veloza *et al.*, 2006).

2.2.1. Effects on feeding and growth rates

Although studies have extensively investigated food quality effects on feeding and growth rates, the results are variable (Cowles *et al.*, 1988; Harris *et al.*, 1986; Kiørboe, 1989; Roman, 1983; Stoecker and Sanders, 1985). Many previous studies have shown zooplankton may maximize the uptake of limiting nutrients, such as N and protein, to support growth (Sterner and Hessen, 1994). Both microzooplankton and mesozooplankton have been shown to have higher ingestion and growth rates when feeding on prey items of higher quality (Cowles *et al.*, 1988; Libourel Houde and Roman, 1987; Stoecker *et al.*, 1986). For example, the copepod *A. tonsa* increases its maximum ingestion rate of N and protein feeding on algal prey with relatively higher N and protein content (dinoflagellate *Amphidinium carteri* vs. senescent diatom *T. weissflogii*) (Libourel Houde and Roman, 1987).

Alternatively, zooplankton may increase N and protein ingestion rates to compensate for lower quality food (Darchambeau and Thys, 2005; Harris *et al.*, 1986; Kleppel, 1983; Mayzaud *et al.*, 1998; Plath and Boersma, 2001; Sterner and Hessen, 1994). Mayzaud *et al.* (1998) found *A. tonsa* copepod protein ingestion rates ranged from 4.2 μg protein ind^{-1} h^{-1} for live diatom prey (*T. weissflogii*) and 4.5 μg protein ind^{-1} h^{-1} for live dinoflagellate prey (*Prorocentrum micans*), to 12.0 μg protein ind^{-1} h^{-1}

for a 50:50 mix of live diatom and detritus formed from senescent *T. weissflogii*. The saturation concentrations of prey (prey concentration at maximum ingestion rate) were 344, 221, and 731 μg protein l^{-1}, respectively, which suggests that *A. tonsa* ingested more cells in the lower protein detritus mixture in order to maximize the intake of protein. However, these saturation concentrations of prey are much higher than those found previously for the copepod *Eucalanus pileatus* feeding on the diatom *Rhizosolenia alata* (62–125 μg protein l^{-1} or 10–20 μg N l^{-1}; Mayzaud *et al.*, 1998; Paffenhöfer and Van Sant, 1985) and for the copepod *Neocalanus plumchrus* feeding on *T. weissflogii* (73 μg protein l^{-1}; Dagg and Walser, 1987). Harris *et al.* (1986) also found ingestion rates varied with prey N and protein content. The copepod *Calanus helgolandicus* feeding on *Cryptomonas maculata* on average ingested 0.098 μg N ind^{-1} h^{-1} and 0.747 μg protein ind^{-1} h^{-1}, while *C. helgolandicus* feeding on *T. weissflogii* ingested 0.202 μg N ind^{-1} h^{-1} and 1.243 μg protein ind^{-1} h^{-1}. Although both diets sustained copepod body protein (60 μg protein ind^{-1}), ingestion rates for N and protein were higher for *T. weissflogii* in order to compensate for the lower N and protein densities of *T. weissflogii* (0.014 and 0.081 pg protein μm^{-3}) compared to *C. maculata* (0.037 pg N μm^{-3} and 0.296 pg protein μm^{-3}) (Harris *et al.*, 1986). Additionally, the phagotrophic microflagellate *Paraphysomonas imperforata* has a lower N ingestion rate (63 pg N ind^{-1} d^{-1}) when N-rich bacteria are present in their food mixture, as opposed to an all-algal diet (80 pg N ind^{-1} d^{-1}) (Goldman *et al.*, 1985).

Lastly, zooplankton may not alter ingestion rates even under high variability of food quality (Kiørboe, 1989). There is, however, a high correlation between food quality and zooplankton growth. For example, zooplankton growth per unit of food biomass decreases as prey algae become increasingly nutrient limited (Kiørboe, 1989; Sterner, 1993). These processes require further investigation in order to fully understand how food quality affects feeding and growth.

2.2.2. Effects on egg production and hatching success

Studies investigating the role of food quality on egg production have found a high correlation between protein and essential fatty acid content of the food source and egg production rate of copepods (Abou Debs, 1984; Jónasdóttir, 1994; Jónasdóttir *et al.*, 2002; Kleppel and Hazzard, 2000; Kuijper *et al.*, 2004; Sterner and Hessen, 1994; Thor *et al.*, 2002). Klein Breteler *et al.* (2005) show that N limitation in phytoplankton decreases both cell protein and the essential fatty acid content, compounds that are essential in the nutrition of reproducing female copepods. Indeed, egg production rates of *Acartia* spp. decreased when these copepods were fed prey items lower in total N, protein, and certain fatty acids (Jónasdóttir, 1994). High prey N conconcentration, however, does not always yield high egg production; in fact, the prey C:N ratio is an important factor in copepod egg production (Augustin and Boersma, 2006; Kuijper *et al.*, 2004). In a dynamic energy budget model, Kuijper *et al.* (2004) show copepod N gross growth efficiency of egg production (the efficiency with which N can be used for producing eggs) increases with increasing prey C:N, reaching a peak with a C:N between 10 and 15. Experiments indicate *Acartia* spp. produces more eggs when fed algae with a C:N of 9.1 compared to algae with a C:N of 4.5 (Augustin and Boersma, 2006). These studies suggest that a moderate C:N ratio (10–15) can maximize both egg

production and N gross growth efficiency of the egg production, whereas copepods feeding on prey with a low C:N have a low efficiency for utilizing the N for egg production and instead use the excess N for maintenance.

A number of studies show diatoms decrease copepod fecundity and egg viability (Ban *et al.*, 1997; Miralto *et al.*, 1999; Poulet *et al.*, 1994; Uye, 1996). Ianora and Poulet (1993) compared egg production and viability of the copepod *Temora stylifera* feeding on two different diets: the dinoflagellate *Prorocentrum minimum* and the diatom *Thalassiosira rotula*. Egg production was similar between the two diets; however, the total number of viable eggs was three times higher with the dinoflagellate diet. This increased hatching success may be due to the higher carbon, nitrogen, protein, amino acid, vitamin, and fatty acid content of the dinoflagellate diet relative to to the diatom diet (Ianora and Poulet, 1993). Additionally, Ban *et al.* (2000) noticed a high percentage (20–40%) of hatched *Pseudocalanus newmani* eggs produced deformed nauplii when diatoms were the major food source for the copepod. The deleterious effects of diatoms on copepod fecundity and egg viability has recently been questioned, however, due to lack of negative correlation of *in situ* hatching success and diatom abundance and dominance in the field (Irigoien *et al.*, 2002; Jónasdóttir *et al.*, 1998; Pond *et al.*, 1996). It is suggested that not all diatoms negatively affect copepod egg viability and, in natural conditions, copepods can compensate for lack of nutrition in certain diatoms (those that are N-limited or low in proteins and fatty acids) by feeding on other prey items such as dinoflagellates and heterotrophic protozoans (Irigoien *et al.*, 2002; Paffenhöfer, 2002).

More recent studies have focused on the effects of toxic phytoplankton species on feeding, egg production, and hatching success of copepods, and again the results are variable. In studies conducted by Lincoln *et al.* (2001) and Palomares-García *et al.* (2006), there were no differences in feeding rates, egg production, or hatching success in copepods feeding on either a toxic diatom or dinoflagellate or their non-toxic counterparts. On the other hand, these parameters were strongly negatively affected when copepods fed on the toxic strain of haptophyte *Prymnesium patelliferum* (Nejstgaard and Solberg, 1996). These studies did not examine the chemical composition of the prey items, however, as many toxins are nitrogenous (e.g., paralytic shellfish toxin, domoic acid), their synthesis may be greatly affected by N limitation (Flynn and Flynn, 1995; Flynn *et al.*, 1994). Ingestion rates of the copepod *Acartia margalefi* and the heterotrophic dinoflagellate *Oxyrrhis marina* were lower when feeding on a toxic *Karlodinium* sp. vs. a non-toxic *Gymnodinium* sp. Furthermore, ingestion rates were also lower when feeding on a P-limited *Karlodinium* sp. compared to a non-nutrient limited *Karlodinium* sp. (Vaqué *et al.*, 2006). Future studies examining the effect of harmful phytoplankton N and toxin composition on copepod production would improve our understanding of the variability characteristic of studies thus far.

2.2.3. Effects on body nitrogen content

Zooplankton body N may also be affected by food quantity and quality. For example, Ikeda (1974) found the protein content of starved *Calanus cristatus* (now *Neocalanus cristatus*) decreased by 45% over 7 days. However, Andersen and Hessen (1991) did not see a change in the N:dry weight of cladocerans *Daphnia longispina*, *Bosmina longispina*, and *Holopedium gibiberum* in different food conditions, thus the effect of food quality on body N content requires further investigation.

2.2.4. Response to variable food quality

Zooplankton have many adaptations to respond to variable food quality. Zooplankton can use chemoreception to detect high quality food, and thus feed selectively on those food items (Cowles *et al.*, 1988; Paffenhöfer and Van Sant, 1985; Stoecker *et al.*, 1981; Stoecker *et al.*, 1986; Urabe and Watanabe, 1993). For example, the copepod *E. pileatus* ingested live *Rhizosolenia alata* diatom cells 1.2–3 times faster than dead *R. alata* cells (Paffenhöfer and Van Sant, 1985). Additionally, *A. tonsa* selectively fed on actively growing *T. weissflogii* with higher protein, dissolved free amino acids, and total N content as opposed to slow growing, high C:N *T. weissflogii* cells (Cowles *et al.*, 1988). Microzooplankton may also exhibit selective feeding. Stoecker *et al.* (1986) found the ciliate *Balanion* prefers dinoflagellates (2 *Heterocapsa* species) over cryptophytes (*Chroomonas salina*), chlorophytes (*Dunaliella tertiolecta*), and prymnesiophytes (*Isochrysis galbana*) because they support the fastest ciliate growth (3 divisions d^{-1} at 15°C). Zooplankton may also vertically migrate to areas of higher quality food (Sterner *et al.*, 1993), such as the primary production maximum where phytoplankton cells are actively growing (Cowles *et al.*, 1988) and richer in N. The ability to feed selectively on a more nutritious food decreases the elemental imbalance between prey and consumer.

Many zooplankton are opportunistic feeders and thus can feed omnivorously on both phytoplankton and microzooplankton such as heterotrophic ciliates and flagellates. Marine protozoa are increasingly realized to be an important part of mesozooplankton diets, either as a nutritional supplement for what can not be acquired from a strict phytoplankton diet, or as the primary food source (Landry and Calbet, 2004 and references therein). Carnivory and omnivory may be metabolically beneficial, as animal prey C is assimilated more efficiently than phytoplankton prey C, and N is assimilated more efficiently than C (Gifford, 1991; Tang and Dam, 1999). Stoecker and Egloff (1987) found that protozoans were an important food source for adult copepods, even in the presence of high concentrations of phytoplankton, suggesting a preference for higher food quality. *A. tonsa* copepods preferentially fed on the tintinnid ciliate *Favella* sp. over a higher concentration (in total C and N) of dinoflagellates *Heterocapsa triquetra* (Stoecker and Sanders, 1985), perhaps due to the higher quality (lower C:N) of the tintinnid compared to the dinoflagellate. Additionally, *A. tonsa* copepods had higher clearance rates for a variety of ciliates and a rotifer species over algae even under high algal concentrations (Stoecker and Egloff, 1987). Omnivory and carnivory is advantageous when phytoplankton prey items are nutrient limited and/or do not contain essential amino acids or polyunsaturated fatty acids necessary for zooplankton growth (Kleppel, 1983). This is especially true in detritus-based food webs where allochtonous organic matter is high in C relative to N (Stoecker and Capuzzo, 1990). Previous studies have shown that protozoan diets may enhance growth and survival of predators and also increase egg production, most likely due to their typically lower C:N and higher levels of essential nutrients such as polyunsaturated fatty acids (PUFAs), sterols, and amino acids, compared to phytoplankton (Gifford, 1991; Goldman *et al.*, 1985; Kleppel *et al.*, 1988; Putt and Stoecker, 1989; Stoecker and Capuzzo, 1990; Stoecker and Egloff, 1987; Stoecker and Sanders, 1985; Verity and Langdon, 1984).

3. Metabolism

3.1. Egestion

A proportion of the nitrogen ingested by zooplankton is assimilated, or taken up into the organism's tissues, while the rest is egested as feces. Fecal pellet production is an important mechanism for N cycling and transport to deep water and the sediments. The cycling of N and the amount of N transported from the euphotic zone to depth via fecal pellet production is dependent upon both the N composition of the pellets as well as on leaching of soluble nitrogenous products from pellets.

The elemental composition of fecal pellets can be affected by the amount, type, and quality of prey that is consumed (Urban-Rich *et al.*, 1998). The N content of fecal pellets has been measured for a variety of zooplankton feeding on natural diets and on unialgal cultures of different concentrations. Table 26.3 (also see Morales, 1987) shows examples of N content and C:N ratio of feces from a number of zooplankton species feeding on various food sources. The N content of feces ranges over three orders of magnitude, from about 13 ng N per pellet for small copepods (*Acartia clausi*), up to 32 μg N per pellet for large salps (*Salpa maxima*). The C:N ratios of freshly egested fecal pellets are generally higher than algal food, indicating preferential assimilation of N over C (e.g., Paffenhöfer and Knowles, 1979; Downs and Lorenzen, 1985; Morales, 1987; Table 26.3). Food quality also effects fecal pellet C:N ratio. During early phytoplankton bloom conditions, the C:N of *A. tonsa* pellets was lower (~4) than during the late bloom (~7), again suggesting copepods preferentially conserve N to maintain appropriate body tissue C:N ratio (Butler and Dam, 1994). However, Madin and Deibel (1998) note that the relatively high C:N ratios of salp fecal pellets, from about 10–20, could also result from the presence in fecal pellets of carbon-rich mucus from the salps' internal feeding net, as opposed to indicating greater absorption of N from ingested food. The superfluous feeding hypothesis (Beklemishev, 1962) predicts that at high food density the fecal pellet C:N ratio should be most similar to the prey C:N, as assimilation decreases at very high food concentration. However, several studies have shown that increasing food quantity does not necessarily decrease fecal pellet C:N ratio as predicted (Butler and Dam, 1994; Morales, 1987; Table 26.3). Several studies have also measured the composition of organic N constituents in feces. Protein constitutes 11.5%, and lipids 1.4%, of the dry weight of salp fecal pellets (Madin, 1982), and protein 4.5–6.2%, and lipids 0.4–0.5%, of the dry weight of euphausiid fecal pellets (Youngbluth *et al.*, 1989). Poulet *et al.* (1986) found the composition of dissolved free amino acids (DFAA) in copepod fecal pellets was dependent upon the type of food ingested, with four amino acids combined (ASP, SER, GLY, and LEU) on average making up 63% of the total DFAA in fecal pellets of four different species of copepods. The diversity of DFAA in fecal pellets was higher than in the surrounding seawater or in their phytoplankton diet, suggesting contribution of DFAAs from the cells of the copepods themselves (Poulet *et al.*, 1986) or from copepod gut bacteria.

Fecal pellets can contain unabsorbed digestive products that then leak into the surrounding water, providing a potentially important source of DOM (Jumars *et al.*, 1989; Lampitt *et al.*, 1990). Fecal pellets may leach relatively more DOM when they

Table 26.3 Composition of zooplankton fecal pellets

Producer	Food conditions	Fecal pellet composition			Fecal pellet C:N	Reference
		Carbon	Nitrogen	Units		
Copepods						
Palaemonetes pugio	*Nitzchia closterium*	20	4.5	% f.p. dry weight	4.5	Johannes and Satomi, 1966

Table adapted and updated from Morales (1987).

Units for carbon and nitrogen reported differ among studies and are given separately. Only studies that reported fecal pellet nitrogen composition are listed. f.p. = fecal pellet.

– = Not determined, or not reported in cited reference.

[a] Mean carbon value.

[b] Nitrogen calculated from carbon using given C:N.

[c] Carbon value assumed from AFDW given in reference.

[d] Nitrogen calculated from AFDW using given C:N.

Deborah K. Steinberg and Grace K. Saba

are newly defecated (Jumars *et al.*, 1989) or DOM losses may be on time scales of hours to days (Strom *et al.*, 1997; Urban-Rich, 1999). The rapid release of DOM via fecal pellet leaching retains the DOM in the euphotic zone, leaving less total POM for vertical transport. Copepods can also enhance DOM leakage by disrupting or breaking apart their own pellets and leaving the pellet vulnerable to physical and microbial degradation (Lampitt *et al.*, 1990). Urban-Rich (1999) and Thor *et al.* (2003) found that *Calanus* spp. and *A. tonsa* fecal pellets, respectively, can leach between 34 and 50% of the total C content of the fecal pellet as DOM in the first 48 hours of egestion. In the only study that has examined DON leakage from fecal pellets, Roy and Poulet (1990) found a rapid decrease in copepod fecal pellet total DFAA concentration within the first 3–5 days of incubation. The amount of DOM leaching from fecal pellets can be a function of food concentration and food type. A higher amount of DOC was leached from copepod fecal pellets when the copepods were feeding on higher concentrations of food (Urban-Rich *et al.*, 1998). Copepod fecal pellets leached higher amounts of DOC when copepods were feeding on dinoflagellates (compared to diatoms) (Thor *et al.*, 2003), and copepod fecal pellets are susceptible to leach higher amounts of DOC when copepods feed on heterotrophs (compared to phytoplankton) (Urban-Rich *et al.*, 1998). Studies examining the relative coupling of C and N during fecal pellet leaching are sorely needed. Daly *et al.* (1999) suggested that C and N release by copepods resulted in quantitatively different fluxes of DOC and DON, which ultimately resulted in highly non-Redfield ratios within those pools.

3.2. Sloppy feeding

Sloppy feeding, the physical breakage of phytoplankton cells, or of prey animals, due to zooplankton grazing can be responsible for the generation of significant amounts of DOM (Dagg, 1974; Jumars *et al.*, 1989; Lampert, 1978; Møller and Nielsen, 2001). The conditions that favor production of DOM via sloppy feeding are when cells are too large to be ingested whole and when prey density is high, such as during phytoplankton blooms (Møller, 2005; Møller, 2007; Møller and Nielsen, 2001; Roy *et al.*, 1989). Most studies to date have solely investigated release of DOC by sloppy feeding. For example, Lampert (1978) found 3–17% of the initial algal C ingested by the cladoceran *Daphnia* feeding on diatoms, flagellates, and green algae was lost as DOC due to sloppy feeding. Measurements of the fraction of phytoplankton POC ingested by copepods lost as DOC via sloppy feeding include 54–69% (Møller and Nielsen, 2001), 49% (Møller *et al.*, 2003), and 7–36% (Møller, 2007). The latter study also demonstrated experimentally that DOC production by sloppy feeding increases as the size of the prey increases relative to the size of copepod grazers (Møller, 2007). Only two studies directly investigating the mechanism of sloppy feeding on N release have been conducted (Roy *et al.*, 1989; Vincent *et al.,* 2007). An investigation of sloppy feeding by copepods feeding on the large diatom *Coscinodiscus* showed that despite significant breakage of the diatom cells, there was little accumulation of DFAA detected (Roy *et al.*, 1989). As *Coscinodiscus* cells have high internal DFAA concentration, the low accumulation DFAA produced by sloppy feeding was attributed to the rapid uptake of DFAA by bacteria and live *Coscinodiscus* cells in the experiments (Roy *et al.*, 1989). In more recent experiments of copepods

feeding on ^{15}N-labelled diatoms, DON release via sloppy feeding was equal to about half of copepod DON excretion. However, only 2–9% of the phytoplankton PON ingested was released as DON via both pathways (i.e., excretion and sloppy feeding; phytoplankton direct release was minimal) (Vincent *et al.*, 2007).

Increased release of amino acids (Furhman, 1987; Roman *et al.*, 1988; Poulet *et al.*, 1991; Williams and Poulet, 1986) or bulk DON (Hasegawa *et al.*, 2000) as a result of zooplankton feeding has been demonstrated, although the proportion of N release attributed to sloppy feeding (vs. excretion or other mechanisms) was unknown. A positive correlation was found between the vertical distribution and abundance of zooplankton and the concentration of amino acids with depth (Poulet *et al.*, 1991; Williams and Poulet, 1986). Although the exact mechanism was not investigated, it was presumed that the correlation was a result of zooplankton sloppy feeding and excretion (Poulet *et al.*, 1991; Williams and Poulet, 1986). Using an isotope dilution approach, Fuhrman (1987) found DFAA release by copepods was comparable to direct release by microplankton. In mesocosm experiments with copepod grazers, release rates of both ammonium and DFAAs were higher in treatments with copepods versus those with microplankton alone (Roman *et al.*, 1988). Other investigations measuring bulk DON release have also found increased release of DON in the presence of grazers, however, release rates when normalized to zooplankton biomass were minor compared to microplankton (<94 μm) (Hasegawa *et al.*, 2000).

3.3. Assimilation

The assimilated portion of food ingested is that which is absorbed through the gut wall and taken up into the animal's tissues, with the rest of the food egested as feces. The assimilation efficiency (AE) = $(I-E)/I \times 100\%$, where I is the ingestion rate and E is the egestion (defecation) rate. Assimilation efficiency varies with prey type, with AE for herbivorous species generally ranging from 60 to 95%, and carnivorous species higher, at more than 90% (Parsons *et al.*, 1984). N is assimilated at a much higher efficiency than carbon, especially in food with lower N and protein contents (Cowie and Hedges, 1996; Hassett and Landry, 1988; Kiørboe *et al.*, 1985; Landry *et al.*, 1984). A review of the literature on copepod assimilation efficiency also notes that on average copepods tend to assimilate nitrogen (AE = 77%) more efficiently than carbon (AE = 63%) (Tang and Dam, 1999; Tang, unpublished). This trend is also reported for salps (*Cyclosalpa bakeri*), with an AE of 71% for nitrogen and 61% for carbon (Madin and Purcell, 1992). The gammarid amphipod *Calliopius laeviusculus* feeding on copepods, however, had a similar assimilation efficiency for nitrogen (89%) and carbon (90%) (Dagg, 1976). Landry *et al.* (1984) found the assimilation efficiencies for both N (73.9–92.5%) and C (68.5–85.4%) for *C. pacificus* feeding on *T. weissflogii* were highest at low food concentrations, most likely due to increased digestive enzyme activity and ingestion capacity. As discussed elsewhere in this chapter (see Sections 3.1. and 3.6.), a preferential assimilation of nitrogen over carbon from ingested food may indicate a N deficiency in the food, thus the animal must assimilate more N relative to carbon to meet its nitrogen requirements. It should be noted, however, that a preferential assimilation of N over C does not necessarily indicate a N deficiency in the food–which always has more C than

N—but rather that zooplankton have evolved to be more efficient at assimilating N compounds which they need for growth.

3.4. Excretion

3.4.1. Products, rates, and pathways of nitrogen excretion

3.4.1.1. *Inorganic*   Inorganic N in the form of ammonium is considered the primary nitrogenous excretory product of mesozooplankton (e.g., Bidigare, 1983) and micro-zooplankton (Caron and Goldman, 1990), a trait shared by most aquatic invertebrates and teleost fishes (Regnault, 1987). Ammonium is produced as an endpoint of the catabolism of proteins and amino acids, via the oxidative deamination of glutamate through the enzyme glutamate dehydrogenase (GDH) (Bidigare, 1983; Le Borgne, 1986; Regnault, 1987). In copepods, excretion is through the maxillary glands which are located in the head region, and in the euphausiids excretion is through the gills (Ruppert and Barnes, 1996). In gelatinous zooplankton such as the cnidarians (e.g., medusae), nitrogenous waste diffuses through the body surface (Ruppert and Barnes, 1996). In marine protozoa waste is excreted via a contractile vacuole, or via diffusion (Weatherby, 1929).

Ammonia excretion rates of zooplankton have been extensively reported in the literature. A number of compilations and reviews (e.g., Ikeda *et al.*, 2001 for epipelagic copepods; Madin and Deibel, 1998 for salps and doliolids; Huntley and Nordhausen, 1995 and Ikeda and Mitchell, 1982 for Antarctic zooplankton; Atkinson and Whitehouse, 2000 for Antarctic krill) report equations to allow prediction of excretion rates for a given animal as a function of body mass and temperature (or on body mass alone). Table 26.4 lists examples of individual animal ammonia excretion rates across a variety of zooplankton taxa and environments. Excretion rates are highly dependent on animal size, temperature, feeding history, and other factors which are addressed in Section 3.4.2. Figure 26.4 shows the relationship between animal dry weight and ammonia excretion for epipelagic copepods from a wide range of environments (Ikeda *et al.*, 2001). When comparing multiple taxa, it is most useful to report excretion rate per unit animal body weight (e.g., per mg wet weight or dry weight, or dry weight of nitrogen or carbon), or for gelatinous zooplankton, body volume (per milliliter) is also used. Studies have shown that mass-specific ammonia excretion rates of gelatinous zooplankton (e.g., salps, cnidarians, ctenophores) are about an order of magnitude lower than other (e.g., crustacean) taxa if dry weight is used as the body mass unit (Schneider, 1990). However, if carbon is used as a body mass unit, the weight-specific ammonia excretion rates of gelatinous zooplankton are comparable to the crustacea (Schneider, 1990), as carbon is a significantly smaller percentage (<10%) of gelatinous zooplankton dry weight than of crustacean dry weight (C ~40% of dry weight).

As shown in Table 26.4, individual animal ammonia excretion rates (µg N ind^{-1} h^{-1}) range over 10 orders of magnitude, from 2.7×10^{-8} to 4.5×10^{-4} for protozoa, to 0.003 for small tropical copepods, up to 546 for large scyphozoan medusae. Weight specific ammonia excretion (µg N mg dry wt^{-1} h^{-1}) is generally highest for the smallest organisms, ranging from 0.2–178 for protozoans, to 0.01–4.51 for copepods, to 0.001–0.33 for larger crustacean zooplankton, and to 0.006–4.7 for gelatinous zooplankton. For copepods, ammonia excretion as a proportion of body N per day on average is generally <10%, with the exception

Table 26.4 Example of ammonia excretion rates for a variety of zooplankton taxa in different environments

When percent body N excreted per day was not available in the reference, it was calculated using body N values provided. If body N data was not provided, we assumed body N = 10% body dry weight (DW) for crustacea, body N = 2% DW for ciliates and body N = 4% DW for flagellates (calculated from Tables 26.1 and 26.2).

— = Not determined, or not reported in cited reference.

[a] Individual mean cell volumes assumed from literature values and converted to wet weight (1 μm^3 = 1 pg wet weight) and dry weight (dry weight = 0.2 $\times$ wet weight) (Caron and Goldman, 1990).

[b] Excretion rate(μg N ind^{-1} h^{-1}) calculated by multiplying average excretion rate (μg N mg DW^{-1} h^{-1}) by average DW (mg).

[c] Body dry weight calculated from dividing average excretion rate(μg N ind^{-1} h^{-1}) by the average weight-specific excretion rate (μg N mg DW^{-1} h^{-1}).

[d] Data listed is from freshly caught krill in filtered seawater (Atkinson and Whitehouse, 2000).

[e] Maximum.

[f] See Table 26.3; Kremer *et al.* (1986).

[g] Excretion rates in Biggs (1977) are given in mg body protein^{-1}, this was converted to dry weight assuming body protein = 23% DW (for gelatinous zooplankton; Table 26.1).

[h] For *Salpa fusiformis*.

[i] Mean dry weight.
Figure 26.4 Scatter diagram showing the relationship between dry weight and ammonia excretion rate for epipelagic marine copepods. The data points represent mean rates for all copepod species from each type of environment, Antarctic, Arctic, boreal, subtropical, and tropical (temperature range: −1.7 to 29°C). (Adapted from Ikeda *et al.*, 2001).

of tropical species which is higher (on average ~20%, calculated from Ikeda *et al.*, 1982, 2001). In a global estimation of open-ocean mesozooplankton excretion in the epipelagic zone, Hernández-León *et al.* (2008) also show that specific ammonium excretion rates are highest in the tropics (~20–25% body N per day), and decrease rapidly toward the poles to <5%. Excretion as a proportion of body N per day for larger crustacean and gelatinous zooplankton, is also generally <10%, but is occasionally high for some taxa, such as the salps, which can turn over their entire body N content in a day (Table 26.4). At the far end of the spectrum are the marine protozoa which are capable of excreting ammonia at a rate hundreds to thousands of times their body weight per day, illustrating their importance in remineralization (Table 26.4).

3.4.1.2. *Organic*

DON, such as urea and amino acids, is generally considered to be excreted at lower, but substantial levels compared to ammonia (Bidigare, 1983). There are, however, few measurements of the relative importance of inorganic versus organic excretion by zooplankton, and rates of DON excretion vary greatly (Steinberg *et al.*, 2000, 2002). Indeed some studies indicate DON frequently exceeds ammonia as the primary nitrogenous excretory product (Miller and Glibert, 1998; Conover and Gustavson, 1999). The handful of studies to date that report excretion of DON by zooplankton indicate DON can make up a substantial proportion of the total dissolved nitrogen (TDN) excreted. Table 26.5 (updated from Steinberg *et al.*, 2002) shows a variety of planktonic crustaceans (copepods, amphipods, euphausiids, mysids, shrimp) with combined urea and amino acid excretion, or excretion of total DON, ranging from 7 to 89% of the TDN excreted (Note: The definition of TDN varies in these studies as is indicated in Table 26.5, but is normally given as ammonia, urea, and amino acids combined). Only a few studies have reported organic N excretion by gelatinous zooplankton. Combined urea and amino acid excretion, or excretion of total DON, for gelatinous zooplankton (ctenophores, pteropods, chaetognaths, salps, and siphonophores) ranges from 16 to 46% of the TDN excreted

Table 26.5 Proportion of total dissolved nitrogen (TDN; inorganic+organic) excreted as DON (the key below denotes how % TDN excreted as DON was measured for each study)

Table is modified and updated from Steinberg *et al.* (2002).

% Urea, % total dissolved nitrogen excreted as urea; % amino acids, % total dissolved nitrogen excreted as amino acids; % TDN excreted as DON, % total dissolved nitrogen excreted as DON. Note: Most studies did not measure actual total dissolved nitrogen, but rather ammonia, urea, and amino acids.

—= Not determined, or not reported in cited reference.

[a] Urea/(ammonia + urea).

[b] (Urea + amino acid)/(ammonia + urea + amino acids).

[c] Total DON/TDN.

(Table 26.5). Mucus production by gelatinous zooplankton may be another important source of DON release. For example, Steinberg *et al.* (2002) found 66% of TDN was excreted as DON for gelatinous, mucus-releasing alciopid worms, and although DON production was not measured, the medusa *A. aurita* may release up to 7% of its assimilated C as DOC mainly through mucus production (Hansson and Norrman, 1995). LeBorgne (1982b, 1986) shows that the organic fraction of nitrogen excretion of a mixed zooplankton assemblage decreases with increasing weight percentage of copepods in the tropical Atlantic, suggesting gelatinous zooplankton and other taxa are relatively more important to DON excretion. There are even fewer data on microzooplankton DON excretion. Tintinnid urea release is 67% of ammonia release, equal to 40% of total N (ammonia + urea) release (calculated from Johansen, 1976, as referenced in Verity, 1985a) (Table 26.5). Studies to date do indicate marine protozoa can release a significant amount of ingested N as DON. Table 26.6 shows 1–22% of the total nitrogen ingested (note—not of total N excreted, as in Table 26.5) by flagellates and ciliates feeding on bacteria is released as amino acids.

The proportion of TDN that is excreted as DON and the DON composition may be affected by the quantity and quality of the food that is consumed (Miller and Roman, 2008; Miller and Glibert, 1998) (also see Section 3.4.2.3. below). For example, some studies show that zooplankton increase their organic, relative to inorganic, excretion of N when starved (Mayzaud, 1973; Miller and Roman, 2008). It has also been suggested that herbivores may be expected to excrete more urea than carnivores, as arginine (a precursor of urea) levels are higher in marine phytoplankton than in zooplankton (Bidigare, 1983). The composition of DON excreted may be dependent upon species, as shown by the relative amounts of different amino acids excreted by several mesozooplankton taxa (Webb and Johannes, 1967). DON may also be released in different patterns from ammonia. While ammonia is released continuously in crustacea (Regnault, 1987), amino acids can be released in high-concentration "spurts" lasting from 20 to 60 min (Gardner and Paffenhöfer, 1982). Steinberg *et al.* (2002) found a decrease or leveling off in DON excretion rates of migrating zooplankton, possibly due to this non-continuous release of DON.

3.4.2. Factors affecting excretion rates

3.4.2.1. Temperature
As described above in Section 3.4.1.1., temperature, along with body mass, is a dominant factor affecting excretion rate, and has been used extensively to predict excretion rates of marine zooplankton using multiple regression models (Ikeda, 1985; Ikeda *et al.*, 2001). Metabolic rate normally increases as temperature increases. The relationship between metabolic rate and temperature for marine zooplankton is described most commonly as the Q_{10} value

$$Q_{10} = \left(\frac{r_1}{r_2}\right)^{\frac{10}{(t_1 - t_2)}}$$

where r_1 and r_2 are the rate of excretion (or respiration) at temperature t_1 and t_2, respectively. The Q_{10}, the factor by which metabolic rates increase for a $10°C$ increase in temperature, is generally around 2 ± 0.5 for zooplankton ammonia excretion, but ranges between ~1 and 4 (e.g., Table II in Bidigare, 1983). Analysis of extensive metabolic datasets compiled for 38 species of copepods from habitats ranging from -1.7 to $29°C$, and a phylogenetically diverse range of epipelagic zooplankton from habitats -1.4 to $30°C$, revealed a range of Q_{10} values for ammonia excretion from 1.8 to 2.0 (Ikeda *et al.*, 2001), and 1.9 (Ikeda, 1985), respectively. Reported Q_{10} values for ammonia excretion of some gelatinous zooplankton include 2.1–2.3 for the salp *Salpa fusiformis* (Andersen and Nival, 1986), ~4 (Kremer, 1977) and 1.6 (Park and Carpenter, 1987) for the ctenophore *Mnemiopsis leidyi*, and 1.3–2.0 for the hydromedusae *Clytia* spp. (Matsakis, 1992). Little information is available on Q_{10} for microzooplankton excretion; the average Q_{10} for ammonia excretion for the microflagellate *Monas* sp. was 5.1 (range 0.7–20.5) (calculated from Table 3 in Sherr *et al.*, 1983). Rearrangement of the above equation by taking the natural logarithm of both sides makes Q_{10} useful for predicting excretion rates of zooplankton at different temperatures due to changes in depth (e.g., vertical migration) or seasons. Temperature can affect different metabolic processes differently, resulting in varying metabolic quotients (e.g., O:N, or oxygen consumption–ammonia excretion ratio, which also varies with the substrate being metabolized) and thus Q_{10} for excretion for a given organism is not always the same as the Q_{10} for respiration (LeBorgne, 1986).

3.4.2.2. Body size (weight)
Excretion (or respiration) rate (Y) can be related to body weight (W) according to the allometric equation:

$$Y = aW^b$$

where a is the species/temperature dependent constant and b is the size-dependent (or "body-mass scaling") constant (Bidigare, 1983). The coefficients a and b have been characterized well due to their usefulness in modeling (LeBorgne, 1986). For most zooplankton, weight-specific excretion rate (e.g., mg N mg dry weight^{-1} h^{-1}) decreases with increasing body weight (size) (e.g., Table 26.4), and b is less than 1, and usually in the range 0.7–0.9 (Vidal and Whitledge, 1982; Ikeda *et al.*, 2000).

Both coefficients vary with the weight unit applied (e.g., dry weight, carbon, or nitrogen) and type of metabolism (e.g., ammonia excretion, phosphate excretion, or respiration) being studied. Schneider (1990), in comparing ammonia excretion rates between gelatinous and nongelatinous zooplankton, found body carbon or nitrogen units were best for making broad interspecific comparisons as they reduced differences in body composition among the different taxa.

3.4.2.3. Nutritional level

The effects of food level and starvation on excretion rates of marine zooplankton have been reasonably well studied. Excretion rates tend to increase with increasing food availability and ingestion rate, and are also dependent upon the type of food. For example, excretion of both ammonia and urea by the copepod *C. helgolandicus* feeding carnivorously on barnacle nauplii increased with increasing food concentration and ingestion rate (Corner *et al.*, 1976), as did excretion of ammonia by the copepod *E. pileatus* feeding on diatoms (Gardner and Paffenhöfer, 1982), ammonia and phosphate excretion of *Metridia pacifica* feeding on algal cultures (Takahashi and Ikeda, 1975), and ammonia excretion of the ctenophore *Mnemiopsis mccradyi* feeding on copepods (Kremer, 1982). However, Miller and Landry (1984) found ammonia excretion rates of the copepod *C. pacificus* were relatively constant with increasing diatom density, implying this copepod increases its growth efficiency as ingestion rate increases. The copepod *T. stylifera* excreted twice as much ammonia when fed on a diet of the prymnesiophyte *Hymenomonas elongata* as when fed on a diet of the diatom *Phaeodactylum tricornutum* (Abou Debs, 1984), indicating food type plays a major role as well. Excretion rates of Antarctic krill acclimated to both filtered seawater and to excess food were 30% higher during feeding periods (Atkinson and Whitehouse, 2000). Similarly, excretion rates of Antarctic krill acclimated to filtered seawater and to six different types of food excreted 4.5 times more ammonia when feeding (Ikeda and Dixon, 1984). Thus, excretion rates measured during long incubations (e.g., 24 h) without food will likely underestimate excretion. In addition to excretion rates of fed animals being higher than starved, the relative proportion of metabolic substrate catabolized (i.e., lipids vs. proteins) can vary, resulting in different O:N, N:P, and O:P metabolic ratios in starved versus fed zooplankton (Ikeda, 1977; Mayzaud, 1973; Quetin *et al.*, 1980).

3.4.2.4. Other miscellaneous environmental factors

While temperature, body size, and nutritional status of zooplankton play the largest role in affecting excretion, other factors such as light and salinity can also play a role. Light can play a significant, indirect role in excretion, and diel patterns in grazing and excretion have been documented. Ammonium excretion in surface waters of the vertically migrating copepod *Calanus helgolandicus* was 1.7 times higher at night than day (Harris and Malej, 1986). This pulsing and periodicity in ammonia input as a result of zooplankton diel migration may be significant for phytoplankton N uptake, especially in oligotrophic waters (Harris and Malej, 1986). Conversely, Miller and Glibert (1998) found ammonia excretion by the calanoid copepod *A. tonsa* was higher in the day, and excretion of urea and dissolved primary amines higher in the early morning and early evening. Pitt *et al.* (2005) found no net ammonia excretion by the scyphozoan medusae *Phyllorhiza punctata* during the day due to ammonia uptake by their

symbiotic zooxanthellae, but net ammonia excretion was measured at night (under nutrient-enriched conditions). A second scyphozoan species with no or few zooxanthellae, *Catostylus mosaicus*, excreted 1.5 times more ammonia during the day than night (Pitt *et al.*, 2005). Thus, the form of N excreted can also be tied to a diel cycle, and the diel pattern varies by species. This may partially be explained by changing phytoplankton metabolism and products of photosynthesis over the diel cycle, resulting in diel alterations in the ratio of phytoplankton protein:lipid: carbohydrate (Cuhel *et al.*, 1984; Morris, 1981). Thus phytoplankton N substrates ingested by herbivorous zooplankton may vary over a diel cycle (Cuhel *et al.*, 1984), which could in turn affect N excretion products. Finally, the interplay between zooplankton grazing and ammonia excretion, and phytoplankton ammonia uptake over the diel cycle can be more important than physical mixing as a generator of cyclic ammonia patterns in surface waters, as noted in the Southern Ocean (Priddle *et al.*, 1997).

Salinity effects on N excretion will be most pronounced in coastal or estuarine environments where organisms are exposed to tidal fluctuations in salinity. Although highly dependent on the osmoregulatory capabilities of the organism in question, studies on the effect of these kinds of salinity changes on zooplankton excretion rates tend to show ammonia excretion rates increase when animals are hyper-regulating (adjusting to less saline conditions, as in an ebb tide), and decrease when they are hypo-regulating (adjusting to more saline conditions, as in a flood tide) (Regnault, 1987). Ammonia excretion and oxygen consumption of the under-ice arctic amphipod *Onisimus glacialis* increased with decreasing salinity (Aarset and Aunass, 1990). Changes in salinity have been reported to cause ionic shifts in estuarine scyphomedusae affecting their size and weight (Wright and Purcell, 1997), thus care must be taken with reporting size or weight-specific excretion of gelatinous zooplankton in differing salinities. Finally, to our knowledge, other effects such as hydrostatic pressure, which can affect oxygen consumption rates (e.g., Childress, 1977) have not been investigated for zooplankton N excretion. The toxic effects of high external ammonia concentration on excretion rates, while investigated for some benthic crustaceans and fish (see Regnault, 1987 for review), to our knowledge have not been investigated for marine zooplankton.

3.5. Growth and reproduction

For completeness we include mention of zooplankton growth and reproduction (which together equal secondary production) in this chapter as a pathway of N metabolism; however, much of the recent literature focus on growth is on carbon-based models of weight-specific growth (for copepods see Hirst and Bunker, 2003; Hirst and Lampitt, 1998; Hirst and Sheader, 1997; Huntley and Lopez, 1992; for the most recent synthesis of metazoan invertebrate zooplankton, including copepods, see Hirst *et al.*, 2003; for microzooplankton see Calbet and Landry, 2004; Landry and Calbet, 2004), and we have previously addressed some of the N-based food quality factors that effect egg production in Section 2.2.2. Zooplankton growth rate is related to body weight or size. An extensive literature review of data on growth and ingestion rates of zooplankton of a broad size range (from protozoans to

metazoans) indicates biomass-specific growth rate scales negatively to weight (smaller organisms grow faster), with the maximum growth rate for protozoans nearly 10 times higher than that for metazoans (Hansen *et al.*, 1997). Hirst and Lampitt (1998) and Hirst *et al.* (2003) used a multiple linear regression model to predict copepod growth rate from temperature and body size (based on 2528 published copepod growth rates, in the latter study, with accompanying body weight and temperature data; note—other studies, e.g., Hirst and Bunker, 2003, have included chlorophyll *a* as a descriptor too). The resulting overall multivariate regression equation that relates intrinsic growth rate, g (d^{-1}) to temperature, T (°C), and copepod body weight, BW (μg C ind^{-1}) from the more recent study is $\log_{10} g = 0.0345[T] - 0.128[\log_{10}BW] - 1.529$ (Hirst *et al.*, 2003). In this compilation, any N-specific growth rates from the literature were assumed to be equal to carbon-specific rates (Hirst and Lampitt, 1998; Hirst *et al.*, 2003), thus estimates of N secondary production for copepods could be made using this model as well by applying a body dry weight C:N ratio. (This assumes regardless of the size and growth rate the copepod has a fixed C:N).

Comparisons between the major metazoan zooplankton taxa indicate that in general the gelatinous zooplankton (with the exception of chaetognaths) have higher weight-specific growth rates than copepods and other crustacea of similar body C weight, with thalacians (e.g., salps, larvaceans) having the highest overall growth rates (d^{-1}) of any taxa (Hirst *et al.*, 2003 and references therein). These high growth rates presumably lead to high N biomass production in gelatinous zooplankton blooms (although gelatinous zooplankton have relatively lower body N content than crustacea, see Section 2.1.3.). Finally, with the exception of Landry and Calbet (2004), there is a dearth of information on microzooplankton production in the oceans. In their study, a synthesis of phytoplankton growth and microzooplankton grazing rates coupled with estimates of gross growth efficiency indicated microzooplankton secondary production is equal to 21–35% (and higher when multiple steps in the grazing chain are considered) of primary production, and that as a group micro-grazers are deriving the majority of their production from consuming phytoplankton (compared to feeding on bacteria). Considering the varying elemental compostion of phytoplankton and bacteria, this has interesting implications for cycling of N and other elements in the microbial food web, as addressed next.

3.6. Stoichiometery of zooplankton nitrogen metabolism with other elements

Due to the high plasticity of phytoplankton prey items and the contrasting strict stoichiometry of herbivores, zooplankton elemental composition, and that of its food, regulate the elemental ratio of nutrients excreted. Thus, a change in the zooplankton taxa or food source can cause wide changes in the quantity and composition of bioavailable regenerated products (Caron and Goldman, 1990; Gismervik, 1997; Pertola *et al.*, 2002; Sterner and Elser, 2002; Strom *et al.*, 1997). For example, a consumer with low N and high P body content feeding on prey with high N and low P content will retain more P and excrete more N and thus favor P limitation in the plankton. Conversely, a consumer feeding on N-limited food would retain more N and excrete more P (Fig. 26.5; Sterner, 1990; Touratier
Figure 26.5 The ratio of nitrogen to phosphorus (N:P) excreted by mesozooplankton (squares) and microzooplankton (circles) plotted against the N:P in the algal pool. Data from Le Borgne, 1982a. (Adapted from Sterner, 1990).

et al., 2001). This has been shown for tropical copepods feeding on a natural plankton assemblage (Le Borgne, 1982a) and for microflagellates feeding on diatoms grown under varying nutrient conditions (Andersen *et al.*, 1986; Goldman *et al.*, 1985, as summarized by Caron and Goldman, 1990).

Stoichiometric theoretical models have been implemented in order to further understand consumer-driven nutrient recycling processes (Andersen, 1997; Elser and Urabe, 1999; Hessen and Andersen, 1992; Sterner, 1990; Touratier *et al.*, 2001). The various combinations of parameters used in these models differ, such as assimilation efficiency of individual nutrients, food quality, quantity of food supply, heterotrophic growth efficiency, and physical parameters such as temperature; however, the models all agree that the stoichiometry of nutrients released from zooplankton is mainly a function of both prey and grazer elemental composition. Anderson and Hessen (1995) have described the theoretical minimum of food C:N based on assimilation efficiencies, net growth efficiency for carbon, and C:N of herbivore and nitrogenous compounds as the threshold elemental ratio (TER). For example, if food C:N = TER, herbivore production is not limited by either C nor N. However, if food C:N > TER, herbivore production is likely limited by N. Additionally, models of the influence of C:N ratios in zooplankton food on C:N ratios in zooplankton biomass and fecal pellets indicate that simply considering elemental (i.e., C:N) composition is not adequate. Rather, considering the biochemical makeup of the ingested food (proteins, lipids, carbohydrates) is important to accurately predict C:N ratios in fecal pellets from that of ingested food, as the assimilation efficiency of a given element depends on the biochemical form in which the element is present (Anderson, 1994; Anderson and Hessen, 1995).

What is clear from studies to date is that non-Redfield excretion and recycling of elements is the norm for zooplankton (Steinberg *et al.*, 2002). For example, a variety of Barents Sea zooplankton exhibit wide ranges of ratios of respiration and inorganic excretion: C:N (range 4–44), N:P (range 2–45), and C:P (range 59–910) (calculated from Table 3 in Ikeda and Skjoldal, 1989). Respiration and inorganic excretion

ratios, as well as organic excretion ratios (DOC:DON) for diel vertically migrating zooplankton in the Sargasso Sea are also non-Redfield (Steinberg *et al.*, 2002). Ingestion of prey in surface waters at night and subsequent non-Redfield stoichiometry metabolism at depth during the day (''active flux'') by these migrators may contribute to nutrient-ratio anomalies present below the euphotic zone in the western Sargasso Sea (Anderson and Pondaven, 2003; Steinberg *et al.*, 2002). Small *et al.* (1983) showed that Pacific tropical zooplankton excrete 38–49% more ammonium N than respired C, relative to body concentrations of N and C, respectively. However, the excess N lost through ammonium excretion was balanced by a like amount conserved during fecal pellet production, yielding a relatively constant body C:N ratio (Small *et al.*, 1983). A more complete understanding the stoichiometry of zooplankton N metabolism will be necessary to fully model the role of zooplankton in ocean nutrient and carbon budgets.

4. Conclusions and Future Directions

Considerable progress in our understanding of the role of marine zooplankton in nitrogen cycling has been made in the last two decades since the first edition of this book. A compilation of ammonia excretion rates alone would be enough to fill an entire book chapter, but even here there are considerable gaps in our knowledge. We are now at the stage where large data sets are being compiled, and it is possible, for example, to reasonably predict ammonia excretion as a function of body mass for a given organism and temperature using regression equations—and avoid doing experimental incubations. These individual, size-specific excretion rates can be scaled up to a community rate if total biomass and size structure of the community is known. However, most of these data, and the algorithms developed from them, are available for crustacean mesozooplankton (e.g., copepods), and considerably less data is available for other groups.

A common theme throughout this review is that more information is needed on the role of marine protozoa, gelatinous zooplankton, and of taxa living below the euphotic zone in N consumption and metabolism. Consumption of phytoplankton and bacteria by microzooplankton are key processes in N transformations in the ocean (e.g., Nagata, 2000; Strom, 2000). Microzooplankton are an important component of the diet of many mesozooplankton, and provide nitrogenous nutrition that can not be gained from phytoplankton alone. In this light, we still know comparatively little about the biochemical composition of marine protozoans, and measurements on ammonia or DON release from microzooplankton are limited. Such information will provide important new perspectives on the stoichiometry of consumer-driven nutrient recycling. Experiments with the delicate gelatinous zooplankton are tricky, as damage can yield erroneous rates of metabolism, and many important gelatinous zooplankton are too large (e.g., scyphozoan medusae) to easily incubate. However, these key members of the planktonic food web are important in biogeochemical cycling, and we need a better understanding of their contribution to N consumption and metabolism. Most work on N cycling by zooplankton has been

carried out on epipelagic organisms. We know little about nitrogenous nutrition and metabolism of zooplankton of the mesopelagic zone, which include full-time residents as well as vertical migrators that actively transport N to and from depth, or on effects of environmental factors such as hydrostatic pressure on N metabolism of the very deep-living organisms.

The processes governing how food quality and quantity affects feeding, growth, and reproduction of zooplankton are complicated, and while significant progress has been made, gaps still remain. Previous studies show effects of food quantity and quality effects on egg hatching success are quite variable, due to species-specific differences in food nutritional quality, toxicity, or some other unexplored cause. Because egg production and hatching success are key determinants of zooplankton secondary production, future studies are needed to further explore the sources of this variability. While a number of studies have found differences in consumer feeding and growth rates based on dead versus live phytoplankton, or phytoplankton versus microzooplankton prey, future studies may need to consider multiple trophic levels to account for quality changes up the food web due to trophic upgrading (Klein Breteler *et al.*, 1999; Tang and Taal, 2005; Veloza *et al.*, 2006).

Studies of the relative magnitude and timing of the various N release mechanisms—excretion versus fecal pellet leaching versus sloppy feeding are needed. While N excretion rates for a variety of zooplankton have been extensively measured, only a few studies have directly investigated the mechanism of fecal pellet leaching or sloppy feeding on N release, thus little is known of the relative importance of each process to N cycling. The effects of food quantity and quality on N release by fecal pellet leaching or sloppy feeding are also not well known, and investigation of the relative coupling of C and N and P by these various release mechanisms would be beneficial.

Given the importance of excretion of DON by zooplankton to the microbial loop, more studies measuring organic excretion rates should be a priority, particularly for the protozoa and gelatinous zooplankton for which there are only a handful of measurements. The role of zooplankton community composition in DON cycling also deserves further attention, as some taxa (e.g., gelatinous zooplankton) may be relatively more important than others (e.g., crustacea) in the release of DON (LeBorgne, 1982b, 1986). Even less is known about the composition of DON released by zooplankton feeding and metabolism, and studies on both the composition and lability of this material are needed. Concerning the latter, experiments designed to explore the use of zooplankton-produced DON by the bacterial community (e.g., Richardot *et al.*, 2001) will provide valuable insight on the role of zooplankton in fueling the microbial loop.

As a general note on experimental work in studying N consumption and excretion, most of the methods that were in use two decades ago for measuring N consumption and excretion rates are still in use and valuable today. Normally zooplankton must be confined in bottles in order to resolve changes in ammonia or DON concentration, for example. Improvements upon this method could be made by employing some of the new nanomolar ammonia sensor technology (Li *et al.*, 2005; Masserini and Fanning, 2000) to detect small changes in ammonia concentration in excretion experiments, and allow for lower densities of animals to be used in

incubations. The measurement of N consumption and release in a natural planktonic assemblage with multiple trophic levels is still difficult, and currently isotopic methods (see McCarthy and Bronk, in this volume) may be the only way to tease apart the various mechanisms and elucidate pathways for N release.

Finally, a high priority should be given to studies linking N consumption and release with other elements. Studies following the pathway of multiple elements from food, to incorporation into zooplankton consumers, to their metabolic products will yield a wealth of information on biochemical nutritional requirements of zooplankton and the role of zooplankton in affecting the stoichiometry of nutrient cycling in the sea.

Nitrogen-Fixing and Nitrifying Symbioses in the Marine Environment

Rachel A. Foster *and* Gregory D. O'Mullan

Contents

1. Introduction

The term ''symbioses'' was first defined loosely by De Bary (1879) as two or more differently named organisms living together. Although symbiotic interactions are ubiquitous in nature, few of the marine planktonic systems have been well characterized, and comparatively less is known of the functional role of the symbiont for the host and vice versa. Many of the planktonic symbioses are between eukaryotic hosts and cyanobacterial symbionts, or cyanobionts. Cyanobacteria are photosynthetic, and many are capable of nitrogen (N_2) fixation, thus often it is presumed

that the cyanobacterial partner functions as a carbon and/or nitrogen source for the host. In a parallel system involving sponges, often the microbial symbionts are a diverse assemblage of heterotrophs, lithotrophs, and phototrophs. One unifying character in sponge–microbe system is the exchange of nitrogen.

Nutrients are often the key limiting factors to primary production in the tropical seas, and symbioses are frequently observed in these types of oligotrophic habitats. From his many microscopy observations, Norris (1967) speculated that a considerable part of the biota in the open ocean were involved at one time or another in a consortium, either temporary or more permanent. Forming a symbiotic association might then be considered an ecological adaptation to life in the oligotrophic ocean.

Compared to their terrestrial counterparts (see Rai *et al.*, 2000), marine symbiotic systems are greatly under-sampled, and thus the many intricacies of these unique relationships remain largely unresolved. Difficulties in isolating and identifying these symbioses have been the primary problems in attaining useful information about them. Without epifluorescence microscopy most of the planktonic associations would go unnoticed. With blue and green excitation, however, the cyanobionts exhibit fluorescence patterns distinct from their photosynthetic (diatom) and heterotrophic (dinoflagellate) partners (Fig. 27.1). In sponge–microbe and other invertebrate associations, the symbionts are more difficult to identify by standard microscopy due to the complexity of the mixed assemblage. For example, microscopy provided some evidence that nitrifying bacteria may associate with *Vesicomya* clams, however the data was insufficient to differentiate between nitrifying and methanotrophic bacteria (Deming *et al.*, 1997).

For the purpose of this text on symbioses as they relate to the marine nitrogen cycle, we will first emphasize the more common open ocean diatom–diazotrophic associations (DDAs), then summarize the recent advances in our understanding of sponge–nitrifying microbial associations, and provide brief introductions to a few other relevant symbioses. In addition, we recommend, the chapter by O'Neil and Capone (Chapter 21) for details on algal–animal symbioses of Coral Reefs as they relate to the nitrogen cycle, Chapter 4 by Carpenter and Capone on Nitrogen Fixation and Chapter 5 by Ward on Nitrification.

2. Diatom–Diazotrophic Associations

2.1. Hosts and cyanobionts

Some of the earliest reports of planktonic symbiosis describe the association of a heterocystous cyanobacterium, *Richelia intracellularis*, with various diatoms, including *Rhizosolenia* (Ostenfeld and Schmidt, 1901), *Hemiaulus* spp. and *Guinardia cylindrus* (Sündström, 1984; Taylor, 1982; Villareal, 1992). Up to 13 different species of *Rhizosolenia* have been reported with *Richelia* symbionts; however some authors (Sournia, 1970; Sündström, 1984) questioned the host identity, argued that many were misidentified, and proposed that most of the *Rhizosolenia* species were just varieties of *R. clevei*.
Figure 27.1 Epi-fluorescent micrographs of the better-studied diatom–diazotrophic associations (DDAs) common to the World's oligotrophic Oceanic Basins. (A) Blue excitation of a *Chaetoceros compressus* chain with attached heterocystous cyanobiont, *Calothrix rhizosoleniae*; inset is *Calothrix* SC01 isolate of Foster and Zehr. (B) A *Rhizosolenia clevei* filament with several *Richelia intracellularis* trichomes at its apical end. Note the chloroplast of host diatom fluoresces red, while cyanobiont excites yellowish-orange under blue light. (C) From top to bottom: Green and blue excitation of a diatom host, *Climacodium frauenfeldianum* with intracellular coccoid cyanobionts. Bottom is a blue excitation of symbioses in free-floating form. (D) A chain of *Hemiaulus membranaceus* diatoms with pairs of *Richelia intracellularis* symbionts in each host. Scale bar 20 μm. All photographs from Foster except 1D was provided by D.A. Caron.

Two of the most common *Hemiaulus* species reported with symbiotic *R. intracellularis* are *H. hauckii* and *H. membranaceus*. A third symbioses, occurs between *Richelia* and *H. sinensis*. In *Hemiaulus* host diatoms, it is not known where the symbiotic *Richelia* reside, whereas in *Rhizosolenia* spp. hosts, the *Richelia* remains as an extracellular endosymbiont residing between the plasmalemma and silica wall of the diatom host (Janson *et al.*, 1995; Taylor, 1982; Villareal, 1990). In *Hemiaulus* diatoms, typically there are two trichomes (series of cells comprised of a few vegetative cells and one terminal heterocyst) per host cell, and in *Rhizosolenia* species occasionally 1–32 *Richelia* trichomes have been observed (Sündström, 1984; Villareal, 1990).

Lemmerman (1905) was one of the first to depict the unique association of another heterocystous cyanobacterium, *Calothrix rhizosoleniae*, attached to the spines of a *Chaetocoeros compressus* diatom. Norris (1961) noted that the cyanobionts only attach transversely to the intercellular spaces of the diatom with the heterocyst closest to the host diatom. Others report the same symbiont as *R. intracellularis* (Gómez *et al.*, 2005; Janson *et al.*, 1999; Karsten, 1907; Norris, 1961), thus there is

conflicting taxonomy. For simplicity, here we report the symbiont attached to *Chaetocoeros* diatoms as a *Calothrix*. There have been a few other reports of a *Richelia* symbiont growing epiphytically on the spines of *Bacteriastrum* diatoms (Carpenter, 2002; Carpenter and Foster, 2002; Rai *et al.*, 2000; Villareal, 1992).

A few other symbioses have been described between a heterocystous cyanobacterium of similar morphology to *Anabaena* and *Nostoc* cells residing with *Coscinodiscus* sp. and *Roperia tessellata* diatoms, respectively (Taylor, 1982; Villareal, 1992). Interestingly, Carpenter (2002; Plate IIb) found the cyanobionts of a *Coscinodiscus* sp. diatom collected near Zanzibar similar in cell morphology and diameter to a unicellular *Synechocystis* sp.

Recently, Carpenter and Janson (2000) also reported that the open-ocean chain forming diatom, *Climacodium frauenfeldianum,* typically contains numerous coccoid cyanobacteria (Fig. 27.1). A similar sized cyanobiont has been described in the freshwater diatom, *Rhopalodia gibba* (Prechtl *et al.*, 2004). The *R. gibba* diatoms are unique since the cyanobionts reside intracellularly and the diatoms have the capacity to fix nitrogen (Floener and Bothe, 1980). It is likely that the cyanobiont partners are fixing the nitrogen since all eukaryotes lack the nitrogenase enzyme (enzyme required for N_2 fixation).

2.2. Cultivation, transmission, and cell divisions

Few have attempted to isolate and cultivate these consortia, and to the best of our knowledge only T. Villareal (1989) was successful for several months in culturing a *Rhizosolenia-Richelia* symbiosis. The division cycles of the host *Rhizosolenia* and *Richelia* were asynchronous in culture, and as such several asymbiotic hosts were observed (Villareal, 1989). Transmission from host to daughter cell is typically vertical, however asymbiotic hosts and free-living *Richelia* observed in the field and culture suggest horizontal transmission as well.

Taylor (1982) described the details of the vertical transmission in the *Rhizosolenia-Richelia* symbioses when he observed several *Richelia* cells migrating to opposite valves of host cells prior to host division. Villareal (1989) estimated the trichome migration at approximately 5 μm s^{-1} and to be independent of host cytoplasmic streaming. The details of symbiont transfer in *Hemiaulus* and *Chaetoceros* have not been clearly described. Gómez *et al.* (2005) observed free trichomes of *Richelia* (note Gómez *et al.* (2005) identify symbionts of *Chaetoceros* as *Richelia*) and suggested that the free filaments, which originate from *Rhizosolenia* (*clevei*) diatoms, colonize senescent *Chaetoceros compressus* diatoms and subsequently spread out after replication. This speculation is not supported by evidence presented by Janson *et al.* (1999) and Foster and Zehr (2006), which showed high sequence divergence between the various symbionts of the different host diatoms, and thus a high degree of host specificity, or in other words, each *Richelia/Calothrix* strain is specific to one host genus (section 2.3).

In Fall 2004, several chains of *Chaetoceros compressus* chains were hand-picked from the subtropical Pacific (station ALOHA) that had several symbiotic *Calothrix* cells attached to the host diatoms spines (Foster and Zehr unpubl.). We were

successful in culturing the symbiont, and the isolate, *Calothrix* SC01, has been maintained free living (without the diatoms) in nitrogen-deplete media. This isolate has been subject to a few experiments, including a phylogenetic study of the precursor gene for the nitrogenase (*nifH*) enzyme (Foster and Zehr, 2006) and several acetylene reduction (AR) assays (proxy for N_2 fixation).

2.3. Specificity and symbiont phylogenetic diversity

In contrast to the co-occurring and free-living cyanobacteria that reside in the open ocean, there are far fewer studies on the phylogentic diversity of the symbiotic *Richelia/Calothrix* and the other open ocean consortias. Difficulties in collection, isolation, and separation from the other phytoplankton populations, have been the primary obstacles. However recent studies (Foster and Zehr, 2006; Foster *et al.*, 2006; Janson *et al.*, 1999) using single-cell approaches were successful with molecular genetic analyses and allowed sequence data to be matched back to particular populations. Subsequently, the sequence data has been directly applicable to other assays (i.e., Quantitative PCR), which estimate cell densities for target phylotype (*Richelia* associated with *Rhizosolenia*) using gene copy abundances (see below, section 2.5).

Janson *et al.* (1999) were first to report on the high host specificity of *Richelia* symbionts associated with four of the DDAs. In their study, the *hetR* gene, a gene that functions in heterocyst and akinete differentiation (Buikema and Haselkorn, 1991; Leganés *et al.*, 1994), was amplified from individual host samples containing several filaments of *Richelia* associated with *Rhizosolenia clevei*, *H. hauckii*, *H. membranaceus*, and *Chaetoceros* sp. The symbiotic specimens were collected from two cruises, one in the Caribbean Sea and one in the South Pacific Ocean. Janson *et al.* (1999) inferred a high degree of host-symbiont specificity since the symbiont sequences from the different host genera were highly divergent (sequence similarity <85%). In addition, the *hetR* nucleotide sequences derived from *Richelia* symbionts associated with *H. membranaceus* sampled in the Atlantic and Pacific Oceans were nearly identical (98.9% identical), suggesting genetic relatedness was not dependent on geographical location (Janson *et al.*, 1999).

A second phylogenetic investigation of the same DDAs by Foster and Zehr (2006) corroborated the results of Janson *et al.* (1999) for the *hetR* gene and analyzed the phylogenetic diversity of two additional genes, *nifH* and 16S rRNA. NifH is a functional gene marker, and encodes the iron subunit of dinitrogenase reductase, the enzyme responsible for N_2 fixation. In this later study, sequence identity was highest (98.2%) amongst the16S rRNA sequences, and more divergent for the *hetR* (83.8%) and *nifH* (91.1%) sequences. This study also identified three previously unidentified heterocystous-like *nifH* sequence groups, which were recently reported from station ALOHA, het-1, het-2, and het-3 (Church *et al.*, 2005; Zehr *et al.*, 2007), as the *Richelia* associated with *Rhizosolenia clevei*, *H. hauckii*, and *Calothrix* symbiont of *Chaetoceros* sp., respectively.

In addition, Foster and Zehr (2006) found a parallel divergence in the *nifH* sequences as Janson *et al.* (1999) reported for *hetR* sequences. In the study by Janson *et al.* (1999), they found that the *hetR* sequence associated with a *Richelia-H.*

hauckii was different than the *hetR* sequence of a *Richelia* associated with a *H. membranaceus*. Thus, the specificity was on a host species level. A similar pattern resulted in the *nifH* phylogenetic data presented by Foster and Zehr (2006), which suggested the further delineation of the het-2 group into het-2A and het–2B, to represent *Richelia* associated with *H. hauckii* and *H. membranaceus*, respectively. The same host species level of specificity may occur within the *Rhizosolenia* sp. hosts, however it has not been investigated.

There have been a few phylogenetic studies of other planktonic symbioses other than the *Richelia*-Diatom symbioses. These however use a 16S rRNA phylogeny and rely on the high similarity between the resultant sequences to known nitrogen fixers as potential evidence for diazotrophy rather than looking for a nitrogen-fixing gene (i.e., *nifH*) directly. A few of these studies are briefly reviewed here.

Carpenter and Janson (2000) reported the 16S rRNA phylogeny of the cyano-bacterial symbionts that reside within the diatom, *Climacodium frauendulum*. They found a high sequence identity (>98%) between the cyanobiont 16S rRNA sequences and a 16S rRNA sequence derived from the unicellular diazotroph, *Cyanothece* sp. ATCC 51142. A similar 16S rRNA sequence was retrieved from the freshwater diatom, *Rhopalodia gibba* (Prechtl *et al.*, 2004). NifD gene sequences were also amplified from *R. gibba,* which were closely related to *Cyanothece* ATCC 51142 *nifD* sequences. In another 16S rRNA study by Foster *et al.* (2006) several sequences similar to16S rRNA sequences of *Cyanothece* sp. 51142 were recovered from a single *Histiones* (Dinoflagellate) sp. host containing symbiotic cells similar in morphology and cell diameter to *Cyanothece*. In the open ocean, *Crocosphaera watsonii*, which is similar in cell diameter size (3–5 μm) and physiology (i.e., temporal segregation of N_2 fixation) to *Cyanothece* ATCC 51142, is a common cell type, and is likely the cyanobiont for many of the above-mentioned symbioses between a marine eukaryote and a coccoid cyanobacterium (Foster, pers. obs.).

2.4. Host–symbiont interactions

In symbiotic systems, like these where the association appears quite intimate or the symbiont population occupies a majority of the host cell volume, the relationship is assumed necessary (Douglas, 1998) and/or beneficial. The benefit of the DDA relationship is not fully understood nor characterized, and because N_2 fixation has been measured when the DDAs are present, it is presumed that some of the nitrogen fixed by the symbiont is transferred to the host diatom. To date, there are only a few studies that have attempted to understand the nature of the symbiosis between the *Richelia* symbiont and the host diatom.

In a micro–autography study, field collected *Rhizosolenia-Richelia* symbioses were incubated with ^{14}C-labelled bi-carbonate. Higher density of silver grains localized on the symbiotic *Richelia* trichomes than on the host *Rhizosolenia* fila-ments, suggesting that the *Richelia* were actively photosynthesizing and the host diatom were inactive (Weare *et al.*, 1974). An equally plausible explanation for less silver grains on the *Rhizosolenia* host is that some of the fixed and labeled photosynthetic products were transferred to the host from the symbiont. Similar scenarios of carbon, and nitrogen transfer, are well documented in terrestrial

symbioses with heterocystous symbionts, i.e., *Azolla-Anabaena*, Lichen–*Nostoc* symbioses (Rai *et al.*, 2000). Weare *et al.* (1974) also speculated that the metabolically active host diatoms act as a source of inorganic nutrients, i.e., phosphate, for their symbionts.

In culture, Villareal (1990) measured growth and nitrogenase activity (acetylene reduction) in the *Rhizosolenia-Richelia* symbioses, and demonstrated light saturation kinetics in both activities. In addition, he demonstrated preliminary evidence for excretion of fixed nitrogen to the surrounding medium (details described in Villareal, 1990), and suggested the extracellular location of the symbiont (between the frustule and the plasmalemma) is mechanistic for nutrient transfer to the medium. Further elucidation of host-symbiont interactions, transfer, and benefit/cost of the relationship is a challenging, yet warranted subject for future investigation.

Janson *et al.* (1995) also verified the previous work of others (Taylor, 1982; Villareal, 1990) that the *Richelia* cyanobionts were always located outside of the host (*Rhizosolenia*) cytoplasm. Using immuno-cytochemistry coupled with transmission electron microscopy (TEM), Janson *et al.* (1995) demonstrated the localization of anti-bodies to nitrogenase and Ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO), in the heterocyst and vegetative cells, respectively, of the *Richelia* symbionts of *Rhizosolenia clevei*. They suggested that ammonia assimilation was potentially repressed in the *Richelia* cells, since they found low localization of antisera to the ammonia assimilation enzyme, glutamine synthetase (GS). It should be noted that immunogold assays do not indicate enzyme activity rather only show presence of the enzymes when the cells were fixed. Thus the results from Janson *et al.* (1999) only suggests *Richelia* symbionts have the potential to function as nitrogen and/or carbon sources for their respective hosts.

Although the *Calothrix* cyanobionts of *Chaetoceros* are attached to the diatom spines, the cyanobionts are only located at the intercellular spaces and attached transversely at the heterocyst (Norris, 1961), which could be seen as a morphological adaptation for nitrogen transfer. Others (e.g., Villareal, 1990) have suggested that the extracellular location of the *Richelia* symbionts with *Rhizosolenia clevei* is mechanistic for nitrogen transfer.

After several months in isolation without the *Chaetoceros* host, our cultured isolate, *Calothrix* SC01, started to change its cell character. For example, the trichome length extended, intercalary heterocysts were observed, and several trichomes appeared to branch. We interpreted such changes in the symbiont trichome and cell integrity as due to loss of control by the diatom host over the symbiont since the symbiont is in a free-living state. These latter observations also suggest that the free-living trichome potentially looks different than that which is observed when it lives symbiotically, and thus could be easily misidentified/overlooked in the field.

Others (Foster *et al.*, 2007; Kimor *et al.*, 1978; Villareal, 1989) have reported that vegetative cells degrade first, and often the heterocysts are the last part of the *Richelia* trichome to remain in a host diatom, which could also suggest host control or some sort of cell signaling between host and symbiont. Gómez *et al.* (2005) observed *Calothrix* symbionts associated with *Chaetoceros* diatoms which lacked chloroplasts suggesting that the host diatoms were senescent; quite possibly though the symbiotic

Calothrix act as a source of fixed carbon to their hosts. Transfer of fixed nitrogen and/or carbon remains undocumented in all the DDAs; it has only been inferred from growth of the *Rhizosolenia-Richelia* symbioses in N-free media in culture (Villareal, 1989).

2.5. Geographical distribution and cell abundances

Generally speaking, *R. intracellularis* associated with *Hemiaulus* spp. have higher abundances in the Atlantic Ocean (Carpenter *et al.*, 1999; Foster *et al.*, 2007; Villareal, 1991, 1994), and *R. intracellularis* associated with *Rhizosolenia* sp. are more commonly reported from the North Pacific central gyre (Ferrario *et al.*, 1995; Mague *et al.*, 1974; Venrick, 1974; Wilson *et al.*, 2008). Villareal (1994) reported the occurrence of *Hemiaulus-Richelia* symbiosis was 5–254 times more abundant in the North Atlantic, Caribbean Sea, and Bahama Islands than the *Rhizosolenia-Richelia* symbiosis. There are no observations of the *Chaetoceros-Calothrix* symbioses in the subtropical and tropical Atlantic Ocean, and some have suggested its geographical limitation to the Pacific and Indian Ocean basins, however, we cannot discount that few have actually looked. Others have reported the DDAs distribution in the Indian Ocean (Norris, 1961), the Red Sea (Kimor *et al.*, 1992), and more recently in the Eastern Mediterranean Sea (Bar–Zeev *et al.*, 2008), and the western China Seas (Gómez *et al.*, 2005), which make *Richelia* and *Calothrix* the most widespread marine heterocystous cyanobacteria described.

There are a few exceptions where the DDAs are capable of penetrating coastal waters. For instance, Kimor *et al.* (1978) reported an ''unusual occurrence of *Richelia* associated with *Hemiaulus membranaceus*'' off the coast of California and one report of *Richelia* associated with *H. hauckii* and *H. membranaceus* in waters off Hawaii (Heinbokel, 1986). Recently, White *et al.* (2007) observed high abundances (100 L^{-1}) of the *Rhizosolenia-Richelia* symbioses in the Gulf of California. *Hemiaulus-Richelia* also occurs at Carrie Bow Cay, Belize (Villareal, 1994), and off the coast of Texas (Villareal pers. comm.).

Most heterocystous cyanobacteria dominate brackish and freshwater environments where they occur in the plankton and the benthos as free–living cells and are seldom found in the open ocean. Few report *Richelia* and *Calothrix* as free-living (Gómez *et al.*, 2005; White *et al.*, 2007), thus both are the exception and have made their successful transition to the open ocean as symbionts.

Some of the highest numbers for the *Hemiaulus-Richelia* symbioses were reported in the western tropical North Atlantic (WTNA). Carpenter *et al.* (1999) observed an extensive bloom off the NE coast of South America in autumn of 1996. They reported cell densities from 10^2 to 10^6 *Richelia* L^{-1}. Recently, in the same vicinity as the study of Carpenter *et al.* (1999), Foster *et al.* (2007) reported extremely high *nifH* gene copy (>10^5 copies L^{-1}) abundances (proxy for cell abundances) for *Richelia* associated *H. hauckii* and *Rhizosolenia clevei*. In addition, they found within the plume waters of the Amazon River runoff a positive correlation between salinity and the abundance of the *H. hauckii-Richelia* abundance (Foster *et al.*, 2007).

Church *et al.* (2005) were first to report the *nifH* gene expression for the het–1 and het–2 groups, which were later identified as *Rhizosolenia-Richelia* and *Hemiaulus-Richelia* symbioses (Foster and Zehr, 2006) from Station ALOHA in the N. Pacific Ocean. They found *nifH* expression for the het-1 group (*Rhizosolenia-Richelia* symbiosis) increased dramatically (10^2 to 10^6 *nifH* cDNA copies L^{-1}) in the early morning (04:00–06:00) and gradually declined throughout the late morning and evening. In addition, they detected *nifH* expression for the het-1 group (*Rhizosolenia-Richelia* symbiosis) down to 200 m at midday and midnight, indicating a very active DDA population throughout the water column during day and night periods.

The abundance reported by Venrick (1974) and Mague *et al.* (1974, 1977) in the North Pacific central gyre were limited to estimates of the *Rhizoslenia-Richelia* symbioses. An interesting oversight reported in these studies was that the diatom *H. hauckii* was also present. In fact, abundance of *H. hauckii* during the Fall 1969 were 250 cells ml^{-1} (Venrick, 1974) and Mague *et al.* (1974) recorded 4000 cells L^{-1}. These abundances for *H. hauckii* were not reported as symbiotic; the *Richelia* in a *H. hauckii* is extremely inconspicuous with light microscopy (Fig. 1), and it is likely that it was overlooked. Venrick (1974) noted that in winter months (Nov.-Feb.) the *Rhizosolenia-Richelia* densities were low, ~60 cells L^{-1}, and reached 10^3–10^4 cells L^{-1} during summer (June-Sept.). Mague *et al.* (1974) observed a subsurface maximum in the abundance *Rhizosolenia-Richelia* symbioses (60–80 cells L^{-1}) at 40 m in the N. Pacific gyre. It was also the depth of maximum acetylene reduction (see below, section 2.6).

2.6. Nitrogen fixation

Although there have been observations of large and expansive blooms of DDAs (Villareal, 1994; Carpenter *et al.*, 1999), there have been relatively few reports of the N_2 fixation or contribution of the DDAs to the global marine nitrogen budget. This is largely due to the difficulty in collection of the symbioses without compromising the integrity of the symbiotic complex and thus the physiological measures. A limited number of field studies (Carpenter *et al.*, 1999; Mague *et al.*, 1974; 1977; Venrick, 1974; Villareal, 1991; White *et al.*, 2007; Bar–Zeev *et al.*, 2008), and fewer culture experiments (Villareal, 1989; 1990) represent the only physiological measures of N_2 fixation by the DDAs.

Venrick (1974) measured primary production rather than N_2 fixation, and recorded the highest carbon fixation rates (154.4 mg C m^{-2}) during a summer bloom (average abundance 1.5×10^7 filaments m^{-2}) of *Rhizosolenia-Richelia* in the North Pacific central gyre. The carbon fixation rate represents the carbon fixed by both host diatom (*Rhizosolenia*) and symbiont (*Richelia*) since both are photosynthetic. She then used the average cell specific N_2 fixation rates reported earlier by Mague *et al.* (1974) to estimate the range (6.2–12.5 mg N m^{-2}) in daily N_2 fixation rate by *Rhizosolenia-Richelia*. Venrick (1974) extrapolated that 30–60% of excess productivity in the North Pacific central gyre was accounted for by the presence of a *Rhizosolenia-Richelia* bloom. Recently, a similar hypothetical estimate of N_2 fixation was provided by Foster *et al.* (2007), where they found that a dense

population of *H. hauckii* with symbiotic *Richelia* accounted for 89–100% of the N_2 fixation (8.1×10^5–7.5×10^6 fmol N L^{-1} day^{-1}) in the WTNA. Villareal (1991) did a similar calculation and noted that only 100 cells L^{-1} of the *Hemiaulus–Richelia* symbioses could provide 15% of the entire N_2 fixation. Although these calculations are a crude means of estimating the rate of N_2 fixation and have obvious bias, they do highlight the potential significant influence of DDAs on the nutrient and energy budgets of phytoplankton in the oligotrophic environments.

Mague *et al.* (1974) reported low (0.02–0.64 µg N mg N^{-1} h^{-1}), but comparable rates of N_2 fixation by *Rhizosolenia-Richelia* to free-living *Trichodesmium*. During the DDA bloom observed by Carpenter *et al.* (1999) in the WTNA, the *Hemiaulus-Richelia* added an average of 45 mg N m^{-2} day^{-1} to the water column, which far exceeded estimates of new nitrogen flux from below the euphotic. Most recently, White *et al.* (2007) estimated that N_2 fixation by *Richelia* associated with *Rhizosolenia*, and to a lesser extent by *Trichodesmium*, supplied 35–48% of the phytoplankton-based nitrogen demand in the central and eastern basins of the Gulf of California. Rates of N_2 fixation were recently estimated by the acetylene reduction technique on bulk water in the Eastern Mediterranean Sea. The highest rates of N_2 fixation (0.4–3.1 nmol N L^{-1} d^{-1}) were recorded in the summer and ∼40–70% of the total N_2 fixation was attributed to populations of symbiotic *R. intracellularis* (Bar-Zeev *et al.*, 2008). Besides the laboratory data of Villareal (1990; 1992), the above-mentioned studies represent the few field data for N_2 fixation by the DDAs and each demonstrate the obvious ecological importance of these diazotrophic populations.

The earlier works by Mague *et al.* (1974; 1977), Venrick (1974), and Kimor (1978) attempted to define some of the environmental factors and conditions that control the N_2 fixation activity and distribution of DDA populations. Some have argued that distribution and activity is largely controlled by latitude, temperature, nutrients (i.e., iron, phosphorous), and wind stress for the other co-occurring cyanobacteria.

Kimor *et al.* (1978) observed that the unusual occurrence of the symbiotic *H. membranceus* off the coast of southern California occurred during an unusually warm period (18.5°C) for that geographical region and season. Later, in Carrie Bow Cay, Belize, Villareal (1994) reported 98% of *Hemiaulus* sp. examined contained *Richelia*, and that symbiotic *Hemiaulus* were present as far north as 31°N in the Pacific, further evidence that the geographical range of these symbioses is capable of penetrating cooler and more subtropical boundaries.

In her 9-year field study in the North Pacific central gyre, Venrick (1974) reported that for most of the years *Richelia* associated with *Rhizosolenia* were relatively low (0.1–1 *Richelia* cell ml^{-1}) in abundance, however, in summer months when the upper water column stratified and nutrients were measurably low, symbiotic populations increased 1–2 orders of magnitude. Environmental parameters, i.e., nutrient concentrations, during bloom and non-bloom summers in the upper 45 m were indistinguishable, suggesting little evidence for a condition to initiate and perpetuate the blooms. Venrick (1974) proposed that the blooms were a localized phenomena occurring independently at various locations within the central Pacific

Ocean basin. Similarly higher rates of N_2 fixation in the eastern Mediterranean Sea were recorded during peak stratification (Bar-Zeev *et al.* 2008), thus it seems water column dynamics play an important role in bloom formation and sustenance.

Gómez *et al.* (2005) observed the *Chaetoceros-Richelia* (note these authors use an alternative nomenclature) symbioses was restricted to the transition zones between the slope waters and the Kuroshio Current in the western Pacific Ocean. They proposed that their distribution was related to local mixing of the Kuroshio Current with the coastal waters, where *Chaetoceros* is a dominant member of the neritic phytoplankton population.

Mague *et al.* (1974) found that highest biological fixation occurred in the summer months in the North Pacific central gyre when resident populations of the *Rhizosolenia-Richelia* symbioses began to increase. The surface waters were stratified and concentrations of phosphate and nitrate were undetectable. Enrichments of 0.5 to 5 µM orthophosphate to samples containing *Rhizosolenia-Richelia* concentrates increased acetylene reduction, but when concentrations >5 µM were added, activity decreased, and at 50 µM amendments the rate was equivalent to the initial. These results suggested that to some extent the symbioses were P limited. To date, there have been no other nutrient manipulation experiments. Since the nitrogenase enzyme complex has a high iron requirement, an interesting and open question would be the effect of increased iron on N_2 fixation rates.

Typically, diatoms thrive in colder waters with high nitrate concentrations. Thus it seems that the DDAs have gained a successful existence into the warm oligotrophic waters of tropical and subtropical seas by their symbiotic partners. There have been few observations or investigations for the presence of the DDAs in higher nutrient environments, i.e., rivers, estuaries, or in regions of intense upwelling. Abundance for two of the three DDA groups (het-1 & het-2) was recently reported in the Amazon River plume in the WTNA (Foster *et al.*, 2007), where elevated nutrients were measured. Cell abundances (5–120 cells L^{-1}) for symbiotic *Hemiaulus* and *Rhizosolenia* populations were recorded within lower salinity waters of the Orinoco River (Corredor, pers. comm). The same DDAs were detected near the Congo River plume in the eastern equatorial Atlantic (EEA) (Foster, unpubl.). Combined, these observations suggest that in the Atlantic Ocean, riverine inputs play an important role in the distribution of the DDAs. Hypothesized, but not yet investigated, is that rivers are the source of free-living *Richelia* populations, since most heterocystous cyanobacteria dominate in brackish and estuarine waters.

These earlier and more recent field measures all demonstrate the importance of these DDAs on the local conditions, however, in most experiments the collection of samples used towed nets, and thus are rather disruptive. Two experiments by Mague *et al.* (1974, 1977) found that preparing samples by concentration caused a significant (17–29%) reduction in acetylene reduction activity. It seems that more attention or creative sampling schemes need to be developed to accurately measure the N_2 (and likely carbon) fixation by these DDAs. Studies similar to those presented by Zehr *et al.* (2007) and Needoba *et al.* (2007), which combine $^{15}N_2$ uptake rates with quantitative PCR approaches for the target diazotrophs are a plausible alternative since assays are run on bulk water.

2.7. Implications

A recent model presented by Deutsch *et al.* (2007) estimates global N_2 fixation by applying an oceanic circulation model to the relative changes of nitrate and phosphate concentrations in the surface ocean. Their model predicts N_2 fixation in all the regions of the world's oceans where these DDAs occur and have been reported. A major shortcoming noted in the model was, "diazotrophs with both a high biomass N:P and an unusually high export efficiency, should they be found, would be underestimated by our approach." The DDAs have extremely high vertical fluxes (Schaerek *et al.*, 1999a,b), and represent an excellent example of a population that would be likely overlooked in this type of model.

DDAs are among the most unique phytoplankton populations because they have a dual function. Large and expansive blooms contribute directly to the vertical flux of organic matter to the deep sea (Schaerek *et al.*, 1999a,b), all the while being widespread and sometimes patchy in distribution in the euphotic zone where they provide fixed N to the co-occurring non-diazotrophic phytoplankton population. Although controversial and limited in direct scientific evidence, we assume that a majority of the carbon and presumably fixed nitrogen associated with the DDAs does in fact fall out below the euphotic into the mesopelagic. Thus the DDAs represent an important link in the biogeochemical cycling of both carbon and nitrogen in the world's oceans, and yet when compared to other larger diazotrophs, e.g., *Trichodesmium*, DDAs are often under-represented in nutrient budgets and far under-sampled.

3. Sponge–Nitrifier Associations

3.1. Sponge–microbe specificity and phylogenetic diversity

Sponges act as filter feeders capable of circulating thousands of liters of seawater through their osculum per day while feeding on organic particles and microorganisms from the water column (Pile, 1997; Vogel, 1977). Some sponges, primarily those in the class *Demospongia* (Vacelot and Donadey, 1977), are populated by microbial symbionts, mostly extracellular, that are able to avoid phagocytosis and digestion while residing in the sponge mesohyl matrix. The microbial density within the host biomass can far exceed that of seawater, reaching concentrations up to 10^{10} bacteria per gram of sponge wet weight (Hentschel *et al.*, 2006). For organisms that can avoid digestion, the host provides a favorable microbial habitat due to increased nutrient availability from the active pumping of seawater and release of ammonia, urea, and organic carbon as by-products (e.g., Davey *et al.*, 2002).

Microscopy and molecular genetic techniques have demonstrated that a single sponge often contains a very diverse microbial assemblage including bacteria (Hentschel *et al.*, 2002), archaea (Margot *et al.*, 2002; Preston *et al.*, 1996) and algae (Usher *et al.*, 2004; Wilkinson and Fay, 1979). These 16S ribosomal RNA surveys have detected microorganisms similar to known heterotrophs,

photoautotrophs, and chemolithoautotrophs. The nitrogen transformations attributed to these groups include N_2 fixation (e.g., Wilkinson and Fay, 1979), ammonia oxidation (e.g., Hallam *et al.*, 2006a,b), nitrite oxidation (e.g., Hentschel *et al.*, 2002), and nitrogen assimilation (e.g., Davy *et al.*, 2002). The phylogenetic diversity and species richness of the symbiont population found within a single host (Hentschel *et al.*, 2002; Hill *et al.*, 2006; Taylor *et al.*, 2004; Webster *et al.*, 2001) are unlike most known marine invertebrate-microbe symbioses which have comparatively low symbiont diversity (Steinert *et al.*, 2000). Nonetheless, the diversity of the sponge-microbe associations are often referred to as host specific. The bacterial symbionts appear to be distinct from the free-living bacterial populations in seawater and seemingly uniform bacterial populations have been detected in many geographically distant sponge species (Hentschel *et al.*, 2002; Hill *et al.*, 2006).

The diversity maintained in the sponge association may be partially attributed to the occurrence of asexual reproduction in sponges, allowing the establishment of a close association without requiring immediate incorporation of microbial cells into the germ line. Usher *et al.* (2005) reported that germ line incorporation does occur in at least some species and that cyanobacteria could be detected in both the egg and the sperm of *Chondrilla australiensis*. Sharp *et al.* (2007) further demonstrated that phylogenetically diverse, yet sponge specific, microbial lineages including bacteria and archaea could be found in *Corticium sp.* embryos. The stability of these complex associations over evolutionary time scales has only begun to be explored.

In summary, sponges form symbiotic associations with phylogenetically and metabolically diverse microbes. Although there is very limited evidence to document the direct benefits of the symbiosis, the microbes are thought to receive increased nitrogen for growth and the host to benefit from the removal of potentially toxic metabolites, i.e., ammonia and urea (Davey *et al.*, 2002). The metabolic versatility of these abundant and diverse microbial assemblages in combination with the increased flow rate provided by the filter feeding host creates a bioreactor that can have a large impact on the carbon and nitrogen cycles of a marine habitat.

3.2. Nitrification in sponges

The process of nitrification in marine sponges was first described by Corredor *et al.* (1988) by measuring the concentration of nitrate released by the coral reef sponges *Chondrilla nucula* and *Anthosigmella varians*. Multiple investigators have re-confirmed the release of nitrate from symbiont containing sponges (Diaz and Ward, 1997; Pile, 1996; Scheffers *et al.*, 2004) although the direct linkage of nitrate release to chemolithoautotrophy has not been established. It is assumed that ammonia released as a by-product of host metabolism is oxidized by microorganisms living within the sponge mesohyl matrix. Corredor *et al.* (1988) observed that the rate of nitrification was not equivalent for all host species and that it varied with symbiont composition. For example, *C. nucula*, a cyanobacteria containing sponge, released nitrate 200 times faster than *A. varians*, a zooxanthellae containing sponge. This difference in nitrate release may be driven by uncharacterized differences in the non-

cyanobacterial symbionts but the difference was generally attributed to bacterial symbioses. Similarly, Diaz and Ward (1997) found higher nitrification rates for sponges associated with cyanobionts, than non-cyanobacterial containing sponges. They found that in *Oligoceras violacea,* nitrite was primarily released, while in the other two spongs species (*Chondrilla nucula* and *Pseudaxinella zeai*) high concentrations of nitrate were released. This difference was attributed to an uncoupling of ammonia oxidation and nitrite oxidation in *O. violacea* but the composition of nitrifier symbionts was not examined. The potential nitrification rates for the sponge symbiont assemblages (up to 2650 nmol g^{-1} h^{-1}) were the greatest weight specific rates that have been reported and areal corrected rates were as much as four orders of magnitude greater than rates reported in coastal sediments (Diaz and Ward, 1997). In Curacao coral reefs, NOx efflux rates from cavities containing sponges were measured as 1.02–9.77 mmol m^{-2} day^{-1} (Scheffers *et al.*, 2004); and 1.9 m^{-2} day^{-1} (van Duyl *et al.*, 2006). These findings suggest that sponge-nitrifier assemblages can be responsible for a large input of oxidized nitrogen to habitats where these associations abound. Marine sponges are unlikely to play a large role in the global nitrogen cycle but in local habitats such as tropical coral reefs, where sponges are both abundant and diverse (Diaz and Rutzler, 2001), their activities could potentially play an important role in controlling the budget of ammonia and NOx (Diaz and Ward, 1997; Scheffers *et al.*, 2004; van Duyl *et al.*, 2006). Thus, the reported decline of sponge biomass (Wulff, 2006) could alter nitrogen cycling in these oligotrophic habitats.

3.3. Genomic studies of nitrifying symbioses

Although molecular analyses have revealed diverse populations of bacteria in sponges (Hentschel *et al.*, 2002; Hill *et al.*, 2006; Taylor *et al.*, 2004; Webster *et al.*, 2001), a single archaeal group was found to dominate the marine sponge *Axinella mexicana* (Preston *et al.*, 1996). This symbiont, *Cenarchaeum symbiosum*, is extremely abundant and can account for up to 65% of the total microbial biomass found within the host. When this association was first identified, the metabolic activity of *C. symbiosum* remained a mystery. Molecular phylogenetics identified *C. symbiosium* as a member of the planktonic, marine nonthermophilic *Crenarchaeota*. This group of *Archaea* is widely distributed in the marine environment (DeLong *et al.* 1992; Fuhrman *et al.*, 1992), is estimated to account for up to 20% of the oceans total picoplankton (Karner *et al.*, 2001) and isotopic analyses suggest that it is capable of autotrophic growth (Pearson *et al.*, 2001; Ingalls *et al.*, 2006).

Metagenomic analyses conducted in the Sargasso Sea identified a gene sequence similar to bacterial ammonia monooxygenase (*amoA*) on a genome scaffold that also contained an crenarchaeotal ribosomal gene. This finding initially implicated the oxidation of ammonia as a chemolithoautotrophic metabolism associated with *Archaea* (Venter *et al.*, 2004). This finding was rapidly followed by cultivation and characterization of *Nitrosopulmilus maritimus* (Konneke *et al.*, 2005), unequivocally demonstrating the oxidation of ammonia to nitrate as an archaeal process and linking this transformation to some members of this abundant marine group. Ammonia oxidation by *Crenarchaeota* is now thought to be ecologically important and widely

distributed in marine, freshwater, and terrestrial environments (Cavicchioli *et al.*, 2007; Francis *et al.*, 2005; Schleper *et al.*, 2005; Treusch *et al.*, 2005; Wuchter *et al.*, 2006), a process previously attributed only to bacteria.

Although *C. symbiosum* remains uncultivated, its abundance within *Axinella mexicana* allowed the use of genomic approaches to characterize its metabolic potential (Schleper *et al.*, 1998; Hallam *et al.*, 2006a,b). These analyses revealed two abundant *C. symposium* symbiont populations co-inhabiting the host. The gene content, order, and orientation for these sympatric populations suggests very little recombination in the evolution of these strains. Localized regions of sequence variation reveal a limited number of genes under strong selective pressure worthy of additional investigation and a subset of candidate genes likely involved in the symbiosis. The genome was ''remarkably distinct from those of other known *Archaea*'' and contained a large number of genes most similar to marine environmental sequences thought to be from free-living planktonic *Crenarchaeota* (Hallam *et al.*, 2006b). Future comparisons between the genomes of free-living *Crenarchaeota* and *C. symbiosum* will lead to an increased understanding of the symbiosis.

More importantly, the genomic analyses enabled by the enrichment of *C. symbiosum* in the tissue of *Axinella* provide an opportunity to learn about the closely related, planktonic *Crenarchaeota.* This group is now predicted to be the dominant marine nitrifiers, but eluded cultivation and characterization for many years. *Axinella*'s two symbiont genomes contain many of the genes required for autotrophy and appear to assimilate carbon using a modified 3-hydroxypropionate cycle. There is evidence of a partial oxidative tricarboxylic acid cycle for mixotrophic growth (Hallam *et al.*, 2006a). Most of the genes encoding proteins involved in chemolithotrophic ammonia oxidation have been identified (including ammonia monooxygenase, ammonia permease, and urease) but a homologue for hydroxylamine oxidoreductase, which encodes a key enzyme involved in energy production from ammonia oxidation, has not yet been identified (Hallam *et al.*, 2006b). This either suggests that the symbiont may utilize novel enzymatic reactions for the oxidation of ammonia or it requires re-evaluation of its role as a nitrifier. In either case, the elucidation of this pathway in *C. symbiosum* requires additional investigation and may shed light on alternative mechanisms for ammonia oxidation in both free-living and symbiotic taxa.

3.4. Implications

Sponge-nitrifier associations appear to play a quantitatively significant role in the nitrogen budget of localized marine environments such as tropical coral reefs. The importance of these associations is not limited to their biogeochemical impact in the environment but also extends to their use as a model system for laboratory analyses. The symbiotic association of *A. mexicana* and *C. symbiosum* allows us an alternative method of studying the abundant, but cultivation-resistant, free-living *Crenarchaeota* picoplankton. Further exploration of the *C. symbiosum* genome may help to uncover a new pathway for ammonia oxidation and factors regulating the newly discovered and globally significant archaeal ammonia oxidizers.

4. OTHER RELEVANT SYMBIOSES

4.1. Diazotrophs in the copepod gut

An interesting and non-traditional example of symbioses, which has received relatively little attention are zooplankters with associated anaerobic diazotrophs (Braun *et al.*, 1999; Zehr *et al.*, 1998). Two independent studies revealed that planktonic copepods are associated with microorganisms, which possess *nifH* sequences phylogenetically related to strictly anaerobic sulfate reducers and clostridia (Cluster III *nifH* sequences) (Braun *et al.*, 1999; Zehr *et al.*, 1998). In the study by Braun *et al.* (1999), they also detected ethylene production during acetylene reduction assays on sorted copepods, indicating an active diazotrophic community. In the study by Zehr *et al.* (1998), zooplankton derived *nifH* sequences were not recovered or similar to any of the sequences derived from parallel bulk water samples, suggesting that the nitrogen-fixing species were likely gut-associated and not associated with the copepod's skeleton. Thus, the invertebrate gut may provide an unexpected refuge of suitable conditions for anaerobic N_2 fixation. And furthermore, considering that copepods are amongst the most abundant grazers in the world's oceans, the presence of N_2 fixing microflora associated with their guts is potentially another underrepresented source of nitrogen to the oceans (Zehr *et al.*, 1998).

4.2. Shipworm–bacterial associations

Nitrogen fixation has also been reported from marine shipworms. Shipworms are bivalves, which live attached to wooden ships, in which they bore holes, and thus have a diet of wood alone. Cellulose is the principal component of wood, and is indigestible to animals. Certain bacterial species, however, contain the necessary enzymes to break down cellulose, and shipworms are often reported with gut associated bacterial symbionts.

   In an early study by Carpenter and Culliney (1975), a bacterium was isolated from the gut of a Sargasso Sea shipworm, *Teredora malleolus*. Under anaerobic conditions and growth in a liquefying cellulose medium, significantly high rates of N_2 fixation rates (up to 1.5 micrograms of nitrogen per milligram dry weight per hour) were recorded. Similarly high rates were also measured in three other coastal shipworms. In a later study, a novel bacterium was also isolated from 6 species of teredinid bivalves (shipworms). Similar to the earlier study, the novel isolate was capable of digesting cellulose and fixing nitrogen (Waterbury *et al.*, 1983). Both studies showed that N_2 fixation associated with the shipworms was significant and suggested that similar symbioses might occur in other organisms that ingest terrestrial plant material (Carpenter and Culliney, 1975).

   Later Distal *et al.* (1991, 2002a, 2002b) identified shipworm symbionts by 16S rRNA ribotyping and cultivated one of the symbiotic bacterium, *Teredinibacter turnerae*, from the gill region (Gland of Deshayes) of a Teredinidae shipworm. More recently it was shown using a multi-isotope imaging mass spectrometry

approach that $^{15}N_2$ is taken up by the bacterial symbionts and some evidence was presented for the transference of fixed N to the host (Lechene *et al.* 2007). Thus, the shipworm–bacterial consortiums represent yet another understudied symbiotic association related to the nitrogen cycle.

4.3. Ascidian–*prochloron* symbioses

There are several didemnids (ascidians) that have been reported with symbiotic *Prochloron* cells. *Prochloron*, a genus of photosynthetic prokaryotes, are found in the marine environment as free-living and also associated with marine invertebrates. The primary role of the *Prochloron* symbionts has been identified as an organic carbon source to their respective ascidian hosts. There is however, some controversial evidence that the nitrogen is also transferred from symbiont to host (Paerl, 1984). Others have investigated nitrogen budgets in ascidian-*Prochloron* colonies and have suggested that the host ascidian and symbiotic *Prochloron* efficiently recycle the nitrogen within the colony (Koike *et al.*, 1993), and thereby act more similar to a nitrogen trap (see below, section 4.4.). In nutrient poor environments where the ascidian colonies thrive, an efficient means of recycling nitrogen is probably essential for their survival, and warrants future investigations.

4.4. The sponge–phototroph nitrogen trap

The coral-zooxanthellae association is a frequently cited example of a successful symbiotic relationship that forms the foundation for a diverse and ecologically important habitat within tropical, oligotrophic environments. This association is successful due to its ability to tightly recycle nitrogen and carbon. The coupling between an endosymbiotic phototroph and its filter feeding invertebrate host, acts as a nutrient and particle trap (Cook, 1983; Hinrichsen, 1997; Rahav *et al.*, 1989; Wild *et al.*, 2004). Sponges are abundant in many oligotrophic environments (Wilkinson, 1983). For example, in the coral reef environment, estimates for the percent areal coverage by sponges are as high as 24% of high light, hard substrates and 54% of low light, rubble substrates (Diaz and Rutzler, 2001). Just like corals, sponges are known to specifically associate with certain phototroph symbionts (Wilkinson and Fay, 1979; Usher *et al.*, 2004).

Recent stable isotopic evidence demonstrated that sponge dissolved inorganic nitrogen (DIN) can be used by symbiotic algae and is sufficient to remove nitrogen growth limitation for the phototrophs (Davy *et al.*, 2002). The system is therefore analogous to the coral-zooxanthellae. It had already been demonstrated that cyanobacteria could provide photosynthetically derived organics to the sponge and were capable of supplying the majority of the host's energy requirement (Cheshire *et al.*, 1997). Interestingly, Trautman *et al.* (2000) observed that sponge–phototroph symbioses are often abundant in areas where corals are scarce, suggesting some degree of competition between these associations in the tropical oligotrophic environment or different responses to environmental conditions such as particle loading. Coral reefs are currently experiencing a sharp global decline and frequent bleaching of the symbiotic phototrophs (Hinrichsen, 1997). It is therefore necessary to understand if

a similar global decline is also occurring for the sponge–phototroph nitrogen trap (Wulff, 2006). If it is, what will be the impact of this decline on metazoan biodiversity in the oligotrophic environment and how does this decline relate to coupling of host and symbiont? This association may take on an altered role rapidly changing reef environment and is an important system for further study.

5. FUTURE OUTLOOK AND PERSPECTIVES

One of the largest obstacles in determining the overall importance of symbiotic associations to the global cycling of nitrogen is the lack of consistent rate measurements. For example, ranges in DDA abundances and N_2 fixation rates from a variety of studies around the world have been reported, however few of the studies measuring DDA N_2 fixation utilized the same means for rate normalization, i.e., biomass, cells, volume. This makes it quite difficult to estimate an overall contribution of these populations to the tropical and subtropical oceanic nitrogen budgets.

It seems that more attention or creative sampling schemes need to be developed to accurately measure the nitrogen (and likely carbon) cycling in the context of these planktonic and invertebrate associations. Studies similar to those presented by Zehr *et al.* (2007) and Needoba *et al.* (2007), which combine ^{15}N isotope rate measurements with quantitative PCR approaches provide a promising path forward. While molecular and microscopic characterization of nitrogen symbioses has helped to elucidate the diversity and distribution of symbioses, future work should target a consistent approach to relate these to their biogeochemical importance.

ANALYTICAL METHODS FOR THE STUDY OF NITROGEN

Matthew D. McCarthy *and* Deborah A. Bronk

Contents

1. Introduction

The study of nitrogen (N) cycling requires sensitive and accurate methods to measure various N compounds. The objective of this chapter is to review existing methods to analyze dissolved and particulate fractions of N with an emphasis on those methodologies that are most commonly used or represent the state of the art, noting that N analysis does indeed seem to be an art at times. Many techniques are temperamental at best and it is not uncommon to find small fetishes devoted to keeping a given mass spectrometer running. This chapter was written to stand alone as a general review of methods; more detailed descriptions of specific methods can be found in other chapters in this book. We begin with a brief note on collecting and preserving samples. The first main section of the review then describes techniques to measure the concentrations of N pools, followed by various approaches to chemically characterize organic N fractions. The last major section reviews techniques to measure N fluxes, including uptake, release, nitrification, denitrification, and N_2 fixation. We conclude with recommendations for future research.

This chapter was written largely from the perspective of water column studies; most of the methods, however, could also be used more broadly to analyze sediments, particles, or pore water samples. The difference between a given method for these sample types is principally one of the detection limit required and matrix-specific analytical challenges. Analyzing water column samples can be difficult because concentrations can be very low. While concentrations are generally much higher in sediment pore waters, extracting the necessary volume of pore water can be challenging. With respect to rate measurements, most of the techniques outlined could be applied in both the water column and the sediment, and several largely sedimentary rate measurements are specifically discussed below. Tracer approaches in sediments can be especially problematic because the substrate is so heterogeneous that getting uniform mixing of the tracer can be impossible (e.g., Middleburg *et al.*, 1996); for a more detailed discussion of methods used in sediments see Chapter 19 by Joye and Anderson, this volume.

Before we begin, we provide a brief comment on units. In general, we recommend that concentrations of N compounds be presented as μmol N L^{-1} (i.e., μM, or some similar metric equivalent) and rates to be presented as μmol N L^{-1} time^{-1}. Historically the μg–at N unit has been used in the presentation of N uptake rates, particularly in culture work; 1 μmol of a compound is equal to 1 μg–at N for a

substrate like NH_4^+ but is equal to 2 µg-at N in the case of a dinitrogen substrate such as urea. Despite the opinion of some of our esteemed colleagues who view the unit as outdated (Luther, *personal communication*; Williams, 2004), we find the µg-at N unit to be useful to standardize substrate additions when measuring N flux rates using both inorganic and organic N that may have variable amounts of N per substrate.

2. Collection and Storage of Samples

Here we provide some very basic guidelines on collection and storage of samples. We stress, however, that each analyst should determine the optimal washing and sampling protocol for each of their own applications.

Nutrient samples are generally stored in plastic bottles such as HDPE or PETG. Prior to use, all plasticware should be washed with detergent (e.g., Liquinox®), rinsed with distilled water (DW) and soaked in an acid bath (most commonly 10% HCl) for a couple of hours, followed by a final rinse with copious amounts of high quality DW or equivalent. Glass bottles or vials are also often used and are the preferred choice for nutrients and organics, such as dissolved organic nitrogen (DON), and dissolved free and combined amino acids (DFAA, DCAA). Glassware has the advantage that it can be wrapped in foil and baked in a muffle oven (minimum of 450°C for 2 h) for unambiguous cleaning; glass also has the disadvantage, however, that it can break during shipping or freezing.

To filter or not to filter—that is the question! If one is measuring dissolved compounds, it is customary to filter the sample prior to analysis. In open ocean systems, however, filtration is often not done because the amount of particulate material is small, and the risk of contamination is large. In coastal or estuarine systems, however, filtration is a must. Filtration of nutrient samples is generally done through a glass fiber filter (i.e., GF/F®) with a nominal pore size of 0.7 µm, or a 0.2–0.45 µm polycarbonate filter (e.g., Supor® or Nuclepore®) (reviewed in Knelfelkamp *et al.*, 2007). Benefits of glass fiber filters are that they are inexpensive, have a high flow rate, and can be cleaned by baking (minimum of 450°C for 2 h). Polycarbonate filters should be used with care as they can introduce high blanks for some analyses. For example, Supor filters can produce high dissolved organic carbon (DOC) and DON blanks; rinsing a 47 mm Supor filter with 200 ml of DW is generally sufficient to lower the blank substantially (C. Carlson, *personal communication*).

Sample storage options include acidification, refrigeration, pasteurization, or freezing (−20 or −80°C). The principle behind acidification is to lower the pH sufficiently to inhibit microbial activity that could alter the concentration of the analytes; HPLC-grade phosphoric acid is often used. If acidification is chosen, the analyst should take the pH change into account prior to analysis because many methods are pH sensitive. Refrigeration should only be considered for samples filtered through a 0.2 µm filter (thus making the sample nearly abiotic). Pasteurization has been pursued as a storage option because of the risk that freezers could fail, as

well as the expense of storing large numbers of samples frozen for long periods of time (Aminot and Kérouel, 1998). Though not appropriate for ammonium (NH_4^+), presumably due to the potential for loss through volatilization, researchers may want to investigate its use for storage of nitrate (NO_3^-) and nitrite (NO_2^-) samples. For most samples, simple frozen storage is generally the most common method and is what we recommend, with some caveats. Care must be taken to allow space for expansion during freezing, and if using glass vials duplicate samples are highly recommended to allow for potential breakage. Also, if storing samples in a freezer, that freezer should be clean and free of meat or animal tissues and high organic sediments, particularly when storing samples for the more sensitive analyses such as DFAA.

3. MEASUREMENT OF NITROGEN CONCENTRATIONS

Nitrogen exists in the ocean at oxidation states from −3 to +5. There are three forms of fixed inorganic N: NO_3^-, NO_2^- and NH_4^+. Nitrate is the final oxidation product and is the dominant form of fixed N in the deep ocean. Nitrite generally occurs at very low concentrations because it is an intermediate in the processes of nitrification ($NH_4^+ \rightarrow NO_2^- \rightarrow NO_3^-$) and denitrification ($NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$) and so seldom accumulates to a large degree. Concentrations of NH_4^+ are highly variable but tend to be near the limit of detection in open ocean surface waters. Each of the inorganic forms has a number of manual and automated methods of analysis. We discuss the most widely used below.

3.1. General principles of nutrient analysis

In general, nutrient analyses are done either manually or using an autoanalyzer. Space limits preclude the presentation of detailed protocols. An excellent general review of nutrient analysis as well as detailed method descriptions and protocols can be found in Grasshoff *et al.* (1999) and Sparks *et al.* (1996).

Many of the methods discussed below are colorimetric techniques. The basic principle behind these techniques is to add a series of reagents that will build a dye molecule containing the analyte in question. The higher the concentration of the analyte, the higher the concentration of dye that will form. The final step in the analysis is to measure the absorbance of the sample using a spectropho-tometer at a wavelength that represents the peak absorbance for the dye in question. The conversion of absorbance to a concentration is described by Beer–Lambert's Law.

A number of basic principles should always be followed regardless of the analysis. First, the concentration in the standard curve should bracket the concentrations of the samples being analyzed. Second, standards should be run at the same time and treated in an identical fashion to the samples being measured. Third, for many analyses, the matrix (e.g., freshwater or saltwater) of the sample will influence the absorbance measured. For this reason, standards should be prepared in a matrix that

matches the matrix of the samples. In the case of seawater samples, artificial or low nutrient seawater should be used in the preparation of the standards. In the case of estuarine samples, where the salinity can change dramatically from station to station, a salt correction is generally used (i.e., Grasshoff *et al.*, 1999). Fourth, the longer the cuvette (i.e., path length) used in the final analysis, the lower the limit of detection that can be reached. The use of long-path liquid waveguide capillary cells (e.g., meters long) has allowed great improvement in sensitivity and detection for a number of analyses (e.g., Zhang, 2000).

3.2. Ammonium (NH_4^+) analysis

Ammonium is present at very low concentrations (0.03–0.5 µM) in oceanic surface waters, at higher concentrations in coastal and estuarine waters (Sharp, 1983), and at concentrations orders of magnitude higher in sediment pore waters. In seawater, NH_4^+ exists as the acid base pair NH_4^+–NH_3 (ammonia); the pK_a of the pair is 9.3. The methods discussed here measure the sum of NH_4^+, the form that dominates at the pH of seawater ($\sim$<8.3), and NH_3, the volatile form that dominates under more alkaline conditions. There are many approaches to measuring NH_4^+, but we will focus on the two most widely used—phenol-hypochlorite and orthophtal-dialdehyde (OPA).

The most common approach to measuring NH_4^+ is a colorimetric one that uses the Bertholot reaction where a blue color is formed by phenol and hypochlorite in the presence of NH_4^+ (Searle, 1984). The reaction requires a catalyst or elevated temperatures to achieve the sensitivity needed for environmental samples. Sodium nitroprusside is commonly used as the catalyst (Solorzano, 1969); salicylate can also be used as the catalyst but the limit of detection is higher ($\sim$0.7 µmol L^{-1}) (Bower and Holm-Hansen, 1980). In either case, the reaction product is an azo dye, the absorbance of which is measured on a spectrophotometer at 630 nm.

To increase the sensitivity of the analysis, it is recommended that a 5 or 10 cm path length cell be used. The detection limit using a 10 cm cell is approximately 0.05 µM, with an upper limit of 40 µM without dilution. Use of a long-path liquid waveguide capillary cell (2 m) lowered the detection limit to 5 nM with a precision of 5% in the 10–100 nM range (Li *et al.*, 2005). Another approach used to decrease the limit of detection is to preconcentrate the NH_4^+ prior to analysis. In one technique, the indophenol is concentrated by extraction into n-hexanol; this method has a precision of 1.9 nM at concentrations ≤50 nM (Brzezinski, 1987). The indophenol can also be concentrated onto solid phase extraction (SPE) octade-cylsilane (C18) columns (Selmer and Sorensson, 1986), with the final concentration determined as outlined in Brzezinski (1987).

There are also a number of matrix issues that the analyst should bear in mind. In seawater there is a small salt effect, with lower absorbances observed in seawater versus distilled water for the same concentration of NH_4^+. Amino acids can cause an interference with the analysis, but at the concentrations of amino acids found in seawater the interference is generally insignificant (Solorzano, 1969); there is no interference with urea. Beware of analyzing samples with a pH higher than 11.0 because blanks become inconsistent; a pH problem is indicated if the sample has a

greenish, rather than blue, color. Also, samples from low salinity environments (<5) with high humic concentrations often have a tea color, which will interfere with the colorimetric protocol. One way to circumvent this problem is to precipitate the humics with a magnesium sulfate solution prior to analysis (Grasshoff et al., 1983). When samples cannot be run right away, another useful modification is the addition of the phenolic reagent immediately after sample collection to bind the NH_4^+. After the reagent is added, the samples can be stored in the refrigerator until analysis, circumventing the need to freeze the samples (e.g., Cochlan et al., 2002).

The phenol–hypochlorite method has also been adapted for use in microplate readers. The advantage is very small sample size (<300 µl) and extremely high sample throughput (~1000 samples per day). The limit of detection, however, is high (~1.6 µM), making it unsuitable for water column studies, although it may be applicable for sediment pore waters or highly eutrophic systems (Baudinet and Galgani, 1991).

The most common alternative to the phenol–hypochlorite method uses OPA. This technique was introduced in an automated version based on the conversion of NH_4^+ to NH_3, which is then allowed to diffuse across a membrane into a flowing stream of OPA to form a fluorescent product (Jones, 1991). This final product is then analyzed fluorometrically with a detection limit of ~1.5 nM (Jones, 1991). Advantages of the method are that it requires only a single reagent and it has a lower detection limit than the standard phenol–hypochlorite method. Furthermore, the salt effect is relatively small ($<3\%$ over a salinity range of 0–35 ‰) and there is no interference from primary amines. The technique has been modified to remove the gas diffusion cell, also with a reported detection limit of 1.5 nM (Kerouel and Aminot, 1997); a manual version has also been published (Holmes et al., 1999).

3.3. Nitrate (NO_3^-) and nitrite (NO_2^-) analysis

Nitrate is often near the limit of detection in surface waters (~0.05 µM) but increases to ~35 µM below the thermocline (Sharp, 1983). Nitrite is an intermediate in the processes of nitrification ($NH_4^+ \rightarrow NO_2^- \rightarrow NO_3^-$) and denitrification ($NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$). Its presence can thus be diagnostic for these processes, but it seldom accumulates to concentrations >1 µM. Concentrations of NO_3^- and NO_2^- are often reported summed in the literature because their measurement is related. There are a number of methods that can measure NO_2^- directly, however, we are unaware of any method for the direct measurement of NO_3^-. To measure NO_3^-, it must first be reduced to NO_2^-, or some other more reduced form, such that the NO_2^- actually measured will include both preexisting NO_2^- plus the NO_2^- produced as a result of the reduction of NO_3^-. The concentration of NO_3^- is then calculated as:

$$[NO_{2+3}] - [NO_2^-] = [NO_3^-] \tag{28.1}$$

The most common method to measure NO_2^- is based on the formation of an azo dye formed when NO_2^- reacts with two aromatic amines added sequentially

(sulfanilamide and N-naphthylethylene-diamine dihydrochloride, NEDA, Strickland and Parsons, 1972). The resulting red azo dye is measured on a spectro-photometer with a linear standard curve up to 10 μM; sample concentrations greater than 10 μM should be diluted before being read. The precision of the method is ±0.01 μM (Strickland and Parsons, 1972). Application of a long-path liquid wave-guide capillary cell (2 m) can lower the detection limit for NO_2^- to 1 nM with a precision of 0.2% (Zhang, 2000).

The most common method for measurement of NO_3^- is cadmium reduction (i.e., the cadmium/copper amalgam method) with the chemiluminescence method the most common alternative. Both involve an initial step to reduce the NO_3^- to NO_2^-. In the former, reduction with copper coated cadmium can be done manually using a reduction column or, more commonly, an autoanalyzer (Hansen and Koroleff, 1999). After the reduction is complete the sample is treated for NO_2^- analysis as described above. The limit of detection of the technique is reported to be 0.05 μM (Strickland and Parsons, 1972); slight modifications to the automated procedure increased the precision of the NO_2^- and NO_3^- analyses to ±1.24 and ±2.87 nM, respectively (Raimbault et al., 1990). Application of a long-path liquid waveguide capillary cell (2 m) can lower the detection limit for NO_3^- to 2 nM with a precision of 0.8% (Zhang, 2000). The speed of automated NO_3^- analysis has also increased dramatically thus allowing higher sample through put, which makes fine scale underway sampling possible (e.g., Hales et al., 2004).

A useful alternative to cadmium columns is reduction of individual samples with spongy cadmium (Jones, 1984). Spongy cadmium is made by placing zinc sticks in 20% cadmium sulfate overnight, during which time the cadmium precipitates on the surface of the zinc. The spongy cadmium is then added to individual seawater samples with ammonium chloride and shaken for 90 min. The spongy cadmium has the advantage of having a much higher surface area than the granules used in cadmium columns. Advantages of the method include the ability to run a large number of samples simultaneously and stability in reductor efficiency over time. In addition, when sample concentrations vary over a wide concentration range, the spongy cadmium method can be used without the need to rerun samples using different calibrations, as is often required with autoanalyzers. This method is especially useful for sediment pore water samples that may have sulfide present, a compound that will reduce the efficiency or completely inactivate a cadmium reduction column. If the sulfide is not completely removed in a given sample only that sample will be compromised, rather than an entire reduction column. The limit of detection of the spongy cadmium technique is reported as 0.033 μM (Jones, 1984) but in practice limits of detection are closer to 0.1 μM, such that we reserve its use for samples from more eutrophic environments.

A common source of error in NO_3^- measurements is caused by a decrease in reductor efficiency over time, which has been reported as ∼1% per 4–6 h of autoanalyzer run-time (Garside, 1993). Reduction efficiency can decrease due to a decrease in surface area, precipitation of hydroxides on the cadmium, and loss of the copper coating. It is recommended that NO_2^- and NO_3^- standards be analyzed periodically during a run and the results used to correct for the loss in reductor efficiency (Garside, 1993). An efficient method to regenerate or reactivate cadmium

columns, manual or in autoanalyzers, is to pass a copper-EDTA complex through the column (Otsuki, 1978). This reactivation method has the advantage that it does not produce an excess of reduced colloidal copper that can clog the column, necessitating the column being unpacked each time it is regenerated.

The other commonly used method to measure NO_3^- and NO_2^- is chemiluminescence. In this technique NO_3^- and NO_2^- are reduced to nitric oxide (NO), which is then measured on a N oxide analyzer after its chemiluminescent reaction with ozone (Garside, 1982). The reduction of NO_3^- to NO_2^- is effected by injecting the sample into a heated reservoir containing an iron(II)-molybdate solution (Garside, 1982). The amount of NO produced is dependent on the volume of sample injected into the machine. Volumes up to 10 ml can be injected for low concentration samples. The range of the method was reported as 0.002–20 µM. The method is more sensitive than the cadmium reduction methods, with a precision of ± 0.002 µM NO_3^- and ± 0.0005 µM for NO_2^- (Garside, 1982). Vanadium(III) has now largely replaced the iron(II)-molybdate solution because it is a more reactive reducing agent, and retains its reducing power at much lower acidities and after repeated injections of seawater (Braman and Hendrix, 1989).

The trend toward monitoring over large spatial and temporal scales and the expense of analyzing discrete samples has greatly increased the interest in sensors that can be deployed within the environment. Nitrate has been the N form to receive the greatest interest in this regard because of its importance in controlling oceanic new production. There are now *in situ* instrument packages that can provide NO_3^- concentration measurements over a range of temporal scales while attached to a fixed location (days to months, e.g., Johnson and Coletti, 2002; Johnson *et al.*, 2007).

3.4. Total dissolved nitrogen/dissolved organic nitrogen analysis

The total dissolved nitrogen (TDN) pool consists of an inorganic N (NH_4^+, NO_3^-, and NO_2^-) fraction and an organic fraction. To calculate the DON fraction, the sum of the inorganic N concentrations are subtracted from the TDN concentration, with the residual being defined as DON.

$$DON = TDN - (NH_4^+ + NO_3^-/NO_2^-) \qquad (28.2)$$

The standard deviation of the DON concentration is calculated by propagating the error with the following equation:

$$s_{DON} = (s^2_{TDN} + s^2_{NH_4^+} + s^2_{NO_3^-/NO_2^-})^{1/2} \qquad (28.3)$$

where s^2 is the variance of the three measurements (Bevington, 1969). Measurements of DON thus have inherently large errors, since the final estimate of DON contains the combined analytical uncertainty of three analyses: TDN, NH_4^+, and combined NO_3^-/NO_2^-. This propagated uncertainty becomes an increasingly large problem in subsurface and deep ocean waters, where DON concentrations are small while dissolved inorganic nitrogen (DIN) concentrations are large.

A discussion of organic pools in general (DON plus DOC and dissolved organic phosphorus) is presented in Sharp (2002).

A cautionary note regarding statistics commonly used in nutrient chemistry—know the difference between Model I and Model II regressions (Laws and Archie, 1981). When one is plotting a standard curve, where the parameter on the x-axis is controlled, a Model I regression should be used. When comparing methods (e.g., as was done with the DON method intercomparison), where the same parameter is measured in a number of different ways, or with most field data, a Model II regression should be used (see Laws and Archie, 1981).

There are currently three methods commonly used to measure TDN concentrations: persulfate oxidation (PO) (Solorzano and Sharp, 1980; Valderrama, 1981); ultraviolet oxidation (UV, Armstrong and Tibbitts, 1968; Armstrong et al., 1966); and high temperature combustion (HTC, Suzuki and Sugimura, 1985); these three methods are reviewed in detail in Sharp et al. (2004). A comparison of the three methods was undertaken with 29 sets of analyses done on five field samples (Sharp et al., 2002a). The coefficient of variations for the five samples ranged from 19% to 46%, with the poorest replication observed on deep ocean samples. No significant differences were found between the different methods. Kjeldahl digestion is another method used to measure TDN that uses sulfuric acid to convert DON to NH_4^+. It has high blanks and low precision and is therefore not recommended for analysis of marine samples (D'Elia et al., 1977).

Analysis of TDN by the PO method involves adding a potassium persulfate oxidizing reagent to a sample and then autoclaving it for 0.5 h at 121°C and 15 lb/in^2 pressure. The oxidation converts the fixed N forms to NO_3^- and then the concentration of the NO_3^- is measured with one of the techniques described above. The PO method often suffers from high blanks that are a function of the relatively large persulfate addition required. If high blanks are obtained, recrystallization of the potassium persulfate once or twice can be done to exclude N contaminants in the crystals thus lowering the blanks (Hansen and Koroleff, 1999); this process, however, is time consuming. The required sample volume generally ranges from 5 to 20 ml, depending on the volume required for the subsequent NO_3^- analysis. Of all the methods, the PO technique has the lowest instrumentation cost. Samples can also be boiled if an autoclave is not available (Bronk et al., 2000). Readers are, however, cautioned against the use of Teflon or HDPE bottles. Teflon bottles are permanently misshapen during autoclaving and Teflon becomes pliable when heated repeatedly, resulting in loose caps and loss of sample. Bottles made of HDPE can be used, but must be autoclaved first because ~10% of them explode or leak during autoclaving. The safest method is to use sealed glass ampoules.

Analysis of TDN by the UV method requires an instrument that can hold samples at a fixed distance from a UV light source without allowing the samples to overheat (Armstrong et al., 1966). One common design for such an instrument was developed by Armstrong and Tibbitts (1968). Most commonly the method uses a 500–1200 W mercury vapor lamp. The sample tubes must be made of quartz to allow the passage of the UV radiation through the sample wall. Hydrogen peroxide (H_2O_2) is often used as an oxidant. Oxidation times generally vary from 18 to 24 h depending on the UV lamp; each new lamp should be tested to determine the

oxidation time required (Bronk *et al.*, 2000). The advantage of the UV technique is the small addition of H_2O_2 used, which results in generally lower blanks than the PO method. Disadvantages of the UV method includes the cost and effort of building a UV machine and the long oxidation time required. Automated approaches have been proposed that could increase sample throughput (Collos and Mornet, 1993; Le Poupon *et al.*, 1997).

With the HTC method, samples are combusted at high temperatures in the presence of oxygen. Though chemically simple, the HTC method requires great care to achieve reproducible results from day to day. In general the HTC method is not considered to have a salt effect (Walsh, 1989). Advantages of the HTC method are the small sample volume required and relatively low blank. The main disadvantage with this method is the expense of the equipment, and the time and effort required for set-up and troubleshooting.

3.5. Particulate nitrogen analysis

Concentrations of particulate nitrogen (PN) are commonly $<1\,\mu M$ in oceanic waters and $<10\,\mu M$ in coastal systems (Sharp, 1983). To measure PN, also known as particulate organic N (PON), a field sample is first filtered, commonly through a baked (450°C for a minimum of 2 h) Whatman GF/F filter (nominal pore size 0.7 μm); silver filters (Gordon and Sutcliffe, 1974) and Anapore® alumina silicate filters can also be used. The filter is then dried and analyzed with a CHN (carbon hydrogen nitrogen) elemental analyzer that combusts the filter and quantifies the resulting gases (Ehrhardt and Koeve, 1999); see Hurd and Spencer (1991) for a discussion of particulate N and C analyses and instruments.

4. DIRECT MEASUREMENT OF MAJOR DON COMPONENTS

4.1. Urea

Urea $((NH_2)_2CO)$ is excreted by larger organisms, can be a product of bacterial organic matter decomposition, and is a highly labile form of N for plankton nutrition (Bronk, 2002). Reports of concentrations in oceanic waters are relatively scarce, but are quite low ($<0.5\,\mu M$; Antia *et al.*, 1991). There are currently two methods commonly used to measure urea concentrations—the urease method (McCarthy, 1970) and the monoxime method (Mulvenna and Savidge, 1992; Price and Harrison, 1987).

In the urease method, urea is enzymatically hydrolyzed to CO_2 and NH_3 (McCarthy, 1970). The released NH_4^+ is then measured using the phenol hypochlorite method described above. The urease method commonly suffers from incomplete hydrolysis, resulting in an underestimation of urea concentrations.

The monoxime method is a colorimetric approach where urea is measured directly using diacetyl monoxime. Difficulties associated with the monoxime method include precipitate formation when the sample cools and rapid loss of color (Mulvaney and Bremer, 1979). The method also needs a higher reaction

temperature (85°C), thus requiring a heated water bath that can limit the number of samples run simultaneously. Goeyens *et al.* (1998) published a modified version of the monoxime method that allowed the reaction sequence to take place at room temperature albeit with a much longer reaction period—72 h versus 20 min for the high temperature method. The limit of detection was similar for the high temperature (85°C) method, 0.14 μM, and the room temperature (20°C) method, 0.10 μM (Goeyens *et al.*, 1998). A monoxime method has also been introduced for use with an autoanalyzer (Cozzi, 2004).

Comparisons of the two methods found that the urease method tends to underestimate concentrations in seawater and so we recommend the monoxime method for analysis of marine samples (Price and Harrison, 1987; Revilla *et al.*, 2005). With respect to estuarine samples, the monoxime method is more accurate and less affected by salinity than the urease method (Revilla *et al.*, 2005). There has been some concern that freezing samples may result in lower urea concentrations (Mulvenna and Savidge, 1992). Other researchers, however, have shown that freezing does not alter the urea concentration measured (Cochlan and Bronk, 2001; Price and Harrison, 1987).

4.2. Humic substances

Humic substances are a broad class of organic compounds operationally defined by their solubility at different pHs and retention on hydrophobic resins (Aiken, 1988; Thurman, 1985). There are three operational sub-categories of humic substances: humic acids, which are soluble at a higher pH but become insoluble at a pH < 2 (isolated using XAD-8 resin); fulvic acids, which are hydrophilic acids soluble under all pH conditions (isolated using XAD-4 resin), and humin, which is insoluble at any pH (Ishiwatari, 1992). For a review of humic substances in aquatic systems, see Hessen and Tranvik (1998), Benner (2002), and Chapter 3 by Aluwihare and Meador, this volume.

There are two common approaches used to quantify humic substances—measurement of fluorescence or extraction onto a resin. The use of fluorescence measurements is of limited use in N studies because the N fraction of the humic substances cannot be quantified directly. In resin methods, humic substances are extracted onto a macroporous acrylic ester resin. The most commonly used resin was formerly Amberlite XAD-8, but now Supelite DAX-8 is most often used. Both resins isolate similar bulk humic fractions from natural waters and produce solutions with similar chemical compositions (Peuravuori *et al.*, 2002). These resins also release small amounts of organic molecules (Aiken, 1988). Therefore, prior to the extraction of humics, the resin should be cleaned over several days via a Soxhlet extraction procedure (solvents include ether, acetonitrile, and methanol) followed by extensive rinses with hydrochloric acid (HCl), sodium hydroxide (NaOH), and DW (Aiken, 1985; Thurman, 1985). When isolating humics, the sample pH is reduced to <2 with 6N HCl, which protonates acid groups, prior to passage of the sample through the resin. After the sample passes through the resin, the column is rinsed with DW to remove residual salts. The humics are eluted from the column with 0.2N NaOH. Complete elution of all humic-N is difficult, however. Therefore, the most accurate

approach to measure humic-N concentrations is to measure the TDN concentration before and after the sample has passed through the column, with the concentration of humic-N taken to be the difference, rather than to measure the concentration of TDN in the eluted humic fraction. There is also a high temperature oxidation method for humic acid analysis that has not been commonly used (Fox, 1991). The relative solubility of humic and fulvic acids can be exploited to measure the concentration of these two fractions (e.g., Van Zomeren and Comans, 2007).

One should be cautious when quantifying humic-N based on the use of resin extraction. Recent work indicates that N associated with humics can dissociate when the pH is taken down to <2 prior to the passage through the resin column (See and Bronk, 2005). As a result, the C:N ratio of the isolated humic substances is likely higher than it is in natural waters.

4.3. Amino acids

Amino acids are the largest component of total DON identifiable at the molecular level, and a wealth of information is available from both molecular and enantiomeric analyses. The fact that amino acids are one of the few compound classes that can be readily quantified in unconcentrated seawater has resulted in a broad literature on marine amino acids evolving for nearly 30 years, using methods that have changed relatively little.

Dissolved amino acids are commonly divided into two pools that must be analyzed separately: DFAA exist as individual monomers in solution, while DCAA are defined operationally as additional amino acids liberated by acid hydrolysis. DCAA are thus presumably present mostly as polypeptides, a supposition supported in at least the high molecular weight (HMW) fraction by ^{15}N-nuclear magnetic resonance (NMR) spectroscopy data (discussed below). The operational nature of the DFAA versus DCAA definitions means that amino acids liberated from difficult matrixes (e.g., humic substances) also could make up a part of DCAA. Total hydrolysable amino acid (THAA) is another term commonly used to denote both pools together, when the sample is hydrolyzed but DFAA are not independently determined. Because the DFAA pool is typically much smaller than DCAA, THAA values are often assumed to be similar to DCAA.

Amino acids are polar and chemically diverse molecules, with side chains including a single proton, aliphatic chains, acids, bases, and aromatic rings. Methods used to determine the 15–20 most common protein and non-protein amino acids generally use derivatives to aid in separation, detection, or both. Because molecular-level amino acid analyses are routinely made in biomedical research, a variety of automated amino acid analyzers are commercially available. These typically consist of liquid chromatography coupled to automated-fluorescent derivatization, detector, and software optimized for common protein amino acids. Automated analyzers offer easy and rapid analysis of biological materials or purified proteins within a well known matrix, and have also been used successfully in ocean research (Ittekkot, 1982; Lee and Bada, 1977). Most recent investigators, however, have opted to set up their own amino acid methods using liquid or gas chromatographic systems tailored to their specific goals. In principle, the only analytical difference separating

DFAA and DCAA is the presence or absence of hydrolysis. In practice, however, the extremely low detection limits needed for DFAA limits the range of chromatography and detection options that can be used, while hydrolysis itself is problematic for some amino acids. For these reasons, DFAA and DCAA analysis are treated individually below.

4.3.1. Free amino acids

While DFAA make up a minor part of the total THAA pool (1–10%) they are nevertheless extremely important as substrates for microbial growth (e.g., Keil and Kirchman, 1991a) and important components of rapidly cycling DON (Bronk *et al.*, 2007). Because of extremely low concentrations, use of fluorescent derivatives that allow fmol to pmol detection levels are necessary in order to make measurements directly in seawater. Reverse-phase high pressure liquid chromatography (HPLC) separations after derivatization with OPA have remained the most widely used approach in ocean sciences since the early 1980s (e.g., Jones *et al.*, 1981; Lindroth and Mopper, 1979; Parsons *et al.*, 1984). Compound-specific DFAA measurements are commonly made directly in filtered seawater using automated pre-column OPA derivatization/injection coupled with reverse-phase chromatography and florescence detection (e.g., Cherrier and Bauer, 2004; Coffin, 1989; Keil and Kirchman, 1991a). For coastal samples, interference by NH_4^+ can be a problem, and corrections may be necessary (Tada *et al.*, 1998). As long as NH_4^+ levels are not high, total DFAA can also be estimated by a bulk fluorometric approach (Parsons *et al.*, 1984), because DFAA concentrations are often equal to the concentration of total dissolved primary amines (e.g., Delmas *et al.*, 1990; Kirchman *et al.*, 1989).

In practice, many difficulties of routine DFAA analysis in open ocean waters stem from the extremely low concentrations present. Great care must be taken to avoid contamination and to monitor procedural blanks. Assuming no special chromatographic problems exist, detection limits can also be affected by the sensitively of the florescence detector used. Simply replacing an old lamp may help substantially, and new generations of florescence detectors (e.g., offered by Shimadzu, Agilent, Varian, etc.) claim substantial improvement in power and optics. It is also possible to use column pre-concentration to increase sensitivity (Lee and Bada, 1975). This approach could be extremely useful for investigation of minor DFAA components, such as D-enantiomers of DFAA (Lee and Bada, 1975, 1977). However, because most of the common DFAA components can be measured directly, pre-concentration approaches have not been widely used.

4.3.2. Combined amino acids

4.3.2.1. Hydrolysis methods   Molecular-level analysis of THAA is dependent on hydrolytic cleavage of peptide bonds. Standard acid hydrolytic conditions developed for pure proteins remain in common use, typically employing 6N HCl at 100–110°C for 20–24 h, done under a N_2 atmosphere to minimize oxidative destruction of sensitive side-chains (e.g., Dauwe *et al.*, 1999; Henrichs *et al.*, 1984; Lee and Bada, 1977; Parsons *et al.*, 1984; Van Mooy *et al.*, 2002; Ziegler and Fogel, 2003). Several amino acids with acid-sensitive side-chains are, however, destroyed or severely degraded under these conditions. Asparagine and glutamine are

quantitatively converted to aspartic acid and glutamic acid, while the side-chains of tryptophan and cysteine are substantially degraded. In order to effectively measure acid-sensitive amino acids, base hydrolysis can be used (Wu and Tanoue, 2002). A number of ancillary approaches have also been devised to protect sensitive side chains from degradation, for example, by adding sacrificial compounds or organic acids (Liu and Chang, 1971). However, because the affected amino acids represent only a minor molar percent of the total amino acid pool, such measures have rarely been used for oceanic THAA analyses.

Alternatives to the standard acid hydrolytic conditions have also been examined for marine samples. Elevated temperatures can reduce reaction time, and addition of multiple internal standards can more effectively track losses related to specific side-chain functionality (Cowie and Hedges, 1992a). Gas phase hydrolysis (Keil and Kirchman, 1991b) is an alternative to standard aqueous hydrolysis that results in much reduced analysis time, and may have an important impact on THAA quantification in some samples. Keil and Kirchman (1991b) observed substantial increases in amino acid yield for a range of oceanic samples using a vapor-phase HCL/TFA mixture at 156°C. The highest increases were for open ocean DOM, suggesting that THAA in DON may have been underestimated by up to 300%. More recently, Jørgensen and Jensen (1997) demonstrated a vapor-phase microwave method using only HCl, which reduced hydrolysis time to ~20 min. while also increasing THAA yields relative to standard aqueous phase protocols. Because of the potential for shortened reaction times and increased recovery of some problem amino acids such as cysteine, vapor-phase has become common for protein hydrolysis in some biochemistry applications (e.g., Strydoma *et al.*, 1993) and has also been used to analyze marine samples (e.g., Cherrier and Bauer, 2004). One caveat, however, is that vapor-phase hydrolysis has been found to strongly affect the enantiomeric ratios of liberated amino acids (Kaiser and Benner, 2005).

4.3.2.2. Derivatization and chromatography   Once individual amino acids are liberated in dissolved form, they are typically separated by either HPLC or gas chromatography (GC) for molecular-level quantification. Both HPLC and GC have been used effectively, with each having strengths and limitations. As with DFAA, reverse-phase HPLC separations after derivatization with OPA (Lindroth and Mopper, 1979) has become perhaps the most widely used method (e.g., Cowie and Hedges, 1992b; Dauwe and Middelburg, 1998; Hubberten *et al.*, 1994; Ingalls *et al.*, 2003; Keil and Kirchman, 1993; Lee *et al.*, 2000; McCarthy *et al.*, 1996; Van Mooy *et al.*, 2002; Yamashita and Tanoue, 2003). Because hydrolyzed amino acids are relatively stable at room temperature, large sample sets can be derivatized and chromatographed automatically using HPLC auto-injectors equipped with sample pre-treatment capability. However, some amino acids are either not derivatized at all by OPA (e.g., proline, secondary amines in general), or typically have poor quantification and high variability (e.g., cysteine). 9-fluorenylmethyloxycarbonyl chloride (FMOC) is a common agent for derivatizing secondary amines, and can be used in combination with OPA to both detect proline as well as increase sensitivity for several other amino acids (Godel *et al.*, 1992). In practice, however, such enhancements to basic HPLC methods have rarely been used for ocean samples because these amino acids are minor

components of TDAA. One inherent drawback to HPLC methods is reduced chromatographic resolution relative to GC. Liquid chromatography–mass spectrometry (LC–MS) methods offer the sensitivity as well as molecular specificity to identify even unusual amino acids without needing to fully resolve components (Whitehead and Hedges, 2002); however, the necessity to desalt samples for electrospray MS applications diminishes its direct applicability for marine DON.

GC methods offer an attractive alternative to HPLC for applications where higher detection limits are acceptable (e.g., Harvey and Mannino, 2001; McCarthy *et al.*, 1998; Ziegler and Fogel, 2003). A wide variety of volatile amino acid derivatives can be made by sequential esterification and acylation of the carboxyl and amino terminal ends, respectively (see Knapp, 1979 for a long list). Additional derivatives, their chromatographic separation with different phases, and especially their applicability for compound-specific isotope analysis have also recently been compared (Corr *et al.*, 2007). These derivatives are readily separated by common GC phases, making GC a good method for quantification, isotopic, and enantiomeric amino acid analyses. Advantages of GC–based analysis include greatly increased chromatographic resolution, the relative ease and reproducibility of GC systems, as well the option for unambiguous peak and mixture identification using common bench–top gas chromatography–Mass spectrometry (GC–MS) instruments. Drawbacks are the relatively labor intensive wet chemistry used to make derivatives and the lower sensitivity of common GC detectors. The need to make derivatives by hand (and thus in small batches) greatly limits sample throughput, and larger samples are required relative to HPLC–florescent detection methods. However, using N and phosphorus selective detectors (NPD), or selective ion monitoring with GC–MS, can increase sensitivity about an order of magnitude versus standard flame ionization detectors (FID), while at the same time producing extremely clean and selective traces composed essentially only of the compounds of interest. Nevertheless, even with these approaches, sensitivity is generally too low for unconcentrated seawater analysis, and the enormous salt content (relative to organic N (ON)) can cause practical problems in performing derivatization reactions on dried seawater samples. These factors make GC techniques most useful for concentrated DON isolates, and in particular for investigation of enantiomeric (D/L), non–protein or minor amino acids where complex traces are anticipated, or MS compound verification is important.

4.3.3. Chiral (D/L) amino acids

Enantiomeric amino acid analysis has recently been of significant interest as an indicator of bacterial DON sources (Amon *et al.*, 2001; Fitznar, 1999; McCarthy *et al.*, 1998). Using GC, amino acid enantiomers can be easily resolved by substituting a chiral column for a non–chiral phase (e.g., McCarthy *et al.*, 1998). The same derivatives applicable for other GC techniques can be used, with the two most common being triflouro and pentaflouro anhydrydes (TFA, PFA). While one derivative is not necessarily preferred over others, the availability of different derivatization agents can be useful for resolving minor peaks in complex traces (such as often result from ocean DON). If a particular peak of interest is not well resolved or its identity is unclear, running the same sample derivatized with a different acylation agent may well resolve it.

For direct analysis of chiral amino acids in total seawater, a diasteriomeric-derivative HPLC approach has recently been described (Fitznar et al., 1999). Florescent diasteriomeric derivatives are made that can then be separated using a standard (and thus relatively inexpensive) reverse-phase HPLC column. This allows chiral amino acids to be measured in unconcentrated seawater samples with a protocol similar to standard OPA-based amino acid analysis (Dittmar et al., 2001). Obtaining good resolution of the doubled number of HPLC peaks can be somewhat challenging; however, the diasteriomeric method has an advantage in that since the derivatization reagent is chiral, two separate diasteriomers can be made for each compound. Each sample can thus be run using each reagent (D and L) in turn, resulting in unique separations that generally allow overlapping peaks in one trace to be resolved in the other (Fitznar et al., 1999). While an increase in effort, this approach also represents a powerful check on peak identification, allowing even minor D-AA peaks to be identified.

One important issue with D/L amino acid analysis is accounting for the racemization that occurs during hydrolysis. Chiral amino acids racemize during a hydrolysis reaction. The rates of racemization are amino acid specific and can be affected by a number of complex factors including position within a peptide, the size of the polymer structure, and the sample matrix (e.g., Bada, 1985). If this procedural racemization is not taken into account, the resulting D/L ratios (and any subsequent calculations, such as estimates of peptidoglycan derived from D–amino acid concentrations) will be in error to some degree. The extent of the problem will depend on the specific amino acid in question, being less severe with slower racemizing species (e.g., alanine), but especially important for the fast-racemizing amino acids like aspartic acid. Various approaches have been used to account for the extent of racemization during hydrolysis, including the use of deuterated HCl hydrolysis coupled with mass spectrometry (e.g., Amelung and Brodowski, 2002), and hydrolysis time series (Nagata et al., 1998). Kaiser and Benner (2005) have recently studied the extent of hydrolysis-related racemization in liquid versus vapor–phase protocols. These authors provide amino–acid specific racemization values, as well as equations that can be used to correct for hydrolysis–induced racemization (Kaiser and Benner, 2005).

4.4. Total protein/peptide

4.4.1. Colorimetric methods for bulk protein

As mentioned above, the large majority of recoverable amino acids are in combined form. This result indicates that peptides, and possibly proteins, are important DON constituents. Operational measurements of the amount of total protein in DON can be made by a wide variety of fluorometric and colorimetric assays. A partial list of those that have been applied to marine samples include coomassie blue (e.g., Mayer et al., 1986; Nunn et al., 2003; Setchell, 1981), Lowry's method (Clayton et al., 1988), the fluorescamine assay (Garfield et al., 1979), the bicinchoninic acid assay (Nguyen and Harvey, 1994), and the CBQCA (3–4–carboxybenzoyl-quinoline-2–carboxaldehyde) assay (Nunn et al., 2003). A number of the more common methods of protein analysis used in biochemical research, including a discussion of issues affecting their quantitative application, have recently been reviewed by Sapan et al. (1999).

Total protein assays have the advantage of being relatively straightforward compared to molecular-level analyses. Methods with fluorescence-based detection are also highly sensitive, and thus amenable directly to DON. Quantitative interpretation for environmental mixtures such as seawater, however, may be problematic for some samples. Most methods react with specific moieties (e.g., coomassie blue binds to lysine and arginine) and thus results obtained can depend on protein composition, size distribution, and even conformation (Sapan *et al.*, 1999), making the careful choice of calibration standards important. In addition, common components of natural samples, such as humic materials (e.g., Mayer *et al.*, 1986), carbohydrates (Sapan *et al.*, 1999), or NH_3 may interfere with quantification. Overall, colorimetric methods can be very useful as quick, likely semi–quantitative estimates of total protein or peptide. However, potential biases inherent in the mechanism of a specific method should be considered before one is chosen, and application of newer molecular assays (e.g., CBQCA) should be carefully examined in terms of natural sample matrix (Nunn *et al.*, 2003).

4.4.2. Specific protein analysis

Isolation and sequencing of specific proteins in the DON pool has recently begun to reveal a wealth of specific source information, as well as suggesting mechanisms for DON preservation (see Tanoue, 2000 for review of literature through 1990s). Proteins can be concentrated from large volumes of seawater using ultrafiltration with a nominal >10 kD size cutoff (discussed below, Powell and Timpermann, 2005). Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) has also been successfully used in both one and two dimensions to isolate discrete proteins from DON (e.g., Jones *et al.*, 2004; Tanoue, 1995; Yamada and Tanoue, 2006). This approach allows estimation of both the number and MW distribution of apparently intact proteins in DON. Total proteinaceous material isolated with this approach has been estimated to be up 10–30% of total DCAA, corresponding to 2–12% of total DON (Tanoue, 2000). Recovery, however, is strongly dependent on the exact protocol used for extracting proteins from seawater (Tanoue, 1995), and it is likely that significant work remains to be done to constrain quantitative estimates. The presence of humic materials and salts can also significantly limit gel quality (Jones *et al.*, 2004). Because of the difficulty of isolating entire proteins, as well as the fact that most proteinaceous material likely exists as smaller, partially degraded peptide units, approaches such as immunological techniques to probe smaller structures (e.g., Orellana *et al.*, 2003) may also be extremely valuable.

While methods for isolating discrete proteins are analytically challenging, when coupled with N-terminal amino acid sequencing (e.g., Tanoue *et al.*, 1995), immunochemical approaches (e.g., Suzuki *et al.*, 1997), or newer mass spectrometric techniques (Powell *et al.*, 2005), specific proteins can be identified, potentially offering a wealth of new information about DON sources. Recently, glycoproteins have also been detected in DON (Yamada and Tanoue, 2003), and 2-D electrophoresis suggests that highly varied glycosolated residues may even dominate the protein distribution of some ocean regions (Yamada and Tanoue, in review). These results suggest that a method for analyzing glyoproteins in DON may be an important future research target.

4.5. Amino sugars

Amino sugars are abundant compounds in plankton and bacteria, and thus constitute one of the largest potential DON sources. Biochemical "interrogation" studies have shown rapid turnover of common amino sugars, such as *N*-Acetyl glucoseamine (e.g., Kirchman and White, 1999; Riemann and Azam, 2002), indicating that amino sugars are key components of a rapidly cycling DON pool. Amino sugars are also major components of structural or cell-wall polymers in prokaryotes such as bacterial peptidoglycan, lipopolysaccharides, and archaeal pseudopeptidoglycan (Brock *et al.*, 1994). These structures are thought to be important sources for preserved DON (e.g., Boon *et al.*, 1998; McCarthy *et al.*, 1998; Tanoue *et al.*, 1995). NMR-based analyses of HMW-DON has also suggested that amino sugars could be a major component of this material (Aluwihare *et al.*, 2005; McCarthy *et al.*, 1997).

Common hexoseamines (glucoseamine and galactoseamine) can be quantified using modifications of standard amino acid HPLC protocols (Dauwe and Middelburg, 1998), or by HPLC after a mild sugar-specific hydrolysis and desalting (Ittekkot *et al.*, 1984a,b). In addition, a range of GC and GC-MS based methods are available that can quantify amino sugars after formation of volatile derivatives (Neeser and Schweizer, 1984; Whiton *et al.*, 1985). GC-MS methods have the substantial advantage of unambiguous peak identification, but as with amino acids making derivatives can be time consuming and result in losses. In addition, even in sediments and sinking particles the relatively small yields of amino sugars obtained by such methods (Dauwe and Middelburg, 1998; Ittekkot *et al.*, 1984a) suggest that they would not be suitable for direct DON analysis, although they can be used for concentrated samples (Aluwihare *et al.*, 2002). Overall, despite the potential importance of amino sugars to DON composition and cycling, relatively little research has directly targeted this compound class, most likely because of the lack of common methods for direct measurements.

The problem of sensitivity has recently been addressed with a high-performance anion-exchange chromatography—pulsed amperometric detection (HPLC-PAD) approach, specifically adapted for amino sugars in seawater (Kaiser and Benner, 2000). A similar method has also been published for amino sugars (as well as neutral sugars) in unconcentrated freshwaters (Cheng and Kaplan, 2003). While seawater samples must still be desalted via resin chromatography, the HPLC-PAD method of Kaiser and Benner (2000) allows fmol detection levels without derivatization, and it is readily coupled to automated sample injection. After optimizing hydrolysis conditions, near quantitative yields were reported for amino sugars spiked in natural DOM, and good recoveries were reported from a variety of natural materials (Kaiser and Benner, 2000). HPLC-PAD thus makes amino sugar molecular-level analysis possible on unconcentrated seawater samples, and also allows direct quantitative comparison with results from HMW DON and ocean particles. The first comprehensive sets of measurements using this technique on natural ocean water are providing a wealth of important new source information based on relative abundances of individual neutral sugar monomers (Benner and Kaiser, 2003; Davis and Benner, 2005). While the absolute contribution of identifiable common amino sugars has been found to be a relatively small fraction of the total DON pool (average

of 2–5% of HMW-DON, Benner and Kaiser, 2003; average of 0.7–1.5% of total DON; Davis and Benner, 2005), when compared to typical yields for amino acids (∼5–20% of total DON) it is nevertheless clear that amino sugars make up a major component of the DON that can be molecularly identified.

Recently several other innovative, if less specific and quantitative, analytical approaches have also been applied to concentrated DON samples, providing information about total amino sugar content and character in isolated DON. Direct temperature-resolved mass spectrometry (DT–MS) coupled with chemical ionization (NH_3) can be used to examine thermal sugar degradation products in solid materials (Boon et al., 1998). Though generally not considered quantitative, both DT–MS as well as Pyrolysis–MS (Lomax et al., 1991) provide information on relative abundance of types of amino sugars, while at the same time possibly accessing material protected from direct acid hydrolysis (Minor et al., 2001). These methods have indicated that both oceanic and estuarine HMW DOM has an important contribution from N-acetylated amino sugars (Boon et al., 1998; Simjouw et al., 2005). Another recent approach has been to apply differential (i.e., weaker vs. stronger) acid hydrolysis in concert with ^{15}N-NMR analysis (Aluwihare et al., 2005). This experiment exploits the relative facility of hydrolyzing acetyl groups from N-acetyl sugars, combined with the clear ^{15}N-NMR distinction between amides versus amines. An estimate of amino sugar in a sample can be obtained by comparing NMR spectra before and after weak hydrolysis. In HMW DON the results of this method suggest that amino sugars may comprise larger amounts, up to half of surface water HMW-DON, but substantially lower amounts in subsurface and deep waters (Aluwihare et al., 2005; see also Aluwihare and Meador, this volume).

4.6. Nucleic acids

DNA and RNA are major N-rich biochemical components of bacteria and viruses, and thus represent important potential sources to the DON pool. Recent methods have found oceanic nucleic acid concentrations in the low $\mu g\ L^{-1}$ range (Karl and Bailiff, 1989), suggesting that intact nucleic acids correspond to only a few percent of the total DON pool, despite the fact that rapid turnover suggests they are important N recycling compounds (e.g., Antia et al., 1991; Jørgensen et al., 1993).

Methods to directly measure concentrations of dissolved DNA (dDNA) and dissolved RNA (dRNA) typically involve an initial concentration or precipitation step, followed by detection and quantification by a florescent stain or dye. Common approaches have included ethanol precipitation followed by Hoechst 33258 staining (e.g., DeFlaun et al., 1986) that detects DNA only. Both DNA and RNA can be simultaneously measured using CTAB precipitation followed by reaction with 3–5 diaminobenzoic acid (Karl and Bailiff, 1989). Filtration and ultracentrifugation approaches for initial concentration steps have also been used (Paul et al., 1991), and have been combined with immunological detection (Jiang and Paul, 1995). Recent improvements have substantially decreased sample volumes and processing times required for dDNA analysis. Use of tetrasodium EDTA coupled with centrifugal concentration and SBYR Green-I florescent dye requires only ∼15 ml of

oligotrophic seawater and several hours processing time per sample (Brum *et al.*, 2004). A similar SBYR Green-I method has also been adapted for freshwater dDNA (Matsui *et al.*, 2004).

One complication for estimating the importance of nucleic acids as a source of *total* DON is, however, that common methods developed with biological processes in mind target relatively "intact" dDNA or dRNA, and may be less sensitive to partially degraded, bound, or otherwise altered material. The initial precipitation steps and dyes used for detection are commonly specific for molecule conformation or size. The SBYR Green-I dye (on which newer methods are based), for example, is a double stranded stain and is at least an order of magnitude less effective with single stranded molecules (Matsui *et al.*, 2004), and the EDTA step used for precipitation is most effective for material larger than 20 base pairs (Brum *et al.*, 2004). In addition, the operationally defined total "dissolved" DNA and RNA includes not only material truly in solution (and thus amenable to precipitation), but also material within viruses and tightly associated with colloids, humics or detritus (e.g., Brum *et al.*, 2004; Jiang and Paul, 1995). DNA present in an unknown "bound" form has been estimated in some marine studies at about half of that present in the "free" pool (Jiang and Paul, 1995). It is thus difficult to estimate what contribution degraded or altered nucleic acids may make to more refractory DON using current compound-specific methods, although NMR data has hinted that such material could be an important source of unsaturated N observed in deep ocean HMW material (McCarthy *et al.*, 1997).

5. BULK ORGANIC NITROGEN CHARACTERIZATION

The compounds that current methods can directly analyze likely make up the bulk of the rapidly cycling DON pool (see Chapter 3 by Aluwihare and Meador, this volume). However, the large majority of the total DON, especially in the subsurface ocean, still cannot be identified at the molecular-level. This presents us with a familiar analytical quandary. Without additional clues about the chemical nature of the majority of unidentified material, it is impossible to know where the methodological challenges lie: is it in the nature of the compounds themselves, i.e., novel or altered molecular structures for which new methods must be devised? In contrast, are there other limitations inherent in current methods related to the natural seawater/DON matrix? For example, are there physical associations or secondary reaction products that cause reduction in hydrolytic efficiency, which are the key barriers? To get beyond this circular problem, an enormous variety of spectroscopic and organic chemical methods exist that could be applied to organic mixtures and supply new information about the nature of bulk DON, including the distribution of compound classes, functional groups, isotopic ratios, etc. However, the devil is in the natural matrix—very few such techniques can be performed directly on aqueous samples. Low natural DON concentrations, coupled with vastly larger salt content, rule out many organic techniques that require a reasonably pure (non-diluted by mineral or salt) and fairly large (milligrams or more) sample. Finally, it is almost a

truism for detailed organic analysis that ''more is better''—the larger the sample, the greater the analytical possibilities become. For these reasons, a method that could quantitatively isolate a salt-free sample of the total dissolved material from seawater is needed (Bronk, 2002). To date no such method has been published, however, a great deal of information continues to be gained from a number of partial DON isolation techniques.

5.1. Organic nitrogen isolation techniques

5.1.1. Ultrafiltration

Tangential flow ultrafiltration (UF), also referred to as ''cross flow filtration,'' has become a widely used method since the early 1990s for isolating and desalting large quantities of DOM from seawater (e.g., Aluwihare *et al.*, 1997; Amon and Benner, 1994; Benner *et al.*, 1992, 1997; Guo, 2000; Guo *et al.*, 1996; Kolowith *et al.*, 2001; McCarthy *et al.*, 1996, 1998). Ultrafiltration is a size-based technique in which the sample is constantly recirculated across a membrane, progressively concentrating components that do not pass the membrane pores. Most seawater studies targeting total DOM have used polysulfone membranes with a nominal size cutoff of 1000 D, mainly because this is the smallest cutoff commonly manufactured that does not begin to retain larger seawater salts, thus allowing the filtration to proceed at a reasonable rate (e.g., Benner *et al.*, 1992, 1997). Dissolved material isolated by UF has been referred to in several different ways in the literature. In papers targeting the composition or cycling of the entire DOM pool, it has typically been abbreviated as UDOM (ultrafiltered DOM); this designation is functionally based, and thus avoids implicit assumptions about the nature of material isolated. Another body of literature uses ''colloidal'' OM to describe the same material, because the nominal >1000 D membrane cutoff also corresponds to a nominal size range for colloidal material, despite the fact that coupled UF and desalting likely destroys any natural non-covalent aggregates. It is also important to bear in mind that while in principle UF membranes retain only the HMW components exceeding the membrane pore size, in practice UF retains material based both on size as well as charge and other interactions with the membrane surface. One consequence of this more complicated mode of retention is that UF actually retains both high and low MW material during filtration (Guo, 2000). Final DOM recoveries thus depend on a concentration factor (i.e., total volume processed/final volume), and heavily on desalting, during which much of the originally retained DOM passes the membrane as ionic strength decreases (e.g., Benner *et al.*, 1997; Guo, 2000). After desalting, UF with 1000 D membranes typically recovers up to 30% of surface DOM and ∼20% from deeper waters. While relatively modest in terms of absolute recovery, because concentration takes place in a natural seawater matrix without chemical treatments or use of selective resins, UF isolates a more representative sample of total dissolved material than had been possible using previous chemically-selective methods (Benner *et al.*, 1997; Kaiser *et al.*, 2003). In addition, because UF systems can be operated in a continuous flow mode, extremely large volumes of water can be processed. This allows isolation of large amounts (grams are possible) of nearly pure DOM, making UF extremely useful for sample-intensive techniques.

An important issue with UF-based studies is how representative UDOM is of the total dissolved pool. For most bulk properties of DOM (e.g., total C:N ratio and stable and radiocarbon isotopes) material isolated by UF has been found to be fairly similar to the bulk pool (e.g., Benner *et al.*, 1997; McCarthy *et al.*, 1996). At the same time UDOM also displays offsets in some of its properties, generally consistent with size-reactivity continuum observations which suggest that HMW material is in general less degraded than LMW DOM (Amon and Benner, 1994). For example, ^{14}C content of UDOM in the subsurface Pacific indicates ages of 4000 to 5000 years (Loh *et al.*, 2004), which are similar to commonly reported values of 4000–6000 for total DOC, and clearly unrelated to modern ^{14}C values typical of POC. At the same time, comparison of measured UDOM ^{14}C values to literature ^{14}C values for total DOC also suggests that UDOM is somewhat younger than the total DOC at the any given depth horizon (Loh *et al.*, 2004).

For DON studies, ON mass balances for UF have not been directly determined. However, UF typically recovers material with C:N of ~14 in surface waters and 17–22 in the deep ocean (e.g., Benner *et al.*, 1997). Comparison to literature C:N ratios (DOC:DON data) from different locations can be problematic, in part because the large uncertainties that can be involved in subsurface DON estimates (discussed above) propagate into the DOC:DON ratio. Broad compilations (Bronk, 2002; Hopkinson and Vallino, 2004) suggest that C:N ratios of UDOM are slightly enriched in C, and thus UF may under sample total DON. In contrast, consistent with ideas that UDOM is enriched in more reactive material (e.g., Amon and Benner, 1994; Repeta and Aluwihare, 2006), as a general rule most identifiable ON compounds are somewhat enriched in the HMW fraction (i.e., "oversampled" by UF). Amino acids appear to be somewhat more representative of total DON in this respect, with THAA content and molar composition being similar between UDON and total DON in some studies (e.g., McCarthy *et al.*, 1996). Enantiomeric (D vs. L) ratios also very similar in some studies (Amon *et al.*, 2001; Dittmar *et al.*, 2001), while others have shown interesting site-specific differences in D/L ratios between high and low MW DON (Kaiser and Benner, 2008). In contrast, carbohydrates are substantially enriched in the higher MW DOM in upper ocean waters (e.g., Benner *et al.*, 1992; Pakulski and Benner, 1994; Skoog and Benner, 1997). Recent work has suggested that amino sugars are also more abundant in surface versus deep water UDOM (Aluwihare *et al.*, 2005). While amino sugar comparisons between LMW and HMW DOM have not been directly made on the same samples, comparison of amino sugars in HMW-DON from several ocean basins (Benner and Kaiser, 2003) versus amino sugars in total DON from the Chukchi/Beaufort Seas (Davis and Benner, 2005) supports the idea that UF also somewhat "over-samples" amino sugars relative to total DON pool, especially in surface ocean.

Overall, UF has numerous practical advantages for isolating large quantities of DON needed for detailed chemical study, and available data suggests its composition does not depart too greatly from the bulk oceanic DON pool. However, uncertainty remains, especially when departing from bulk composition and considering specific N-containing compounds that cannot be analyzed directly in seawater—caution should always be used in extrapolating results to the bulk

DON pool. Additional molecular-level and isotopic data comparing UDON with total DON will be extremely valuable, in particular comparison between $\delta^{15}N$ of UDON versus total DON as new methods for measuring $\delta^{15}N$ of total DON evolve.

5.1.2. Ion retardation resins

Perhaps the easiest method for isolating DON is through the use of ion retardation resin (e.g., BioRad AG 11 A8), which retards the flow of charged particles. The resin quantitatively removes salts including NH_4^+, NO_3^-, and NO_2^-, allowing DON to be isolated in the eluate (Bronk and Glibert, 1991, 1993a; Hu and Smith, 1998; Nagao and Miyazaki, 1999). Unfortunately, we know of no current distributor of ion retardation resin that is suitable for use with aquatic samples. DOW Chemical, the company that manufactured the resin marketed by BioRad and other distributors, changed the manufacturing process of the resin sometime in the mid 1990s such that the resin now retains variable amounts of DON. This DON retention is believed to be due to an accumulation of an organic film on the resin beads during manufacturing (BioRad, *personal communication*). To overcome this problem, AG 11 A8 resin can be manufactured and purified by buying another resin (Dowex anion exchange resin, BioRad AG1-X8) and then chemically altering it to produce AG 11 A8 as described in Hatch *et al.* (1957). The homemade resin, however, tends to breakdown rapidly, a problem not previously encountered with the resin produced by BioRad (Bronk, unpublished data).

5.1.3. Hydrophobic resin isolations

Another approach that could potentially be used for DON isolation is chemically selective resins. As discussed above, hydrophobic resin isolation has long been used in both terrestrial (Ertel *et al.*, 1986; Thurman and Malcolm, 1981) and marine waters (e.g., Stuermer and Harvey, 1974; Wilson *et al.*, 1983) to study dissolved humics. Thus, as a bulk isolation technique, resins are appropriate mainly for the humic component of DON, as described above for XAD-type isolations. A somewhat different spin on this theme is the use of SPE with C-18 columns, which has recently become widely used as a method to isolate hydrophobic DOM components for analyses that require desalting (e.g., Kaiser *et al.*, 2003; Kim *et al.*, 2003b; Koch *et al.*, 2005; Louchouarn *et al.*, 2000; Schwede-Thomas *et al.*, 2005). SPE has also been used in combination with UF in estuarine waters to increase the amount of total DOM recovered to near 70% (Simjouw *et al.*, 2005). Analysis of SPE-isolated material indicates, however, that SPE preferentially recovers the humic-like fraction (as would be expected), at the expense of polar biopolymers such as sugars and amino acids (Simjouw *et al.*, 2005). This is consistent with observations that SPE can strongly discriminate against total N, isolating material with significantly elevated C:N ratios (Koch *et al.*, 2005; See and Bronk, 2005). To overcome such resin-specific issues, it has been reported that a variety of different resins with a range of polarities and retention characteristics can be used in series to isolate nearly the entire DOM pool as discrete fractions, from both fresh and saline waters (Leenheer *et al.*, 2004). Such multi-resin experiments might be useful in the design of investigations targeting a specific fraction of the DON pool. However, their relatively labor-

intensive nature and concerns about blank contamination makes them less attractive for routine DON study.

5.1.4. Dialysis

Dialysis of discrete water samples is another approach that could potentially be used to isolate smaller samples of DON. Dialysis can be used effectively to isolate HMW DOM material (Heissenberger and Herndl, 1994), and with small membrane pore sizes could potentially be used to purify discrete DON samples. In freshwaters, dialysis has been used to remove inorganic N as a way to increase the accuracy of total DON measures, however, losses due to passage of LMW DON through the membrane and adsorption were concerns (Lee and Westerhoff, 2005). Dialysis has also been used in freshwaters for isolating DON for δ^{15}N measurement (Feuerstein et al., 1997). To date, however, dialysis has not been extensively investigated for seawater DON. Contamination and adsorption issues, as well as the relatively small amounts of material that can be collected, make dialysis most promising for compound-specific investigations. Other potential problems with the dialysis approach are the large amount of time needed to process samples (100 and 200+ h for fresh and salt water samples respectively), the lack of complete removal of salts and inorganic N, and the risk of bacterial contamination that could chemically alter the final dialyzed product.

5.2. NMR spectroscopy

Nuclear magnetic resonance spectroscopy has proven to be one of the most powerful techniques for characterizing complex natural geochemical samples because of its ability to non-destructively probe the chemical character of a range of organic nuclei that include most building blocks of organic matter (^{13}C, ^{15}N, ^{1}H, and ^{31}P). Basic techniques, theory and applications have been reviewed in a variety of articles and texts (e.g., Preston, 1996; Sanders and Hunter, 1988; Wilson, 1987). NMR spectra for geochemical samples such as DOM primarily differ from those of pure compounds in having broad and overlapping spectral lines, reflecting the fact that natural mixtures contain multiple variations within structural families. While specific compounds can thus rarely be identified, integration of spectral regions provides a broad view of the composition of the entire sample, in contrast to very narrow but detailed information available from molecular-level analyses. Coupled with sample isolation methods, both solid and liquid-state NMR techniques have been used to study oceanic DOM (e.g., Aluwihare et al., 1997; Benner et al., 1992; Clark et al., 1998; Hedges et al., 1992; McCarthy et al., 1996; Repeta et al., 2002; Stuermer and Payne, 1976), as well as to target nitrogenous material (Aluwihare et al., 2005; McCarthy et al., 1997).

Solid-state experiments use a dry sample that is packed into a rotor and spun at high frequency inside the spectrometer's magnetic field. This approach is termed cross-polarization magic angle spinning (CPMAS), and is the standard protocol for solids. It relies on transfer of magnetization from protons to C (or other nuclei) in order to achieve rapid analyses with reasonably narrow spectral lines. Cody et al.

(2002) contains a recent compact overview of solid-state NMR techniques in geochemical samples. With CPMAS essentially the full range of material in a mixture can be examined, including very HMW or insoluble components, making it particularly valuable for materials that have undergone major diagenetic alteration. CPMAS also has the advantage (especially significant for N studies) of concentrating the maximum amount of sample inside the magnetic field. The most common solid-state experiments on DOM isolates have been ^{13}C-CPMAS (e.g., Benner *et al.*, 1992; Hedges *et al.*, 1992; McCarthy *et al.*, 1993); [15]N (McCarthy *et al.*, 1997) and [31]P (Clark *et al.*, 1998) experiments can also be readily performed.

Liquid-state experiments are the more familiar variety used for organic structural elucidation. The sample is dissolved in a specialized solvent that is as free as possible of the nucleus of interest (e.g., if a ^{1}H-NMR liquid experiment is to be performed using an aqueous solvent, D_2O is used). Liquid state experiments inherently produce much sharper spectral lines, and thus have potential to provide more detailed structural information. In practice, however, very complex mixtures such as natural DOM produce complex overlapping resonances resulting in spectra that can closely resemble the broad lines of their solid state counterparts (e.g., Repeta *et al.*, 2002). ^{1}H-NMR experiments can be conducted rapidly on marine DOM, revealing the major distribution of those structural types that are soluble (e.g., Aluwihare *et al.*, 1997, 2002). In addition, liquid-state NMR offers the possibility of a wider variety of elaborate experimental possibilities, including multi-dimensional experiments targeting linkages between specific nuclei (e.g., Hertkorn *et al.*, 2006; Kaiser *et al.*, 2003; Kim *et al.*, 2003a).

For the nitrogenous component of DOM, as indicated above, ^{15}N nuclei can be examined directly (e.g., Aluwihare *et al.*, 2005; McCarthy *et al.*, 1997). Even with sample concentration, however, the relatively low natural abundance of ^{15}N generally makes solid-state experiments the method of choice. Experiments with ^{15}N-CPMAS have been valuable in revealing the major functional distribution of N in HMW DON (McCarthy *et al.*, 1997), and when combined with variable hydrolysis methods have been used to probe the relative amounts of amino-sugar and peptide amide bonds (Aluwihare *et al.*, 2005; Aluwihare and Meador, this volume). However, the fairly limited range of common N biochemical functionality makes the information potential of ^{15}N-NMR more limited than that for either C or H. [15]N spectra for DON study are thus most valuable when used in combination with other approaches mentioned above. Multi-dimension experiments to directly examine the linkages between N and C are possible, however, the low abundance of ^{15}N precludes their use on natural samples with current technology. Such techniques might, however, be employed in the future in mesocosms with DON production and degradation studies. Solid-state double cross-polarization experiments between C and N have been conducted with degrading plant remains, but these required isotopically enriched samples in both ^{13}C and [15]N (Knicker, 2002). A great deal more solid-state ^{15}N work has been described in the terrestrial and sedimentary literature (e.g., see Knicker, 2004 for a review), which might be applied to future work with isolated DON material, and particularly the more humic fraction from the deep ocean.

> ## 6. Basic Principles for the Measurement of Nitrogen Fluxes

6.1. Bioassays

There are two main approaches used to determine uptake rates—bioassays and tracers. In bioassays, the concentration of a given substrate is monitored over time (e.g., Seitzinger *et al.*, 2002). The advantage of bioassays is that they are relatively easy, and require only that suitable incubation conditions be maintained and the ability to measure the concentration of the substrate of interest. There are, however, drawbacks and limitations to their use. First, they only provide net uptake (or production) rates. If there is substantial substrate regeneration, such as one would expect in the case of NH_4^+, the uptake rate will be underestimated or even unmeasurable if the rate of regeneration is greater than the rate of uptake. Second, there is a fine line between incubating a sample long enough so that there is a detectable change in concentration and incubating it so long that bottle effects skew the results. Care must also be taken to maintain the sample under as close to *in situ* conditions as possible.

6.2. Stable isotopes

6.2.1. Basic principles

The other approach used to measure flux rates is the application of isotopic tracers and this approach is reviewed in detail in Glibert and Capone (1993) and Chapter 31 by Lipschultz, this volume. In the case of N, there are two isotopes that have been used—radioactive ^{13}N and stable ^{15}N. Unfortunately, ^{13}N has a very short half–life ($\sim$10 min) such that easy access to a nuclear reactor is required (e.g., Fuhrman *et al.*, 1988; Suttle *et al.*, 1990). The isotope ^{15}N, however, is widely used to trace N flow in the water column and sediment both in short-term, small volume incubations (e.g., Dugdale and Goering, 1967) and long-term, whole-system enrichments (e.g., Tobias *et al.*, 2003).

   The use of stable isotopic tracers is based on following a labeled compound from one pool (the source pool) to another (the target pool) (Sheppard, 1962). The principles described below are the same regardless of whether one is measuring rates in the water column or sediment. What changes are the protocols used to isolate the different fractions prior to isotopic analysis. The basic equation to calculate the flux rate from one pool to another is:

$$\text{Rate} = \frac{\text{Atom \% (R) of the Target Pool}}{\text{Atom \% (R) of the Source Pool} \times \text{Time}} \times [\text{Target Pool}] \qquad (28.4)$$

where atom %, often referred to as R in the literature, is the ratio of $^{15}N:^{15}N + ^{14}N$ in a pool, time is the length of incubation, and the brackets denote concentrations (see Chapter 31 by Lipschultz, this volume, for nuances in the use of this equation).

Relative to bioassays, advantages of the isotope tracer method include higher sensitivity, shorter incubation times, ability to measure gross uptake (e.g., total uptake corrected for any release of N during the incubation), and the ability to measure uptake in the presence of high rates of regeneration. One of the disadvantages of the approach is that the addition of a tracer may perturb the system if the addition is substantial, relative to the ambient concentration of the added substrate. This is particularly problematic in open ocean studies where ambient NH_4^+ and NO_3^- are at or near the limit of detection. Under these conditions, even a small "trace" addition (e.g., 0.03 μM) can be a serious perturbation.

6.2.2. Isolation of pools

Prior to isotopic analysis, either for natural abundance measurements or at the end of tracer incubations, the relevant N pools must be isolated. Here we review the isolation of the most important N fractions: PN, NH_4^+, NO_3^-, NO_2, DON, and urea.

6.2.2.1. NH_4^+ There are several methods available to isolate NH_4^+, including distillation, SPE, wet chemical, and direct diffusion. In distillation, the pH of the sample is raised to convert soluble NH_4^+ to volatile NH_3, generally with NaOH or MgO (e.g., Gilbert *et al.*, 1982). The sample is then heated, preferably under vacuum, condensed in a cool condenser, with the condensate ultimately trapped in a mildly acidic solution that converts the isolated NH_3 back to soluble NH_4^+. The acidified NH_4^+ is then evaporated and spotted on a filter (e.g., Harrison, 1978) or captured on a molecular sieve (e.g., Hoch *et al.*, 1992; Velinsky, 1989). Lipschultz (1984, cited in Glibert and Capone, 1993) used the molecular sieve to directly isolate NH_4^+ by placing it on a filter and then pouring the sample through the filter. While this is a quick and efficient method for freshwater, it is not usable with brackish or seawaters.

In SPE, the NH_4^+ in the sample is converted to indophenol following a variation of the phenol/hypochlorite method described above for measuring NH_4^+ concentrations. The indophenol solution is passed through an octadecyl C18 SPE column that binds the indophenol to the resin. The indophenol is then eluted with methanol. The recovery of NH_4^+ with this method is generally low, less than 30% (Selmer and Sorensson, 1986). Alternately, the indophenol can be extracted into dichloromethane (Dudek *et al.*, 1986); recovery is not explicitly stated but the blank calculations appear to assume it is quantitative. Recently the SPE approach has been modified to allow the analysis of low N seawater (0.01–0.1 μM) samples to be analyzed using a GC–MS (Clark *et al.*, 2006).

There are also a number of wet chemical approaches used to isolate NH_4 including precipitation with mercuric chloride (Fisher and Morrisey, 1985). This method, however, is problematic with marine samples and generates particularly toxic waste. A newer method converts NH_4^+ in natural waters to NO_2^-, via hypobromite, and then to N_2O using a sodium azide/acetic acid buffer solution; the N_2O produced is than analyzed using a mass spectrometer (Zhang *et al.* 2007).

Ammonium has also been isolated using direct diffusion (Brooks *et al.*, 1989; Kelley *et al.*, 1991; Sigman *et al.*, 1997; Slawyk and Raimbault, 1995). In this method, the pH is raised and an acidified glass fiber filter is suspended above the sample and the bottle is sealed. The sample is then placed in a heated oven or placed on a shaker table. The increase in pH will produce volatile NH_3, which is then captured on the acidified filter (Brooks *et al.*, 1989); another variation of this approach places the acidified filter into a Teflon envelope (Sigman *et al.*, 1997). Any method that requires a change in pH, such as diffusion or distillation, should be used with care because of the risk of hydrolyzing amino groups from organic compounds (Bronk and Ward, 2000; Sigman *et al.*, 1997). Hydrolysis will result in transfer of label from the DON pool into the NH_4^+ pool and this transfer would be difficult to quantify. Another potential artifact to consider is that incomplete isolation can lead to isotopic fractionation. This is especially problematic with distillation and diffusion methods. Holmes *et al.* (1998) published a diffusion method that used large sample volumes (up to 4 L) but that accounts for the isotope fractionation. Finally, whatever method is selected it is important to quantify the method blank and to correct the final atom % enrichment accordingly (see section below).

6.2.2.2. NO_3^- and NO_2^-   Isolation procedures for NO_3^- generally involve converting the NO_3^- to some other form. Nitrate can be converted to NH_4^+ with DeVarda's Alloy (e.g., Bronk and Ward, 1999), zinc dust (e.g., Gardner *et al.*, 1995) or titanium(III) chloride ($TiCl_3$, Cresser, 1977), and then the NH_4^+ is isolated using any of the suite of NH_4^+ isolation methods described above.

Nitrate can also be converted to NO_2^- using cadmium reduction (columns or spongy cadmium) as described above. Once the NO_3^- is in the form of NO_2^-, the NO_2^- can be isolated via organic extraction (e.g., Olson, 1981) or with SPE after the NO_2^- is converted to an azo dye (Kator *et al.*, 1992). Nitrate can be isolated by conversion to N_2O via sodium azide in an acetic acid buffer solution (McIlvin and Altabet, 2005). Another approaches uses a genetically engineered denitrifier to convert NO_3^- to N_2O (Sigman *et al.*, 2001); the bacteria will denitrify NO_3^- in a sample to N_2O, but lacking nitrous oxide reductase the bacteria cannot take the reaction to completion and form N_2. The N_2O produced by either approach can then be analyzed on a mass spectrometer. A more detailed discussion of these methods is presented in Chapter 31 by Lipschultz, this volume.

6.2.2.3. DON   At present, there are three basic approaches used to isolate DON for tracer experiments: wet chemical isolation, ion retardation or dialysis, described above. The suitability of a method is judged by its ability to remove all of the DIN forms (NH_4^+, NO_3^-, and NO_2^-) and to isolate the DON pool with high efficiency. Ultrafiltration is not a suitable isolation method for use in determining DON release rates because it only isolates the higher MW fraction and thus allows the LMW moieties, which are likely important short-term release products, to be lost.

There are several variations of the wet chemical approach, first introduced by Axler and Reuter (1986), but all involve removing inorganic N species from

solution so that the remaining DON can be analyzed. In this approach, NH_4^+ is removed by raising the pH slightly, thus effecting a change from soluble protonated NH_4^+, to the more volatile NH_3 via diffusion in a heated oven (Slawyk and Raimbault, 1995) or vacuum distillation (Bronk and Ward, 1999). A high-speed concentrator (e.g., SpeedVac) is particularly useful for NH_4^+ removal because the process can take place at room temperature or lower, thus decreasing the possibility of acid hydrolysis (Bronk, unpublished data). Nitrate in the sample can then be converted to NH_3 with DeVarda's alloy, with the NH_3 again removed through volatilization (Bronk and Ward, 1999; Miyajima $et\ al.$, 2005; Slawyk and Raimbault, 1995) or any of the other approaches outlined above. Both of these techniques can suffer from the artifact of losing labile DON as a result of base hydrolysis (Bronk and Ward, 2000). The problem in the isolation is likely the lengthy diffusion step undertaken to remove NH_4^+, NO_3^-, and NO_2^- from solution. A number of other protocols have been used with varying success to remove NO_3^- and NO_2^-, including vanadium (VIII, Cox, 1980; Garside, 1982), titanium (TiIII, Cresser, 1977; Cox, 1980; Bronk $et\ al.$, unpublished data), and other DeVarda's alloy approaches (Page $et\ al.$, 1982). Breakdown and loss of DON is always a danger due to the rigorous reducing conditions needed to remove NO_3^-. Some researchers even use heated diffusion as a mechanism to remove labile DON before isolation of NO_3^- (Sigman $et\ al.$, 1997). For a review of potential artifacts during wet chemical DON isolation and the different types of DON release rates and their calculation protocols see Bronk and Ward (2000) or Chapter 31 by Lipschultz, this volume.

6.2.2.4. Urea
Urea can be isolated for isotopic analyses by using urease to break down urea to NH_4^+ (e.g., Lomas $et\ al.$, 2002; Slawyk $et\ al.$, 1990). Before urease is added to the sample, however, the preexisting NH_4^+ must be removed, ideally with distillation. Rysgaard and Risgaard-Peterson (1997) removed the preexisting NH_4^+ with high efficiency using cation exchange.

6.2.2.5. Particulate nitrogen
Particulate N is isolated by filtration with a filter capable of withstanding the combustion needed to convert the N on the filter to N_2 gas so that the sample can be analyzed isotopically. The most commonly used filter is composed of glass fibers; these include the GF/F or GF/C filters with nominal pore sizes of 0.7 and 1.2 µm, respectively. Many other commonly used filters, such as polycarbonate or cellulose filters, produce a large amount of CO_2 upon combustion, which will rupture ampoules or combustion tubes in mass spectrometers. One problem with using glass fiber filters, however, is that they retain a variable amount of detritus and bacteria, in addition to phytoplankton. Some separation of bacteria and phytoplankton can be achieved using size fractionation, but any filter used must withstand the combustion required with mass spectrometric analysis. Suitable filters include those made of silver or alumina silicate (e.g., Anopore®). Silver filters are available in a range of pore sizes (0.2–5.0 µm), but they are expensive with notoriously slow filtration rates. The alumina silicate filters come in 0.2 µm pore sizes, suitable for isolating the bacterial fraction, however, they too have very low flow rates as well as being very brittle. If one wants to collect the bacterial fraction, it is

often quicker to preconcentrate over a 0.2 μm filter with a higher flow rate, such as a Supor$^®$ membrane, and then filter the concentrated sample onto a silver or Anopore$^®$ filter as a final step. Regardless of the filter type used, all should be baked (450°C for a minimum of 2 h) to remove contaminant N; be sure to remove the plastic ring on Anopores$^®$ prior to backing.

Flow cytometry can also be used to separate phytoplankton from bacteria and detritus (e.g., Lipshultz, 1995; Casey *et al.*, 2007). Another technique being used to remove detritus from particulate samples is centrifugation with colloidal silica (Hamilton *et al.*, 2005). With this technique the sample is mixed with the colloidal silica and then centrifuged. Detritus and living cells are separated based on density differences; detritus tends to be heavier.

6.2.3. Isotopic analysis

Isotopic analysis separates isotopes on the basis of small but significant differences in mass (see Chapter 31 by Lipschultz, this volume). This can be done using an emission spectrometer or a mass spectrometer. With both types of instruments, the sample must be converted to a gas prior to analysis. Emission spectrometers operate based on the principle that a N_2 gas molecule comprised of a ^{15}N and ^{14}N will fluoresce at a different frequency then a molecular comprised of two ^{14}Ns or two ^{15}Ns (reviewed in Preston, 1993). Isotope ratio mass spectrometers separate and quantify the different N_2 gas molecules based on their behavior when they are accelerated through a magnetic field (reviewed in Mulvaney, 1993). Emission spectrometers seem to have fallen out of favor in the quest for bigger and better instruments. They do have advantages, however. Emission spectrometers are much cheaper to purchase and maintain, they are portable, they require smaller masses of N for analysis than many mass spectrometers, and there is no possibility for carry over from sample to sample because each sample is sealed in an ampoule prior to analysis.

7. Measurement of Nitrogen Uptake and Release Rates

7.1. Uptake rates

7.1.1. Substrate additions

A large suite of substrates are now available with ^{15}N label (NH_4^+, NO_3, NO_2, urea, amino acid mixtures, and individual DFAA). Many of the organic forms are also available with dual labels (^{15}N and ^{13}C) such that the flux of both N and C can be followed simultaneously. Similarly, ^{13}C–labeled sodium bicarbonate can be added to ^{15}N incubations such that an estimate of primary production and N uptake can be derived from the same sample (Dauchez *et al.*, 1995; Legendre and Gosselin, 1997; Parker, 2005; Slawyk *et al.*, 1977).

In addition to commercially available tracers, methods exist for making a number of other labeled substrates. In the case of DON uptake studies, one option is to have the resident plankton community make the DON tracer by adding ^{15}N–labeled

NH_4^+ or NO_3^- and then incubating (Bronk and Glibert, 1993b; Veuger *et al.*, 2004). During the course of the incubation the labeled substrate is incorporated and some fraction is released as $DO^{15}N$. This $DO^{15}N$ can then be isolated and added back to a new water sample to quantify DON uptake (Bronk and Glibert, 1993b; Bronk *et al.*, 2004). Labeled humic substrates can be made by growing *Spartina alterniflora*, a common marsh plant, with ^{15}N-labeled NH_4^+ in the sediment for several months (See and Bronk, 2005). The *Spartina* is then cut, dried, ground in a mill, and then incubated in the dark while stirring in recently collected coastal seawater. The resident bacteria in the seawater ''humify'' the *Spartina* particles generating humic substances. These labeled humics can then be isolated from solution using macroporous resins, as described above, and then used to quantify humic-N uptake (See, 2003; See *et al.*, 2006). The humics can also be dually labeled with ^{13}C by enclosing the *Spartina* plant in a bag and volatizing ^{13}C-labeled sodium bicarbonate with acid (See *et al.*, 2006).

7.1.2. Incubation considerations

Three things must be considered when incubating samples—light, temperature, and time. To measure *in situ* (in place) rates, ideally, all conditions during the incubation would the same as those where the sample was collected—or as close to it as possible. With respect to light, the light field should mimic the location and depth where the samples were collected. This can be accomplished by neutral density screens or, better yet, neutral density film (e.g., Cochlan and Bronk, 2003). Temperature is also important to consider, particularly when measuring rates (think Q_{10}). If vertical profiles are done, cells deeper in the water column are generally much cooler than those at the surface and must be incubated accordingly. Temperature controlled water baths are ideal. In a pinch a cooler and ice can do the job but care must be taken to keep the water well mixed. One way to avoid issues of light and temperature is to do *in situ* incubations where samples are tethered on a line at the depths where they were collected (e.g., Smith *et al.*, 2000). With respect to length of incubation time, generally speaking, the shorter the better. The shorter the incubation time, the lower the likelihood and severity of bottle effects (e.g., Venrick *et al.*, 1977). The desire for short incubations must be balanced, however, with the need for incubations to be long enough to see measurable changes in the parameter of interest. One common exception to the shorter is better rule occurs when daily integrated rates are needed, in which case, 24 h incubations are used.

7.1.3. Uptake rate calculations

Traditionally, N uptake rates have been based on the accumulation of ^{15}N-label in cells, defined as a net uptake rake (Bronk *et al.*, 1994), and are calculated based on the tracer principles described above with the extracellular substrate pool (e.g., NH_4^+) as the source pool and PN as the target pool:

$$\text{Uptake Rate} = \frac{\text{Atom \% (R) PN}}{\text{Atom \% (R) } NH_4^+ \times \text{Time}} \qquad (28.5)$$

Uptake rates can be presented as specific uptake (often designated as V), with units of per time, or absolute uptake (often designated as rho, ρ), with units of mass N per volume per time. Specific uptake rates are useful when comparing size fractions or systems that may differ substantially in biomass as they are more a measure of the physiological process of uptake. The absolute uptake rate is calculated by multiplying the specific uptake rate by the PN concentration (see Chapter 31 by Lipschultz, this volume).

During the course of the incubation, two processes can occur that impact uptake rates: isotope dilution and DON release. In the case of isotope dilution, unlabeled substrate is released during the course of the incubation, diluting the atom % enrichment of the source pool. In the case of NH_4^+ this occurs as a result of bacterial remineralization and zooplankton excretion (e.g., Dugdale and Wilkerson, 1986; Glibert et al., 1982). Failure to account for isotope dilution in the case of NH_4^+ uptake can result in large underestimates in NH_4^+ uptake rates. In the case of NO_3^- and NO_2^- uptake, isotope dilution can occur as a result of nitrification (e.g., Ward et al., 1989). Most studies do not take into account isotope dilution of the NO_3^- pool, with some notable exceptions (e.g., Lipschultz, 2001). Evidence suggests, however, that nitrification can be an important process at the base of the euphotic zone and so NO_3^- isotope dilution should be quantified (Ward et al., 1989). Methods to isolate NH_4^+ and NO_3^- for isotopic analysis are described above (also see Chapter 31 by Lipschultz, this volume). Isotope dilution could also affect uptake rates of organic substrates such as urea, which can have high rates of regeneration (Bronk et al., 1998), though this correction is not commonly done due to the labor intensive methods involved. To correct uptake rates for isotope dilution an exponential average is calculated based on the initial and final atom % enrichment of the source pool (e.g., Glibert et al., 1982).

In addition to isotope dilution of the DIN pools, DON can be released during the course of the experiment. The DON pool can be isolated so that the amount of ^{15}N released to the pool can be quantified. This recently released N was taken up by the cells and so should be included in the uptake calculation. This rate is referred to as a gross uptake rate, ρ_G, and is the sum of measured uptake plus any N that was taken up and released as DON. The difference between gross and the traditionally measured net uptake rates results from the release of ^{15}N-label to the DON pool. When ^{15}N-labeled DON is released to the extra cellular DON pool, it is no longer in the pool and so is not included in the traditional calculation of N uptake (Bronk and Ward, 2000; Bronk et al., 1994). The following equation is used to calculate a gross N uptake rate p(ρ_G):

$$\rho_G = \frac{(PN \times PN\ at\%xs) + (DON \times DON\ at\%xs)}{DIN\ at\%xs \times Time} \quad (28.6)$$

where PN and DON are the mass of N in the PN and DON pools, PN and DON at%xs are the ^{15}N atom % enrichments of the PN and DON pools minus the atom % of an atmospheric N standard, DIN at%xs is the atom % excess enrichment of the DIN pool, and time is the period of incubation (Bronk et al., 1998).

7.2. Release rates

7.2.1. NH_4^+ regeneration

Here we describe methods to measure three release rates: NH_4^+ regeneration, urea regeneration and DON release. Rates of NH_4^+ regeneration can be measured using the principle of isotope dilution. To measure regeneration, a tracer addition (generally at <10% of the ambient concentration) is added to a water sample. At the end of the incubation the atom % enrichment of the NH_4^+ pool is either measured directly, using HPLC (Gardner and John, 1991; Gardner et al. 1991, 1993), or using a mass spectrometer after the pool is isolated using one of the methods outlined above. The assumption is made that any NH_4^+ released during the incubation is $^{14}NH_4^+$. This will dilute the $^{14}NH_4^+$ and $^{15}NH_4^+$ present at the start of the experiment. The regeneration rate is then measured by following the flow of the unlabeled NH_4^+ into the labeled NH_4^+ pool (Blackburn, 1979; Caperon et al., 1979). To measure rates using the principles of isotope dilution one must measure the change in isotopic composition of a pool over time and then solve the following equations:

$$P_t = P_0 + (d - u)t \qquad (28.7)$$

$$\ln(R_t - R_a) = \ln(R_0 - R_a) - [d/(d - u)][\ln P_t/P_0] \qquad (28.8)$$

where P_t and P_0 are the ambient concentrations of NH_4^+ at the end and beginning of the incubation, respectively, u is the absolute uptake rate, d is the regeneration rate, t is the incubation time, R_t and R_0 are the atom % enrichments of PN at the end and beginning of the incubation and R_a is the atom % of ^{15}N in the atmospheric standard.

7.2.2. Urea regeneration

Rates of urea regeneration can be calculated in an analogous fashion to that used for NH_4^+. The urea pool can be isolated using the urease method described above. The atom % of the isolated urea pool is measured at the start and end of the experiment and the regeneration rate is calculated using the equations above after replacing NH_4^+ with urea. Urea uptake and regeneration can also be measured simultaneously by performing parallel incubations with comparable concentrations of ^{14}C and ^{15}N-labeled urea. The ^{14}C-labeled samples are used for the determination of isotope dilution and the rate of urea regeneration (Hansell and Goering, 1989).

7.2.3. DON release

There are two general ways to calculate a DON release rate. The first is to measure the passage of ^{15}N from an intracellular ON pool to the extracellular DON pool (Bronk and Glibert, 1991, 1993a). This rate is specified "the intracellular pool (IP) DON release rate" to indicate that intracellular pools are used in its calculation. The isolation of the intracellular DON pool also allows the calculation of a transformation rate, which is a measure of the transformation of NH_4^+ to organic N intracellularly (Bronk, 1999). There are a number of different methods used to isolate the intracellular N pool including bursting cells with boiling distilled water and rupturing the cells with trichloroacetic acid (e.g., Clayton et al., 1988, Lanvin and Lourenço, 2005).

An easier, less labor intensive means of measuring DON release rates was later introduced by Bronk *et al.* (1994) that was based solely on the change in the ^{15}N atom % enrichment of the extracellular DON pool and did not require isolation and measurement of the intracellular ON pool (Bronk *et al.*, 1994). This DON release rate is calculated as the difference between the gross N uptake rate (ρ_G) and the traditionally determined net N uptake rate (ρ) defined above:

$$\text{DON release rate} = \rho_G - \rho = \frac{\text{DON at\%xs} \times [\text{DON}]}{\text{DIN at\%xs} \times \text{Time}} \qquad (28.9)$$

where DIN and DON at%xs are the ^{15}N atom % enrichments of the DIN and DON pools respectively, minus the atom % enrichment of the atmospheric N standard, [DON] is the concentration of DON, and time is the incubation time (Bronk and Ward, 2005).

This DON release rate, referred to as the extracellular pool (EP) release rate, is equivalent to the rate termed ρDIN by Slawyk *et al.* (1998). We suggest that the more common EP DON release rate should be taken as "the DON release rate" (Bronk and Ward, 2000; Bronk *et al.*, 1994). When the transfer of N from the intracellular to the extracellular DON pool is being measured, that rate should be specified an IP DON release rate as originally described (Bronk, 1999).

Though in general the IP and EP DON release rates are similar, short-term variations in the atom % enrichment of the intracellular ON pool can cause some variations between them (Bronk, 1999; Mulholland *et al.*, 2004). The IP DON release rate is also very labor intensive and requires a host of assumptions, and therefore is less robust than the EP DON release method. The IP and EP distinctions are only necessary when both types of rates are being discussed (Bronk and Ward, 2000).

There are three potential artifacts that must be considered when measuring DON release. First, is the breakage of cells during filtration (e.g., Goldman and Dennett, 1985). If cells break releasing ^{15}N into the DON pool the rate of DON release will be overestimated. Second, is the potential for stressing cells during collection or incubation. Every effort should be made to maintain samples at *in situ* light and temperature conditions at all times and to avoid any additional environmental stresses. Third, underestimation of DON release can also occur due to loss of DON during the isolation process. Any method that includes heating of the sample under basic conditions has the potential to cause base hydrolysis and loss of recently released DON, and thus should be carefully evaluated before use on a given set of samples (Bronk and Ward, 1999; Slawyk and Raimbault, 1995). Loss of DON would be expected to vary depending on the composition of the DON pool, which could explain the different DON recovery efficiencies reported using various methods. These include 91.2% to 98.9% recovery for waters off the coast of France (Slawyk and Raimbault, 1995), generally less than 80% in Japanese coastal waters (Hasegawa *et al.*, 2000), and 42.7%±8.8% in waters from two rivers in Georgia and the South Atlantic Bight (Bronk, unpublished data).

8. Natural Abundance Measurements

The stable isotope ^{15}N is useful as tracer because it has the chemical characteristics of ^{14}N—almost! There is a kinetic isotope effect that causes the rate of reaction of molecules containing ^{15}N to be slightly different than those containing ^{14}N (reviewed in Shearer and Kohl, 1993). In chemical reactions that involve phase changes (i.e., evaporation), or that are catalyzed by enzymes, this kinetic isotope effect will result in a slight discrimination against the heavier isotope, a process known as fractionation. For example, if one were to boil a solution containing NH_3, of a known enrichment, the NH_3 that evaporated initially would have a slightly higher proportion of ^{14}N and the pool of NH_3 remaining in solution would become progressively more enriched with ^{15}N. These slight differences in ^{15}N natural abundance can be exploited to determine nutrient sources (e.g., Peterson, 1999; Tobias *et al.*, 2001), define trophic relationships, or to decipher large-scale biogeochemical changes (e.g., Altabet *et al.*, 2002). For a thorough coverage of natural abundance methods and applications see Lajtha and Michener (1994), Fry (2006) and Chapter 29 by Montoya (this volume).

Natural abundance measurements are made against a standard, atmospheric N_2 in the case of ^{15}N measurements, and are expressed in delta (δ) units:

$$\delta^{15}N = \frac{R_{sample} - R_{standard}}{R_{standard}} \times 1000\% \qquad (28.10)$$

R is defined in equation 4 above; data are described as the per mil ^{15}N excess. Prior to isotopic analysis, the various inorganic and organic N fractions must be isolated as described in the sections above.

9. Measurement of Other Nitrogen Transformation Rates

9.1. Nitrification

Nitrification is the process that converts NH_4^+ to NO_2^- and then NO_3^-. There are four main methods for measuring nitrification—bioassays, incubation with $^{14}CO_2$ with N-serve inhibition, incubation with $^{15}NH_4^+$ or $^{15}NO_2^-$, and ^{15}N isotope dilution (see method comparison by Enoksson, 1986). We offer a brief review here but direct the reader to Chapter 5 by Ward (this volume) for a more detailed discussion of the nitrification process and its measurement.

The bioassay approach involves incubating a sample in the dark and then measuring the change in NO_2^- and NO_3^- concentrations over time after the addition of NH_4^+. This is the simplest method but it suffers from all the problems of bioassays noted in earlier sections, most notably the requirement of long incubation times and the simultaneous uptake of the recently produced NO_2^- and NO_3^- resulting in an underestimated or unmeasurable rate. Some studies have

supplemented this approach with the application of inhibitors. For example, acetylene and N-serve have been used to inhibit NH_4^+ oxidation and chlorate has been used to inhibit NO_2^- oxidation (Bianchi *et al.*, 1997; Billen, 1976). If NO_2^- oxidation is inhibited by the addition of chlorate, for example, any change in NO_2^- concentration can be attributed to NH_4^+ oxidation.

One of the most sensitive ways to measure nitrification is to combine the inhibitor N-serve with ^{14}C incubation (Enoksson, 1986). This approach exploits the chemolithoautotrophic nature of nitrifiers whereby they incorporate $^{14}CO_2^-$ while oxidizing N. Fixation of $^{14}CO_2^-$ is measured in the presence and absence of the N-serve (see Chapter 5 by Ward, this volume for nuances of N-serve use) with the difference being attributed to nitrifiers. To convert the $^{14}CO_2^-$ fixation rate to a nitrification rate requires the application of a conversion factor, which can be problematic (e.g., Glover, 1985).

In the ^{15}N method, $^{15}NH_4^+$ or $^{15}NO_2^-$ is added to a sample and then the appearance of ^{15}N label in the NO_2^- or NO_3^- pools is measured over time (e.g., Olson, 1981). The advantage of this technique is that it is a direct, unambiguous measure of the process. One disadvantage is that the increase in NH_4^+ or NO_2^- concentrations caused by the tracer addition can result in enhanced NH_4^+ or NO_2^- oxidation rates (e.g., Helder and De Vries, 1983; Ward *et al.*, 1984). When small additions of ^{15}N are used, the isotope dilution of the substrate pool must be monitored over time.

Another tracer approach that has been used is to quantify nitrification is isotope dilution; this is an analogous approach to the much more commonly applied NH_4^+ isotope dilution approach discussed earlier (Glibert *et al.*, 1982). In this method the isotope dilution of the NO_2^- pool (in the case of NH_4^+ oxidation) or the NO_3^- pool (in the case of NO_2^- oxidation) is monitored over time (e.g., Capone *et al.*, 1992; Clark *et al.*, 2007).

9.2. Denitrification

Denitrification is the reduction of $NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$ gas that is mediated by bacteria under anaerobic conditions, most generally in microbial mats and sediments. There are a number of methods to measure denitrification: acetylene inhibition, isotope pairing, changes in N_2 fluxes, and changes in the N_2 to argon (Ar) ratio. Each of the techniques has their pros and cons and none is clearly superior under all conditions (see reviews by Cornwell *et al.*, 1999; Chapter 6 by Devol, this volume).

In the acetylene inhibition technique, acetylene is added to a water sample, which inhibits the reduction of N_2O to N_2 (Sorensen, 1978). The accumulation of N_2O is then measured using gas chromatography and an electron capture detector and the denitrification rate is taken to be equal to the total N_2O flux. One potential problem is incomplete inhibition of N_2O reduction to N_2, particularly in the presence of hydrogen sulfide, a compound commonly found under anaerobic conditions. Another potential problem with the technique is that acetylene also inhibits nitrification, a process that often supplies the NO_3^- and NO_2^- substrates for denitrification. To inhibit nitrification is to inhibit denitrification if it is at all substrate limited (Hynes and Knowles, 1978).

The isotope pairing approach was developed to quantify what fraction of measured denitrification was fueled by substrates in the water column, versus coupled nitrification–denitrification (Nielsen, 1992). In this approach, $^{15}NO_3^-$ is added to water overlying sediments. The denitrification rate is calculated from the rate of formation of $^{29}N_2$ and $^{30}N_2$ (Rysgaard et al., 1993). N_2 gas formed from denitrification in the water column will incorporate $^{15}NO_3^-$ while denitrified N_2 from coupled nitrification–denitrification will incorporate $^{14}NO_3^-$.

The most direct approach to estimate denitrification is the direct measurement of N_2 fluxes. Concentrations of dissolved N_2 gas are very high in natural waters, however, such that any direct measurement of N_2 gas flux must be done against a huge background. One way to get around this is to incubate cores with N_2-free water. Seitzinger (1987) used this approach in long-term incubations where N_2-free water overlying the sediment was changed daily for 10 days. After the tenth day, the sediment was incubated for 24 h, and the change in N_2 gas concentration in the overlying water (measured with gas chromatography) was taken to be the denitrification rate. One potential problem with this technique is the long incubation time needed and resulting depletion of labile organic substrates (e.g., Boynton et al., 1995). Multiple intercomparisons of the various methods have been done. In general the direct measure of N_2 gas fluxes gives higher denitrification rates than the acetylene inhibition or isotope pairing techniques (Cornwell et al., 1999).

The newest approach to measuring denitrification uses a mass spectrometer that can rapidly measure the N_2/Ar ratio in water using membrane inlet mass spectrometry (MIMS, Kana et al., 1994, 1998). In this approach, sediment cores are incubated under continuous flow conditions. The N_2/Ar ratio is then measured at the inlet and outlet of the core over time. Advantages of the technique are the short incubation times needed (usually less than 12 h), and the high throughput and small sample size ($\sim$5 ml) of MIMS analysis.

Anammox (i.e., anaerobic ammonium oxidation) is a recently discovered process that also results in N_2 gas production and so is another form of denitrification (see Chapter 6 by Devol, this volume). The overall anammox reaction is $NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O$. To date anammox rates have been quantified using parallel incubations with either ^{15}N-labeled NH_4^+ or ^{15}N-labeled NO_3^- and then analyzing the mass of the N_2 gas formed in the two incubations (e.g., Thamdrup et al., 2006). The formation of $^{29}N_2$ in the $^{15}NH_4^+$ treatment indicates anammox. The formation of $^{30}N_2$ in the $^{15}NO_3^-$ treatment indicates classic denitrification (see Chapter 6 by Devol, this volume for a more detailed discussion).

9.3. N_2 fixation

In the process of N_2 fixation, dissolved N_2 gas is taken up and converted to NH_4^+ and ultimately biomass (see Chapter 4 by Capone and Carpenter, this volume). Nitrogenase, the enzyme that catalyzes the fixation of N_2, is deactivated by oxygen so care must be taken not to introduce oxygen during the measurement. There are two commonly used methods to measure N_2 fixation—$^{15}N_2$ incorporation and acetylene reduction. Using the tracer approach, $^{15}N_2$ is injected into a gas tight bottle containing the water sample (e.g., Montoya et al., 1996; Mulholland et al., 2004). At the end

of the incubation (generally 1–12 h) the sample is filtered and analyzed mass spectro-metrically in a fashion analogous to the ^{15}N uptake samples described above. During the course of the incubation $DO^{15}N$ release can occur such that the rate measured using the tracer approach is a net uptake rate (Mulholland *et al.*, 2006).

The acetylene reduction approach is based on the ability of nitrogenase to reduce substrates with triple N bonds. During the measurement, acetylene gas ($HC\equiv CH$) is reduced to ethylene ($H_2C=CH_2$) in a theoretical molar ratio of 3:1 relative to N_2 gas ($N\equiv N$). To estimate N_2 fixation with this approach, a water sample is sealed in a gas-tight container and acetylene is added (Capone, 1993; Montoya *et al.*, 1996). At the end of the incubation, the concentration of acetylene and ethylene is measured using flame ionization gas chromatography. The rate of N_2 fixation is then calculated using a conversion factor to convert acetylene reduction to N_2 gas fixation. Release processes do not affect the acetylene reduction method such that the rate measured approximates a gross N_2 fixation rate.

Of the two approaches, the acetylene reduction technique is much simpler and less labor intensive. It is also considerably easier to take a gas chromatograph to sea so that rate measurements can be made at a field site. The acetylene reduction method is also more sensitive and reproducible than the tracer approach, and requires smaller sample volumes. The advantage of the tracer approach, however, is that no conversion factor is needed. The use of the 3:1 conversion factor has been debated for some time. A recent study compared rates of N_2 fixation in the Gulf of Mexico over a three-year period and found that the ratio of acetylene reduction to $^{15}N_2$ fixation was seldom 3:1 (Mulholland *et al.*, 2006). A review of the literature found that it varied from 0.9 (Capone *et al.*, 2005) to a high of 22 (Mulholland and Bernhardt, 2005; Mulholland *et al.*, 2004) suggesting that the difference between N_2 fixation rates measured with acetylene reduction (gross uptake) versus those measured with $^{15}N_2$ gas (net uptake) could be exploited to estimate N release during the incubation (i.e., gross − net, Mulholland *et al.*, 2004).

10. RECOMMENDATIONS FOR FUTURE RESEARCH

In this review we have tried to cover a broad range of topics relating to the analysis of both organic and inorganic N in the sea. Necessarily, the treatment of each has had to be relatively brief, but we hope as a whole it will provide the reader a useful reference to the current state of the art at the beginning of the twenty first century. We close below with a series of notes regarding the limitations of current methods, promising ideas for ongoing research, and new areas that are rapidly evolving.

10.1. Reference materials

The increased focus on building large global datasets of nutrient and organic concentrations has highlighted the wide disparity that can exist in results measured in different labs (Hopkinson *et al.*, 1993). These discrepancies were especially problematic for the measurement of DOC (Sharp *et al.*, 1993, 2002a) and DON (Sharp *et al.*, 2002b). Two

of the most important steps in achieving consistency between laboratories have been the development of suitable reference material (Sharp *et al.*, 2002a) and agreement on standard procedures (e.g., Knap *et al.*, 1997). Community standards for DOC analysis are now widely used (Hansell, 2005) and standard humic substances are available from the International Humic Substances Society (http://www.ihss.gatech.edu), which can be used for chemical characterization and NMR studies. There are, however, currently no corresponding community-wide sets of reference materials commonly used for most of the other analyses discussed here. A widely available set of different sample types (including sediments, plankton, or different waters) for which values would be commonly reported would be an invaluable asset for standardizing results from specific organic and other analyses. A push to identify, produce, and promote the standard use of such materials could be one of the most important of analytical efforts.

10.2. Improving DON isolation methods

A ''holy grail'' for DON (and DOM in general) remains a rapid and portable method to quantitatively isolate and desalt a large dissolved sample (Bronk, 2002). Such a method would not only allow a wealth of diverse techniques to be brought to bear on the largest unknown fraction of DON, but would allow direct isotopic measurements and compound-specific mass balances. Examples of some approaches currently being explored to improve DON recovery on both small and large scales include 'homemade' ion-retardation resins (Bronk, unpublished data), electrodialysis (Vetter *et al.*, 2007), and use of nano-filtration membranes coupled to standard ultrafiltration approaches (McCarthy *et al.* unpublished data).

Until new methods are perfected, however, improvements might be made by altering existing isolations, and by paying closer attention to the relationship between isolated material and the total DON pool. For example, as discussed above, UF isolates $\sim$20–30% of DOM after desalting, but the material retained by UF membranes before desalting can be much larger (Guo, 2000, McCarthy, unpublished data). For analyses that do not require desalting (e.g., wet hydrolysis protocols) substantial increases in the fraction of total DON recovered might be achieved by simply eliminating desalting steps, while carefully monitoring losses associated with increasing concentration factors. Confidence in any DON isolation method could also be increased by routinely examining the relationship between isolated material and the bulk DON. Careful DON mass balance should be measured for any isolated fraction, and direct comparisons should be made where possible with specific compound classes examined.

10.3. Hobbled by hydrolysis? Chipping away at the black box

The initial step in molecular-level analysis of DON's most abundant organic compound classes is typically acid hydrolysis, necessary to break polymeric biomolecules into monomers for separation and detection. While the subsequent derivatization and chromatography steps can be shown to be quantitative (it is only on the basis of these post-hydrolysis steps that molecular-level methods are usually termed ''quantitative'' in the first place), the efficiency of the key initial hydrolysis remains largely a black box—overall efficiency is not known, extent of side reactions are not well

understood, and compound-specific losses are difficult to quantify. Data from the HMW-DOM literature suggest that this hydrolysis step itself may be problematic, and could account for an important part of the gap between total DON and the fraction we can identify at the molecular-level. Comparisons between ^{15}N–NMR data for HMW-DOM, and molecular-level recoveries discussed above just do not add up. They suggest either that very large amounts of unknown amide-compounds (or small variants of known structures such as common amino acids and amino sugars) dominate detrital ON composition, or alternately that despite the efficiency of hydrolysis for pure compounds, efficiency in detrital natural mixtures is far lower. While it is almost certain that no single explanation accounts for the low recoveries of identifiable DON components (i.e., multiple structural variants certainly are likely, and have been demonstrated for some newly discovered carbon DOC components, e.g., Hertkorn *et al.*, 2006), potential problems with the key hydrolysis step are typically ignored, but may be a key issue.

Some possible hydrolysis issues include secondary condensation reactions (e.g., Allard *et al.*, 1998) or the physical environment of biopolymers (e.g., Knicker and Hatcher, 1997; Nagata and Kirchman, 1997; Nguyen and Harvey, 2001), which might act to limit efficiency of standard aqueous methods. Since hydrolytic cleavage will likely remain central for molecular-level analyses, investigating hydrolysis methodology may be a very important, if highly un-glamorous, analytical endeavor. A series of extraction and hydrolysis method comparisons has recently been published for sugars in marine samples (Panagiotopoulos and Sempere, 2005). A similar systematic study specifically aimed at DON components has not been done, but would be extremely valuable. In particular, approaches designed to minimize melanoidan formation during hydrolysis (e.g., Allard *et al.*, 1998) should be investigated, and vapor-phase hydrolysis conditions might also be re-examined. The reasons for the substantial increases in vapor-phase amino acid yields noted in some samples, but not others (e.g., Jørgensen and Jensen, 1997; Keil and Kirchman, 1991b), have not been resolved, but might be consistent with increased penetration of shielded or encapsulated OM. Finally, overall extent of formation of secondary products and fate of major biochemicals might be examined by a combination of solid-state NMR and isotopic tracers. Overall, while improvements in hydrolysis conditions may be made, devising a perfect hydrolysis is not likely. This makes understanding and quantifying the extent of losses (i.e., is hydrolysis 80%, 50%, or 25% efficient for major N compounds?) and especially the selectivity of any hydrolytic losses extremely important to closing DON compositional budgets. As rapidly advancing mass-spectral approaches give us new tools to examine complicated ranges of structures (see below), a parallel effort to define the limitations of commonly used hydrolyses could help to significantly narrow the mystery of the majority "unidentified" DON.

10.4. DON Geomolecules? Exploring the nature of "humic" DON

New methods in ultra-high resolution mass-spectrometry are making progress in understanding complex distributions of similar structural variants, providing the promise of new tools to understand how wide the distribution of ON structures

in DON really is, as well as at last getting at nitrogenous humic materials. Despite the fact that the majority of DON appears to be composed of familiar biomolecules (like amino acids and amino sugars), solid state NMR of HMW-DON also suggests that increasing levels of unsaturated N compounds are present in the mid-water and deep ocean (McCarthy *et al.*, 1996). Electrospray ionization (EI) coupled to Fourier transform cyclotron resonance mass spectrometry (FTCR-MS) is a rapidly evolving ultra-high resolution MS approach that can potentially resolve the entire suite of individual compounds in dissolved humic materials (see Kujawinski *et al.*, 2002 for a good overall introduction, and Marshall *et al.*, 1998 for a full review). It has been shown that every individual compound can be resolved for natural humic and fulvic samples with mass accuracy up to 0.001 D (Kujawinski *et al.*, 2002; Stenson *et al.*, 2003), suggesting it is possible to generate molecular formulas for all components across the range of MW falling within ocean DOM (Koch *et al.*, 2005), and thus focus on compounds containing N. Drawbacks include the fact that ESI is not a quantitative technique (i.e., ionization is selective), and for ocean DOM it is necessary to obtain both concentrated and desalted samples, which introduces an additional level of selectivity.

Despite these limitations, the detailed molecular information of EI-FTIR-MS promises an important increase in our knowledge of the most murky of DOM components. The few studies that have so far been done on ocean waters use some form of SPE with acidified samples to simultaneously achieve both ends (e.g., Koch *et al.*, 2005; Kujawinski *et al.*, 2004), while at the same time likely removing much of the DON (Koch *et al.*, 2005). For investigating the humic fraction of DON, this selectivity may actually be an advantage. SPE isolates the smaller MW components that make up majority of ocean DOM, and also likely account for the most refractory components (Amon and Benner, 1994).

10.5. Higher order of information: Proteomics in DON

At the other end of the molecular size spectrum, rapidly advancing mass spectrometry techniques for determining protein sequence are being coupled with advances in genomics, creating new tools to decipher information locked in DON's largest surviving biomolecules. Proteomics employs the rapidly evolving field of protein mass spectrometry to examine the range of proteins expressed by organisms (e.g., Aebersold and Mann, 2003; Tyson *et al.*, 2004; Venter *et al.*, 2004). For study of DON these constitute new tools for understanding both the phylogeny of major groups contributing to the DON pool, as well identifying active enzymes that may be important in DON cycling. Using ultrafiltration to isolate the protein size fraction, proteomics has just begun to be applied to DON (Powell *et al.*, 2005) and has already suggested that a broader range of dissolved protein types may exist than had been previously identified. Proteomics approaches should be highly complimentary to the growing literature using N-terminal sequence approaches discussed above (Tanoue, 2000). Finally, expanding projects undertaking broad surveys of ocean genomes (''Metagenomics,'' e.g., Rusch *et al.*, 2007) may provide key background databases needed to interpret newly acquired proteomic information.

10.6. Compound-specific isotopes: New molecular level tools for cycling and origin

The instruments to make rapid, compound–specific isotope measurements have provided one of the most important new set of organic geochemical tools for tracing OM source and process. The large majority of this work has been done with non-polar compound classes using GC coupled to isotope ratio mass spectrometry (GC-IRMS). Compound-specific isotopic analysis of amino acids, and to a lesser extent sugars, are becoming common and represent a powerful new approach to understanding source and transformation of ON in the environment. Differences between diagnostic amino acids can reveal a new level of information about ON including original autotrophic δ^{15}N and number of subsequent trophic transfers (McClelland and Montoya, 2002), food webs of origin (Corr *et al.*, 2005), and potentially extent of microbial heterotrophic processing (McCarthy *et al.*, 2004, McCarthy *et al.*, 2007; Ziegler and Fogel, 2003).

As continuous flow IRMS instruments become common, it is likely that these measurements will greatly extend information from standard molecular % data of N biopolymers. While most early work has been done on either non–marine samples or biota, compound specific δ^{13}C– (McCarthy *et al.*, 2004) and δ^{15}N–amino acid (McCarthy *et al.*, 2007) have been made in HMW-DOM. Similar GC-IRMS techniques have also been developed for sugars (e.g., Derrien *et al.*, 2003; Macko *et al.*, 1998; Teece and Fogel, 2007), although they have not yet been explored for amino sugars in DON. Obtaining enough sample would be a challenge here, however, compound-specific analyses of amino sugars might be capable of addressing source issues as well as provide an independent means to assess the relative contribution of these compounds to the total DON.

In addition to stable isotopes, since the mid-1990s molecular-level radiocarbon (^{14}C) measurement has become a frontier in compound-specific isotopic measurement (Eglinton *et al.*, 1996). Compound-specific ^{14}C provides another independent dimension of source information, and in many cases a way to directly investigate cycling rates of compound-classes of interest (Aluwihare *et al.*, 2002; Eglinton *et al.*, 1997; Pearson and Eglinton, 2000; Repeta and Aluwihare, 2006). Compound-class or compound-specific ^{14}C offers, for the first time, the ability to directly estimate relative cycling rates of major DON components, independent of bulk DOC. Compound class-level isolations and ^{14}C measurement of total amino acids can be made using modifications of standard hydrolysis and cleanup protocols (Wang *et al.*, 1998; Loh *et al.*, 2004). Evolving compound-specific ^{14}C methods for collecting and purifying individual major nitrogenous compounds will in the future significantly improve resolution and accuracy of these initial efforts.

10.7. Rates—Who is doing what?

Currently the bulk of all N uptake rates ever measured have used some form of glass fiber filter. As a result, the rates represent uptake by autotrophs as well as a variable fraction of the bacterial community. This has broad implications when one considers the use of such commonly calculated parameters as the f-ratio, the ratio of new to

total (new plus regenerated) production (Eppley and Peterson, 1979). The f-ratio is estimated using ^{15}N-based uptake rates of NO_3^- uptake (new production) to NO_3^- plus NH_4^+ uptake (regenerated production). Now consider that a significant fraction of the NH_4^+ uptake measured is not fueling primary producers at all but is instead being taken up by heterotrophic bacteria caught on the GF/F filter. Flow cytometry, when combined with other techniques, has a great potential for expanding our understanding of competitive interactions because microbial groups can be distinguished optically, sorted, and then collected for specific analyses (e.g., Pel *et al.*, 2004a,b). Consequently, incubations can include intact communities, maintaining ecological integrity, while rate processes can be evaluated on a group-specific basis. Another advantage of using flow cytometry is that detritus, an often large but inactive component of the PC and PN pools, can be removed or sorted out of samples so as not to bias estimates of cellular C and N in the active pools.

Nitrogen Stable Isotopes in Marine Environments

Joseph P. Montoya

Contents

1. Introduction

Nitrogen is a critical constituent of organic matter and is in short supply in many oceanic environments. The marine nitrogen cycle is complex, involving multiple oxidation states of nitrogen and multiple pathways interconnecting most of the biologically active pools. These processes occur on a broad range of spatial and temporal scales; some of which are not readily accessible using traditional biological measurements such as the ^{15}N-tracer studies described elsewhere in this volume (see Lipschultz, Chapter 31, this volume). The natural abundance of the rare stable isotope of nitrogen, ^{15}N, can provide critical insights

into processes acting on a variety of scales with minimal alteration and manipulation of the system being studied and with spatial and temporal integration that complements experimental studies using ^{15}N-labeled substrates, which generally involve short-term incubations of small, isolated samples of water under *in situ* or simulated *in situ* conditions.

The distribution of nitrogen isotopes within marine ecosystems can provide a record of the sources of N supporting biological production and the major pathways and mechanisms moving nitrogen through the biota. In general terms, the isotopic composition of a pool of nitrogen can be used in identifying the relative importance of sources that are isotopically distinct, or in identifying processes that add or remove nitrogen with a characteristic pattern of isotopic discrimination. The primary challenge in using this biogeochemical approach is the complexity of the marine nitrogen cycle and the potential influence of multiple processes on the isotopic composition of many of the biologically active pools of nitrogen. Successful use of nitrogen isotopes in resolving N cycle fluxes and processes requires an understanding of the general distribution of nitrogen isotopes in marine systems, the nature of isotopic fractionation, and a careful consideration of the processes at work in the system of interest. Here I provide an overview of the general isotopic systematics of nitrogen in marine systems and the ecosystem-level processes that lead to variations in isotopic composition. I will use examples drawn from marine systems with a focus on processes occurring in the water column of the modern ocean. Paleoceanographic applications of nitrogen isotopes are discussed elsewhere in this volume (see Galbraith *et al.,* Chapter 34, this volume), as are experimental approaches using substrates artificially enriched in ^{15}N (see Lipschultz, Chapter 31, this volume).

2. BACKGROUND

Substantial variations in the natural abundance of ^{15}N in marine systems were first documented in the 1950s (Hoering, 1955; Parwel *et al.,* 1957), and the earliest focused studies of nitrogen isotopic abundance in marine biota were carried out beginning about a decade later (Miyake and Wada, 1967; Wada *et al.,* 1975; Wada and Hattori, 1976; Minagawa and Wada, 1984). These and subsequent studies of the distribution of nitrogen isotopes in marine systems suggested that the natural abundance of ^{15}N in marine systems could be used as an indicator of the sources of nitrogen entering an ecosystem and supporting biological productivity, and as an index to the trophic position of marine animals. These general themes continue to motivate much of the ongoing work on the stable isotopes of nitrogen in marine systems.

2.1. Basic definitions

^{15}N is a minor stable isotope, constituting 0.365 at% of the global pool of nitrogen (Nier, 1950). As a practical matter, it is much easier to quantify the difference in isotope abundance or in isotope ratio (e.g., ^{15}N:^{14}N) between two samples than to

measure the absolute isotope ratio in either one. This analytical constraint leads to the common use of the "δ" convention for expressing the natural abundance of ^{15}N in a sample relative to the isotopic composition of a standard reference material:

$$\delta^{15}N = \left(\frac{R_{\text{sample}}}{R_{\text{standard}}} - 1\right) \times 1000 \qquad (29.1)$$

where R_{sample} and R_{standard} represent the isotope ratio $^{15}N{:}^{14}N$ in a sample and in atmospheric N_2, respectively. $\delta^{15}N$ values therefore represent the "per mil" (‰) difference between the isotope ratio of a sample and that of atmospheric N_2. For natural samples in marine environments, $\delta^{15}N$ varies between about -2‰ and 30‰. Extreme values tend to be associated with regional dominance of either N_2-fixation or denitrification, providing one of the broadest scale nitrogen isotope contrasts in the ocean (see later text). Note that the $\delta^{15}N$ of a sample is a simple linear transform of its isotope ratio ($^{15}N{:}^{14}N$). For natural abundance level samples, the isotope ratio is effectively equal to the mole-fraction of ^{15}N (^{15}X) in the sample:

$$^{15}X = \frac{^{15}N}{^{15}N + {}^{14}N} = \frac{R}{1 + R} \approx R \qquad (29.2)$$

when R is small relative to 1. This equation makes it simple to convert between $\delta^{15}N$ values and the at-% units commonly used in tracer-level studies of the nitrogen cycle (e.g., Lipschultz, Chapter 31, this volume) since

$$\text{at\%}^{15}N = 100 \times \frac{R_{\text{sample}}}{1 + R_{\text{sample}}} \qquad (29.3)$$

and

$$R_{\text{sample}} = \left(\frac{\delta^{15}N}{1000} + 1\right) \times R_{\text{standard}} = \left(\frac{\delta^{15}N}{1000} + 1\right) \times 0.00366 \qquad (29.4)$$

2.2. Kinetic fractionation

Most biologically mediated reactions in the marine nitrogen cycle involve measurable discrimination against the heavy isotope, ^{15}N, which is critical in producing the ecosystem-level patterns we observe in $\delta^{15}N$ of marine nitrogen. Kinetic isotope fractionation reflects the difference in reaction rate for molecules containing the two isotopes of nitrogen, which in turn reflects the different bond strengths and mobilities of these isotopic species. The degree of isotopic fractionation associated with a reaction is commonly expressed as a dimensionless

fractionation factor, α, which is simply the ratio of rate constants for molecules containing the different isotopes:

$$\alpha = {}^{14}k/{}^{15}k \qquad (29.5)$$

In this case, ${}^{14}k$ and ${}^{15}k$ are the rate constants for molecules containing the light and heavy isotopes, respectively, and most reactions discriminate against the heavier isotope, yielding $\alpha > 1$. The inverse convention ($\alpha' = {}^{15}k/{}^{14}k$) is also used by some authors (e.g., Mariotti *et al.,* 1981), potentially leading to confusion when fractionation factors reported by different authors are compared. For most reactions, α falls between 1.000 and 1.030, making it convenient to define an isotopic discrimination factor that more clearly highlights this range of variation:

$$\epsilon = (\alpha - 1) \times 1000 \qquad (29.6)$$

For systems not artificially enriched in ${}^{15}N$ (e.g., tracer experiments), the discrimination factor is essentially equal to the difference between the $\delta^{15}N$ of the substrate and the $\delta^{15}N$ of the product of a fractionating reaction:

$$\epsilon \approx \delta^{15}N_{substrate} - \delta^{15}N_{product} \qquad (29.7)$$

This relationship holds for the substrate pool undergoing reaction and the product being formed from that pool, i.e., for the instantaneous state of the reaction system. The preferential removal of ${}^{14}N$ in the course of a reaction will naturally lead to a progressive increase in the $\delta^{15}N$ of the remaining substrate pool. For example, phytoplankton assimilation of nitrate (NO_3^-) typically shows a discrimination factor (ϵ) of 1–10‰ (Montoya and McCarthy, 1995; Waser *et al.,* 1998a,b; Needoba *et al.,* 2003, 2004). Figure 29.1 shows the trajectory of $\delta^{15}N$ of NO_3^- and phytoplankton biomass in a closed system (e.g., a culture flask) initially containing 20 μmol L^{-1} NO_3^- and a very small inoculum of phytoplankton that discriminate against ${}^{15}N$ with $\epsilon = 5$‰. Note that both the NO_3^- and the phytoplankton biomass become progressively enriched in ${}^{15}N$ (i.e., $\delta^{15}N$ increases), but that the mean $\delta^{15}N$ of the combination of NO_3^- and phytoplankton must remain constant because of the conservation of mass and isotopes within a closed system. When the reaction has gone to completion and all the NO_3^- has been converted to phytoplankton biomass, the phytoplankton $\delta^{15}N$ is equal to the $\delta^{15}N$ of the original pool of substrate (Fig. 29.1). In other words, there is no record of the isotopic fractionation once the reaction has gone to completion. Isotopic fractionation is observable only under conditions of partial consumption of the substrate pool, or in an open system with continuous addition of substrate or removal of product as the reaction proceeds. The openness of a system, i.e., the degree to which it exchanges nitrogen with the rest of the world, has important implications for its isotopic systematics (Wu *et al.,* 1997; Sigman *et al.,* 1999) and is a critical consideration in the design and interpretation of isotopic studies of ecosystems.
Figure 29.1 Changes in $\delta^{15}N$ of nitrate and phytoplankton biomass in a closed system during phytoplankton growth and consumption of nitrate with an isotope discrimination facter (ϵ) of 5‰. As phytoplankton grow, the $\delta^{15}N$ of the residual nitrate and phytoplankton biomass pool both increase, as does the $\delta^{15}N$ of the biomass formed at any instant ("phytoplankton production").

2.3. Isotopic fractionation and oceanic nitrogen

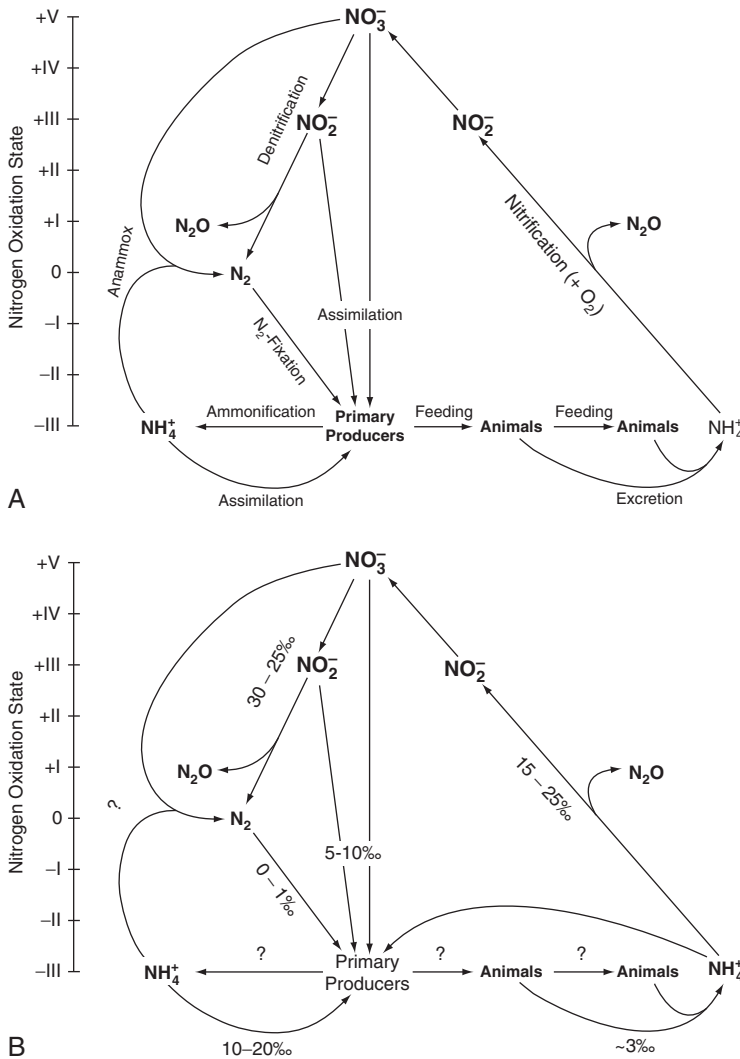
As an isotopic system, the nitrogen cycle is quite complex, with multiple pathways, many with significant isotopic fractionation, connecting many of the pools of interest (Fig. 29.2). From a process point of view, primary producers clearly play a central role by assimilating inorganic nitrogen and injecting it into the food web, where it may be passed from one organism to another through trophic interactions before being ultimately remineralized (Fig. 29.2A). The isotopic point of view is somewhat different since the strongest fractionations are associated with dissimilatory processes that do not move nitrogen directly into or through the food web (Fig. 29.2B), but rather from one inorganic pool to another. For example, denitrification (dissimilatory nitrate reduction) converts NO_3^- to N_2, which has the net effect of depleting the ocean's supply of combined nitrogen and doing so with strong discrimination against ^{15}N. This results in an increase in the $\delta^{15}N$ of the major pool of oceanic combined nitrogen (NO_3^-) concomitant with a reduction in its overall size. In contrast, N_2-fixation adds combined nitrogen with a low $\delta^{15}N$ to the ocean, counteracting both the mass and isotopic effects of denitrification (Brandes and Devol, 2002).


Figure 29.2 Schematic overview of the marine nitrogen cycle. A: Important species, their oxidation state (vertical axis), and major biological transformations of nitrogen (arrows). B: Typical values of the isotopic enrichment factor (ϵ) are shown for reactions that have been characterized isotopically. Estimates of ϵ were drawn from the available literature on N_2–fixation and the $\delta^{15}N$ of diazotrophs (Carpenter *et al.*, 1997; Delwiche and Steyn, 1970; Hoering and Ford, 1960; Macko *et al.*, 1987; Montoya *et al.*, 2002), denitrification (Barford *et al.*, 1999; Cline and Kaplan, 1975; Delwiche and Steyn, 1970; Mariotti *et al.*, 1981, 1982; McCready *et al.*, 1983; Miyake and Wada, 1971; Voss *et al.*, 2001; Wada, 1980;), nitrification (Delwiche and Steyn, 1970; Mariotti *et al.*, 1981; Miyake and Wada, 1971; Yoshida, 1988), NO_3^- uptake (Montoya and McCarthy, 1995; Needoba *et al.*, 2003; Needoba and Harrison, 2004; Pennock *et al.*, 1996, 1998; Wada and Hattori, 1978; Waser *et al.*, 1998a, 1998b;), NO_2^- uptake (Wada and Hattori, 1978; Wada, 1980), NH_4^+ uptake (Cifuentes *et al.*, 1989; Montoya *et al.*, 1991; Pennock *et al.*, 1988; Wada, 1980; Wada and Hattori, 1978), and zooplankton excretion (Checkley and Miller, 1989).

2.3.1. Nitrate

Nitrate is the largest pool of combined nitrogen in the ocean, with deep water concentrations around 20 to 30 μmol L^{-1} in the Atlantic and up to 45 μmol L^{-1} in the Pacific. The isotopic composition of the NO_3^- pool is affected by a variety of processes that move N in and out of the ocean or its biota (Fig. 29.3), and subsurface NO_3^- acts as a critical isotopic end member for biological production in the upper water column. Of the processes shown in Fig. 29.3, pelagic denitrification and N_2–fixation are generally viewed as the major, long-term controls on the size and isotopic composition of the oceanic pool of NO_3^- (Brandes and Devol, 2002).

Under suboxic conditions, microbial nitrate respiration is an important energetic pathway that ultimately leads to removal of combined N from the ocean. This process is accompanied by strong isotopic discrimination (Barford *et al.,* 1999; Brandes *et al.,* 1998; Cline and Richards, 1972; Mariotti *et al.,* 1981; McCready *et al.,* 1983; Voss *et al.,* 2001), so the partial consumption of NO_3^- that typically occurs during pelagic denitrification in the large oceanic Oxygen Minimum Zones (OMZs) has a strong impact on the $\delta^{15}N$ of the residual NO_3^- pool (Fig. 29.3). In contrast, sedimentary denitrification generally results in complete consumption of NO_3^-, whether it diffuses in from the overlying seawater or is generated *in situ*
Figure 29.3 Schematic showing the impact of different processes on the $\delta^{15}N$ of oceanic NO_3^-. The trajectories for denitrification, nitrate uptake, and sedimentary denitrification were each calculated using a closed-system Rayleigh model with an isotope discrimination factor (ϵ) in the middle of the range given in Fig. 29.2. The two nitrification trajectories shown were calculated with a mass balance model for remineralization and nitrification of organic matter produced from average deep water NO_3^-, or diazotrophic organic matter with a $\delta^{15}N$ of -2‰ (Montoya *et al.,* 2002).

through nitrification of ammonium produced in the sediments (Brandes and Devol, 1997, 2002). As a result, sedimentary denitrification results in no expression of the strong isotopic fractionation associated with the denitrification process itself (Fig. 29.1), making this loss term isotopically invisible (Fig. 29.3).

Nitrification is another process that discriminates strongly between the nitrogen isotopes (Delwiche and Steyn, 1970; Miyake and Wada, 1971; Mariotti $et\ al.,$ 1981; Yoshida, 1988) as microbes oxidize NH_4^+ to NO_3^- under oxic conditions. Nitrification is a critical process in the remineralization of organic matter and its conversion to NO_3^-, so this isotopic fractionation could potentially be a source of ^{15}N–depleted NO_3^- in the water column (Ostrom $et\ al.,$ 1997; Sutka $et\ al.,$ 2004). In the upper and mid water column of oligotrophic waters, however, a situation similar to the case of sedimentary denitrification applies: nitrification typically goes to completion, leaving behind little or no residual substrate (NH_4^+) in solution. As a result, nitrification simply transfers the nitrogen initially present in NH_4^+ into the NO_3^- pool along with its isotopic signature. When the organic matter remineralized is itself derived from deep water NO_3^-, then there is no net impact on the $\delta^{15}N$ of NO_3^- when remineralization and nitrification occur (Fig. 29.3). In contrast, when the organic matter is derived from an isotopically distinct pool of nitrogen (e.g., diazotroph biomass), remineralization and nitrification can lead to a significant change in the $\delta^{15}N$ of the ambient NO_3^- pool (Fig. 29.3).

In summary, the $\delta^{15}N$ of NO_3^- acts as an integrator of the major biological sinks and sources of nitrogen within a water column. As shown in Fig. 29.3, pelagic denitrification and N_2-fixation are the major processes that strongly alter the $\delta^{15}N$ of oceanic NO_3^-. Denitrification reduces the size of the oceanic pool of NO_3^- while increasing its $\delta^{15}N$. In contrast, N_2-fixation lowers the $\delta^{15}N$ of NO_3^- while increasing the overall size of the pool of oceanic combined nitrogen. Both processes generate isotopic signatures that can propagate into other components of the ecosystem, including the near surface biota (Voss $et\ al.,$ 2001; McClelland $et\ al.,$ 2003; Montoya $et\ al.,$ 2002;) and benthic sediments (Altabet $et\ al.,$ 1995; Ganeshram $et\ al.,$ 1995). In effect, the isotopic discrimination associated with these ecosystem-level processes creates isotopic signals that can potentially be exploited to study the nitrogen cycle on a broad variety of spatial and temporal scales.

2.3.2. Particulate organic matter

Most marine autotrophs require combined nitrogen as a substrate for growth, making the oceanic pool of NO_3^- a critical determinant of the isotopic composition of the biota. Phytoplankton express significant isotopic discrimination during uptake of NO_3^- (Montoya and McCarthy, 1995; Waser $et\ al.,$ 1998a,b; Needoba $et\ al.,$ 2003; Needoba and Harrison, 2004), leading to production of biomass depleted in ^{15}N relative to the available substrate and progressive enrichment of the residual NO_3^- as uptake proceeds (Fig. 29.1). In most waters, however, the complete consumption of nutrients entering the upper water column results in production of biomass with a $\delta^{15}N$ that reflects that of the NO_3^- entering the mixed layer, though a gradient in NO_3^- concentration and $\delta^{15}N$ is generated at the base of the mixed layer (Altabet $et\ al.,$ 1986).

Not all marine producers are dependent on NO_3^- uptake to sustain growth. A variety of prokaryotes are able to reduce and assimilate N_2 into biomass, making them potentially independent of existing pools of combined nitrogen in the ocean. These N_2-fixers, or diazotrophs, are taxonomically diverse and include a variety of cyanobacteria and bacteria (Zehr et al., 1998, 2000, 2001; Langlois et al., 2005). N_2-fixation is accompanied by only modest isotopic discrimination (Hoering and Ford, 1960; Delwiche and Steyn, 1970; Macko et al., 1987), so diazotroph organic matter is slightly depleted relative to atmospheric N_2, which is used as the standard reference material for nitrogen isotope measurements and therefore has a $\delta^{15}N$ of 0‰ by definition. Field measurements show that marine diazotrophs, including the colonial cyanobacterium Trichodesmium as well as diatom–diazotroph assemblages all have a $\delta^{15}N$ of -1 to -2‰ (Carpenter et al., 1997; Montoya et al., 2002).

Finally, the role of remineralization and recycling of nitrogen within the upper water column deserves consideration. This recycling pathway is quite efficient in the sense that NH_4^+ does not accumulate in significant quantity in the mixed layer of oceanic systems. As a result, remineralization simply redistributes nitrogen among the different components of the bulk field of particulate organic matter and does not appear to have a significant impact on the distribution of isotopes in the upper water column.

2.3.3. Animals and food webs

Animals consistently show a "trophic" enrichment in ^{15}N abundance in which the tissues of a consumer have a $\delta^{15}N$ that is 2–4‰ higher than the $\delta^{15}N$ of the animal's food (DeNiro and Epstein, 1981; Fry, 1988; Minagawa and Wada, 1984; Montoya et al., 1990, 1992, 2002; Mullin et al., 1984; Wada et al., 1987;). The physiological and biochemical processes that generate this trophic effect are not well understood, though excretion of isotopically depleted NH_4^+ appears to play a primary role in enriching animals tissues in ^{15}N (Bada et al., 1989; Gannes et al., 1997).

An animal at isotopic steady state must consume and release nitrogen with the same average $\delta^{15}N$. These isotopic fluxes are not well characterized for any animal (Gannes et al., 1997, 1998), let alone marine zooplankton, but a generally consistent picture has emerged from two independent lines of evidence summarized in Fig. 29.4. First, little isotopic fractionation occurs during ingestion and assimilation of food, which results in production of fecal pellets with a $\delta^{15}N$ typically similar to that of the food (Altabet and Small, 1990; Checkley and Entzeroth, 1985; Montoya et al., 1992). Second, because marine animals typically produce NH_4^+ as their major nitrogenous waste product, the primary driver of the trophic effect in marine ecosystems appears to be the isotopic fractionation associated with production of NH_4^+ through deamination of proteins and amino acids (Bada et al., 1989; Macko et al., 1986). Loss of the isotopically depleted NH_4^+ generated through deamination will tend to increase the $\delta^{15}N$ of the remaining organic nitrogen within an animal's tissues (Fig. 29.4).

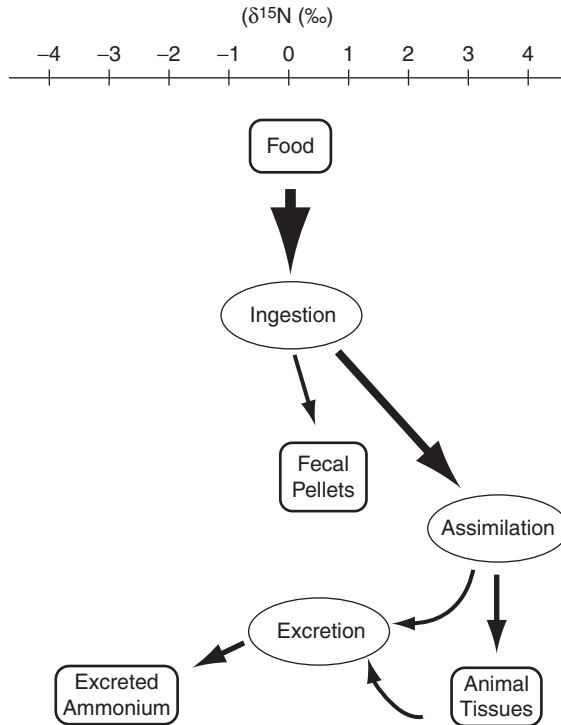
One interesting implication of the qualitative model shown in Fig. 29.4 is that the size of the trophic effect is a function of the partitioning of assimilated nitrogen between new biomass and excreta. The greater the excretory losses, the greater the difference in $\delta^{15}N$ between an animal and its food. This implies that the "trophic


Figure 29.4 Schematic showing the major steps in the processing of nitrogen by an animal. Arrows represent fluxes of nitrogen, ovals label processes, and rectangles show important pools of nitrogen. Limited or no isotopic fractionation appears to occur in connection with the assimilation of food (Altabet and Small, 1990; Checkley and Entzeroth, 1985; Montoya *et al.*, 1992). In contrast, deamination reactions, which play a central role in excretion by marine animals, fractionate significantly (Bada *et al.*, 1989; Macko *et al.*, 1986). The net result of this process is to partition the ingested nitrogen between animal tissues that are enriched in ^{15}N relative to the food and excreted NH_4^+ with a $\delta^{15}N$ lower than that of the food.

effect'' is more a measure of nitrogen transfer efficiency from food to tissues than a measure of the animal's average trophic position. Viewed in slightly different terms, the increase in $\delta^{15}N$ between an animal's food and its tissues is really a measure of the animal's net growth efficiency rather than trophic position as such.

3. ANALYTIC CONSIDERATIONS

The increasing availability of mass spectrometers and on-line interfaces for sample preparation has made ^{15}N natural abundance measurements accessible to a broad community of biological oceanographers, and stable isotope measurements are becoming a routine tool in studies of marine ecosystems. In general, ^{15}N measurements are now carried out with continuous flow systems that integrate a

preparatory system (e.g., an elemental analyzer) with a mass spectrometer (Barrie *et al.,* 1990; Owens and Rees, 1989). The mass spectrometer typically measures the isotopic composition of N_2 generated by combustion and carried in a stream of He gas to an open split interface that introduces a small fraction of the gas stream into the ion source for measurement. This analytical approach generally requires little or no manipulation of organic samples, though rigorous care must be taken to avoid contamination with exogenous nitrogen, particularly when tracer-level ^{15}N experiments are being carried out in the vicinity (see Lipschultz, Chapter 31, this volume). Since N_2 is typically the analyte, the reduction of atmospheric contamination in the preparatory system is also quite important.

Samples of oceanographic interest often pose additional analytical challenges simply because they are difficult to obtain in large quantities and most mass spectrometry systems require fine-tuning and careful attention to leaks in order to process samples containing less than a few micromoles of nitrogen. In practice, open ocean samples including suspended particles, small zooplankters, and sinking organic matter are often available only in μmole or sub-μmole quantities. This creates a strong incentive to minimize the mass requirements of the analytical systems used for marine samples, and to develop methods for correcting for the influence of any analytical blank, which will disproportionately affect small samples. Even with substantial care to reduce this source of contamination, a nitrogen blank on the order of 0.05–0.15 μmol N is typical for systems in current use. For analysis of the smallest samples, the influence of this blank can be removed numerically provided that an appropriate range of mass and isotopic standards is run, allowing estimation of the size and $\delta^{15}N$ of the blank.

3.1. Blank corrections: Theory

Operationally, isotope ratio mass spectrometers measure the difference in ^{15}N abundance between a sample and a reference gas calibrated to atmospheric N_2. This reference gas calibration may be carried out directly by comparison to atmosphere scrubbed of O_2 (Mariotti, 1983), or indirectly using any of a number of organic and inorganic secondary standards (e.g., nitrate and ammonium salts, acetanilide, glutamic acid) available from NIST or IAEA. For precise system calibration and correction of blank effects, it is also important to analyze a size series of a working standard that is chemically similar to the samples of interest. Although many samples are now analyzed by fee-for-service facilities that carry out these corrections for individual investigators, an understanding of the blank correction methodology is helpful in the interpretation of isotopic data and provides a framework for carrying out any isotope mass balance calculation (e.g., mixing models to resolve isotopically distinct source contributions).

Correcting for an analytical blank is a multi-step process involving separate regression analyses to evaluate the size of the blank and the dependence of $\delta^{15}N$ values on size. This information can then be used in a mass balance model to remove the isotopic influence of the blank. In general, the nitrogen analytical blank is small enough that blank corrections are minor for samples containing more than 1.5–2 μmol of nitrogen.

Any real sample can be treated as a mixture of sample material and contaminants of various origins. If the blank contribution is constant in composition and magnitude across analyses, then a simple mass balance can be constructed for the mixture analyzed:

$$M_{\text{mix}}\delta^{15}N_{\text{mix}} = M_{\text{sample}}\delta^{15}N_{\text{sample}} + M_{\text{blank}}\delta^{15}N_{\text{blank}} \tag{29.8}$$

where M_X is the size of an individual pool X (sample, blank, or the mixture). Since M_{mix} is just the sum of the other masses, Eq. (29.8) can be easily rearranged to produce an expression for $\delta^{15}N_{\text{sample}}$:

$$\delta^{15}N_{\text{sample}} = \left(\frac{M_{\text{mix}}\delta^{15}N_{\text{mix}} - M_{\text{blank}}\delta^{15}N_{\text{blank}}}{M_{\text{mix}} - M_{\text{blank}}} \right) \tag{29.9}$$

which can be used to extract the $\delta^{15}N$ of the sample independent of the analytical blank. To do so, the size of the blank and its isotopic composition must be measured independently, which is straightforward provided that size series of standards of known elemental and isotopic composition are included in each analytical run.

3.2. Measurement of sample and blank size

We use separate standards, methionine and peptone, interspersed in each analytical run to estimate the mass and isotopic composition of the blank. The separate standards provide some redundancy since both blank parameters can be estimated independently with each standard. In practice, calibrating the mass response of the mass spectrometer and the size of the blank require pure standards of known elemental composition and mass, while the isotopic composition of the blank can be readily measured by analyzing an isotopic standard whose elemental composition is less well constrained (e.g., peptone).

We use precisely weighed samples of methionine or another pure nitrogenous compound to calibrate the mass response of the analytical system. Sample size is typically measured as the integrated response (beam area) of the mass spectrometer ion collectors, and a regression of beam area as a function of the known nitrogen content of the sample will yield a good estimate of both the system sensitivity (slope of the regression) and the size of the blank (intercept of the regression), M_{blank}. These quantities in turn allow calculation of the size of any sample or standard analyzed.

Once the size of the blank is known, its isotopic composition ($\delta^{15}N_{\text{blank}}$) can be calculated from analysis of a range of sizes of a standard of uniform isotopic composition (e.g., peptone). A regression of the $\delta^{15}N$ measured as a function of the inverse of the size of the analytes will have the form:

$$\delta^{15}N_{\text{mix}} = \delta^{15}N_{\text{sample}} + \left(\frac{1}{M_{\text{mix}}} \right) \times M_{\text{blank}}(\delta^{15}N_{\text{blank}} - \delta^{15}N_{\text{sample}})$$

$$\tag{29.10}$$

which is simply a rearrangement of Eq. (29.8). This regression will have an intercept equal to the true $\delta^{15}N$ of the standard and a slope equal to the term:

$$\text{Slope}(\text{Eq.}(29.10)) = M_{\text{blank}}(\delta^{15}N_{\text{blank}} - \delta^{15}N_{\text{standard}}) \qquad (29.11)$$

which can be rearranged to give an expression for $\delta^{15}N_{\text{blank}}$ in terms of known or measured quantities:

$$\delta^{15}N_{\text{blank}} = \delta^{15}N_{\text{standard}} + \left(\frac{\text{slope}(\text{Eq.}(29.10))}{M_{\text{blank}}}\right) \qquad (29.12)$$

Finally, the size and $\delta^{15}N$ of the blank can be used in Eq. (29.9) to correct for the influence of any analytical blank. This approach allows measurement of the $\delta^{15}N$ of small samples with high precision and accuracy. We estimate that the overall error in our measurement is less than 0.15‰ for samples containing more than 0.6 μmol N.

4. ECOSYSTEM LEVEL PATTERNS IN δ^{15}N

The $\delta^{15}N$ of oceanic organic matter shows a number of broad-scale patterns that reflect the impact of nitrogen cycle processes on both a regional and a global level. The simplest application of $\delta^{15}N$ measurements is in resolving the relative contributions of different, isotopically distinct sources of N to biological production. Simple isotopic mixing models can be used to calculate these contributions provided that no more than two end members are important in the system of interest. In general, for a system that depends on two such sources (1 and 2), the $\delta^{15}N$ of any target pool that integrates these two sources will be the weighted average of the source terms:

$$\delta^{15}N_{\text{target}} = X_1 \times \delta^{15}N_1 + X_2 \times \delta^{15}N_2 \qquad (29.13)$$

where X_1 and X_2 represent the fractional contributions of Sources 1 and 2, respectively, to the target pool. Since $X_1 + X_2 = 1$, this equation is easily solved for the contribution of either source pool to the target pool:

$$X_1 = \frac{\delta^{15}N_{\text{target}} - \delta^{15}N_2}{\delta^{15}N_1 - \delta^{15}N_2} \qquad (29.14)$$

$$X_2 = \frac{\delta^{15}N_{\text{target}} - \delta^{15}N_1}{\delta^{15}N_2 - \delta^{15}N_1} \qquad (29.15)$$

Note that Eq. (29.13) is simply a general case of the isotope mixing model used in blank corrections above (Eq. (29.8)) and is applicable to any situation in which a

mixture is derived from two isotopically distinct pools. This approach can be extended to food web studies with the inclusion of a trophic effect to account for the increase in $\delta^{15}N$ with trophic position (Montoya *et al.*, 2002).

Next, I will examine several examples in which isotopic contrasts provide insight into nitrogen cycle dynamics in different marine environments. Since the choice of system is important in ensuring that isotope budgets are appropriate and tractable, my goal is to provide examples of systems in which $\delta^{15}N$ measurements can be used profitably rather than attempt exhaustive coverage of the diverse and growing literature on nitrogen isotopes in the ocean.

4.1. Terrigenous inputs

On average, the $\delta^{15}N$ of terrestrial organic matter is lower than that of marine nitrogen, an isotopic contrast that can be exploited to trace the impact of terrigenous nitrogen in coastal marine systems (De Brabandere *et al.*, 2002; Heaton, 1986; Rau *et al.*, 1981; Sweeney *et al.*, 1980; Tucker *et al.*, 1999; Van Dover *et al.*, 1992;). This is a particularly interesting area of research given the increasing impact of anthropogenic nitrogen in coastal and nearshore systems. As in any ecosystem, stable isotope studies of nearshore waters require careful consideration of the potential inputs of nitrogen, the possibly complex pathways of nitrogen movement through the system, and the frequent involvement of both sedimentary and water column processes in nitrogen cycling. Nonetheless, isotopic approaches often provide the best tool for linking changes in coastal production or biomass to exogenous nutrient inputs. Rather than relying simply on correlative studies of loading and ecosystem response, ^{15}N budgeting approaches allow tracing of anthropogenic nitrogen as it moves into the biota and through the food web.

The generally low $\delta^{15}N$ of terrestrial systems is typically retained in sludge and particulate matter produced by sewage plants. Nitrogen isotopic studies in a number of coastal systems have demonstrated that this low $\delta^{15}N$ propagates into the benthic food web and can be used to quantify the impact of solid materials in sewage on the nearshore biota (Rau *et al.*, 1981; Spies *et al.*, 1989; Tucker *et al.*, 1999; Van Dover *et al.*, 1992).

When dissolved pools of nitrogen are considered, the isotopic scenario becomes substantially more complicated, often involving multiple sources and pathways to/ from each of the major dissolved pools of nitrogen. The major dissolved forms of nitrogen in sewage, terrestrial runoff, and groundwater are often enriched in ^{15}N because of isotopic fractionation during nitrification and volatilization in the case of NH_4^+, or denitrification in the case of NO_3^- (Heaton, 1986; McClelland and Valiela, 1998b; Schlacher *et al.*, 2005; Sheats, 2000; Voss and Struck, 1997). The degree of isotopic enrichment depends strongly on the details of the system, but terrestrial inorganic nitrogen entering coastal waters often has a $\delta^{15}N$ significantly higher than the $\delta^{15}N$ of marine pools of inorganic nitrogen. This isotopic contrast in turn can be exploited to trace the incorporation of terrigenous nitrogen into various components of nearshore systems including sediments, primary producers, plankton, and fish (Cole *et al.*, 2006; Lapointe *et al.*, 2004, 2005; McClelland *et al.*, 1997; McClelland and Valiela, 1998a,b; Schlacher *et al.*, 2005; Sheats, 2000; Voss and Struck, 1997).

4.2. Nitrogen sources for pelagic primary production

As noted earlier, deep water NO_3^- plays a central role in setting the $\delta^{15}N$ of oceanic biota through its large contribution to primary production. The $\delta^{15}N$ of NO_3^- shows significant regional variation, particularly in oxygen minimum zones where denitrification consumes NO_3^- and raises the $\delta^{15}N$ of the residual NO_3^- (Fig. 29.3 and below). Deep water NO_3^- typically has a $\delta^{15}N$ between 3 and 6‰, with a global average of about 4.8‰ (Liu and Kaplan, 1989; Sigman *et al.*, 2000).

In high latitude systems, the $\delta^{15}N$ of NO_3^- is closely linked to the $\delta^{15}N$ of mixed layer organic matter and spatial variations in the $\delta^{15}N$ of both NO_3^- and particulate organic matter reflect the isotopic fractionation associated with phytoplankton uptake of NO_3^- (Altabet and François, 1994, 2001; Sigman *et al.*, 1999; Wu *et al.*, 1997). Similar variations have been found in the equatorial upwelling system, where consumption of NO_3^- creates a latitudinal gradient in the $\delta^{15}N$ of organic matter (Altabet, 2001). In general, the $\delta^{15}N$ of surface and mixed layer particles varies inversely with NO_3^- concentration in these systems, reflecting the impact of isotopic fractionation during NO_3^- uptake (Fig. 29.1) by primary producers.

On a basin scale, data from the Atlantic Meriodional Transect (AMT) program show clear regional and temporal variations in the $\delta^{15}N$ of particles collected at the surface. Data from two cruises, AMT-3 in September–October 1996 and AMT-10 in April–May 2000, show similar patterns for the North Atlantic but differ markedly south of the equator (Mahaffey *et al.*, 2003, 2004; Mino *et al.*, 2002). During the autumn cruise (AMT-3) the distribution of $\delta^{15}N$ values was similar in both the North and the South Atlantic, with low values in the oligotrophic gyres, near the Equator, and at high southern latitude (Mino *et al.*, 2002). For the transect as a whole, Mino *et al.* (2002) found a strong negative correlation between the $\delta^{15}N$ of surface particles and the depth of the nitracline. This relationship was even stronger when data from stations in the tropical North Atlantic with significant populations of *Trichodesmium* were excluded from the analysis. At these tropical stations, Mino *et al.* (2002) used a mass balance approach to estimate that N_2-fixation contributed at least 38% of the standing stock of nitrogen at the surface. Interestingly, $\delta^{15}N$ values from the tropical South Atlantic were even lower than those from the North Atlantic, but Mino *et al.* did not attempt to estimate the importance of N_2-fixation in that region, presumably because *Trichodesmium* was not observed at those stations (2002). This may deserve reexamination in view of recent molecular and biogeochemical studies highlighting the importance of diazotrophs other than *Trichodesmium* in oligotrophic waters (Montoya *et al.*, 2004; Langlois *et al.*, 2005; Zehr *et al.*, 1998, 2001, 2007; Montoya *et al.*, 2007).

The lowest $\delta^{15}N$ values from the spring cruise (AMT-10) occurred at the northern end of the transect where a phytoplankton bloom was under way and the low values reflected isotopic fractionation during NO_3^- uptake (Mahaffey *et al.*, 2003, 2004). In the oligotrophic gyre of the North Atlantic, low values similar to those reported by Mino et al. (2002) were found and attributed to N_2–fixation (Mahaffey *et al.*, 2003, 2004). In contrast to the general similarity between cruises in the North Atlantic, the data from cruise AMT-10 did not show low $\delta^{15}N$ values in the oligotrophic gyre of the South Atlantic. Mahaffey *et al.* (2004) argued that the uniform $\delta^{15}N$ of particles between the Equator and 40°S implied production based

on NO_3^-. As noted above, the isotopic data from AMT–3 are consistent with a significant input of nitrogen through N_2-fixation in the South Atlantic, which suggests a seasonal or interannual shift between diazotrophy and production based on NO_3^- in that basin. In any case, the difference between hemispheres in the spring is quite striking and deserves additional attention.

The AMT data set provides clear evidence for the regional importance of N_2-fixation, at least in the North Atlantic. This general picture is consistent with a number of other isotopic studies of N_2-fixation in the subtropical North Atlantic (Capone *et al.*, 2005; McClelland *et al.*, 2003; Montoya *et al.*, 2002). In this region, isotope mass balance calculations indicate that N_2-fixation is the dominant source of nitrogen supporting production of mixed layer biomass throughout the western half of the basin (Montoya *et al.*, 2002). The N_2-fixation contribution appears to be particularly high in the southwestern region affected by the plume of the Amazon River, where dense populations of both *Tricho-desmium* and diatom–diazotroph associations occurred (Carpenter *et al.*, 1999) and a mass-balance calculation indicated that N_2-fixation accounted for an average of 68% of the standing stock of particulate nitrogen in the upper 100 m of the water column (Montoya *et al.*, 2002). For a zonal survey across the subtropical North Atlantic, Montoya *et al.* (2002) estimated that 36% of the standing stock of particulate nitrogen was derived from N_2-fixation. This esti-mate agrees very well with that of Mino *et al.* (2002) and implies a regional rate of N_2-fixation of 850 µmol N m^{-2} day^{-1} (Capone *et al.*, 2005). This general approach has also been extended to the zooplankton, though the calculations are complicated by the trophic effect within foodwebs. Nonetheless, Montoya *et al.* (2002) estimated that as much as 60% of the zooplankton standing stock in the southwestern North Atlantic, and 47% of zooplankton biomass in the central part of the basin, was derived from N_2-fixation. Although the movement of diazotroph nitrogen into the food web is not surprising, the trophic linkages and pathways involved are not yet well understood.

The AMT data set provides clear evidence for both spatial and temporal changes in $\delta^{15}N$ on a broad scale in the Atlantic. In this context, it's worth noting that a recent study carried out at the Bermuda Atlantic Time Series (BATS) station has shown a limited role for N_2-fixation in the annual nitrogen budget there (Knap *et al.*, 2005), suggesting that this process may be less important in the northern portions of the Subtropical Atlantic. This is in sharp contrast to findings at the Hawaii Ocean Timeseries (HOT) station, which has produced the longest and most detailed time series of upper ocean $\delta^{15}N$ available to date. At the HOT station, Dore *et al.* (2002) have measured the $\delta^{15}N$ of sinking particles for a period extending from 1989 to 2001. Over this interval, the $\delta^{15}N$ of sinking organic matter at HOT varied seasonally and the twelve year record shows a clear secular trend of decreasing $\delta^{15}N$ with time (Dore *et al.*, 2002). A mass balance calculation allowed Dore *et al.* (2002) to estimate that N_2-fixation accounted for about half of the total export production at Station ALOHA over this time period, with the remainder supported by NO_3^- injected into the mixed layer from below (see Karl *et al.*, Chapter 16, this volume).

4.3. Impact of denitrification on water column nitrogen

Denitrification is the largest loss term for oceanic nitrogen and plays a key role in regulating the availability of combined nitrogen in the ocean on long time scales (Codispoti *et al.,* 2001; Codispoti, 2007) (see Devol, Chapter 6, this volume). While sedimentary denitrification is unlikely to alter the $\delta^{15}N$ of oceanic NO_3^- (Fig. 29.3), pelagic denitrification plays a central role in the isotopic balance of the ocean since it does not typically go to completion and therefore produces residual NO_3^- with an elevated $\delta^{15}N$ (Fig. 29.3 and Section 2.3.1).

Both NO_3^- and particles in and near the major oceanic denitrifying regions have a $\delta^{15}N$ that is high relative to typical open ocean values (Brandes *et al.,* 1998; Cline and Richards, 1972, 1975; Liu and Kaplan, 1989; Sutka *et al.,* 2004; Voss *et al.,* 2001). Within the oxygen minimum zones (OMZs) proper, the $\delta^{15}N$ of NO_3^- varies with the NO_3^- deficit, frequently approaching 20‰ in the core of the OMZ (Brandes *et al.,* 1998; Cline and Kaplan, 1975; Voss *et al.,* 2001). This elevated $\delta^{15}N$ signature can propagate into suspended particles in the water column, presumably through vertical mixing and injection of ^{15}N-enriched NO_3^- into the surface mixed layer, where it can in turn be consumed by primary producers (Voss *et al.,* 2001; Montoya and Voss, 2006). Although the further movement of this isotopic signature into animals has not been investigated in detail, this strong isotopic signal may provide a useful tool for investigating food web dynamics in and near the productive waters above the major OMZs in the world ocean.

The high $\delta^{15}N$ generated within the major oceanic OMZs can also propagate substantial distances horizontally through advective processes. For example, the high $\delta^{15}N$ generated in the Eastern Tropical North Pacific may affect ecosystems hundreds or thousands of kilometres away from the OMZ proper (Liu and Kaplan, 1989; Montoya and Voss, 2006; Saino and Hattori, 1987; Sutka *et al.,* 2004). The location of the major OMZs either adjacent to (Eastern Tropical Pacific) or within (Arabian Sea) oligotrophic regions where N_2-fixation can play a large role in supporting primary production creates a very strong regional isotopic contrast. This is particularly notable in the Arabian Sea, where dense blooms of *Trichodesmium* occur directly above a major OMZ (Capone *et al.,* 1998), creating very strong isotopic contrasts between the surface layer and the waters below (Montoya and Voss, 2006). These isotopic gradients provide what are in effect large scale tracer experiments that can be exploited in studies of the nitrogen cycle on a basin scale.

5. CURRENT CHALLENGES AND OPPORTUNITIES

Nitrogen isotope measurements are becoming increasingly accessible to the oceanographic community and large field programs (e.g., HOT and AMT) now routinely include the $\delta^{15}N$ of particulate organic matter as a core measurement. The two examples discussed above have generated the broadest spatial (AMT program) and temporal (HOT program) coverage of nitrogen isotopic variation in the ocean.

Extending these studies to other regions and other components of marine ecosystems, including the pelagic food web and microbial community, is an ongoing challenge. Several specific examples of open questions and opportunities for research in nitrogen isotope biogeochemistry follow.

5.1. Isotope budgets

Animals show a consistent enrichment in ^{15}N relative to their food, but the factors and processes that generate this trophic effect are not yet well understood. I argue above (Section 2.3.3) that the magnitude of the trophic effect should depend on the partitioning of nitrogen between growth and catabolism in individual animals. Stable isotope measurements may thus provide a novel tool for quantifying the net growth efficiency of animals in the field, but this application will require a more detailed understanding of the ways that animals fractionate the nitrogen isotopes. A complete isotope budget for a representative zooplankter would provide the theoretical framework for understanding and interpreting the trophic effect quantitatively. In addition, a mechanistic understanding of isotope fractionation in animals will greatly facilitate the interpretation of temporal variations in δ^{15}N associated with animal growth. Both of these applications would allow use of stable isotope measurements in studies of trophic structure and energy flow in marine ecosystems.

On a broader scale, ecosystem–level isotope budgets can provide insight into the major fluxes of nitrogen in and out of the ocean. For the ocean as a whole, the overall δ^{15}N of combined nitrogen must be strongly affected by the balance between N_2-fixation and pelagic denitrification since these two processes have opposing effects on both the nitrogen content and isotopic composition of oceanic nitrogen. Brandes and Devol (2002) have used an oceanic nitrogen isotope budget to estimate a global rate of sedimentary denitrification on the order of 280 Tg N year^{-1}. For the oceans to be at or near steady state, this high a loss rate would require an oceanic N_2-fixation rate several times greater than even the highest among current estimates (Capone *et al.,* 2005; Lee *et al.,* 2002; Montoya *et al.,* 2004). While the ocean may indeed be out of steady state today, a flux imbalance of the magnitude implied by this isotope budget could not be sustained for long without significantly reducing the overall oceanic inventory of combined nitrogen (Brandes and Devol, 2002). The isotope budgeting approach is sensitive to the δ^{15}N of both NO_3^- in the ocean and the N_2 produced through denitrification. Increased spatial coverage of δ^{15}N measurements, particularly in and near the major denitrifying zones will be important in refining oceanic isotope budgets and improving the flux estimates they produce. Similarly, direct experimental measurement of the δ^{15}N of nitrogen lost through denitrification will be very important in resolving the current state of the oceanic nitrogen budget, particularly the magnitude of denitrification removing nitrogen from the ocean.

5.2. Analytical advances

Automation and reduced sample size requirements are both important factors in making stable isotope measurements practical in oceanographic studies. New generation instrumentation is compact, often modular in design, and contains relatively

few mechanical parts (e.g., the Isoprime). In addition to the increased availability and flexibility of isotope ratio mass spectrometers, the variety of specialized, automated systems for sample preparation is expanding. Although isotope ratio mass spectrometers still require too much fine-tuning and care to be treated as turnkey systems, it is becoming increasingly feasible for an individual investigator to acquire a dedicated system for his/her lab group. Stable nitrogen isotope measurements are well on their way to being a routine, if not always straightforward, analytic tool in ocean science.

A number of recent developments have extended the range of environments where stable isotope budgets can be applied to studies of the nitrogen cycle. For example, the ''denitrifier'' method for extracting nitrate for isotopic analysis has greatly reduced the quantity of nitrate required for analysis (Sigman *et al.,* 2001) and has allowed measurement of the $\delta^{15}N$ of nitrate in profiles extending into the upper part of the nitracline (e.g., Knapp *et al.,* 2005). By combining this approach with a persulfate oxidation step, Knapp *et al.* (2005) have been able to measure the $\delta^{15}N$ of both nitrate and dissolved organic nitrogen in the upper water column at the Bermuda Atlantic Time Series site. Taken together, these methodological developments hold great promise for ongoing efforts to use nitrogen isotope budgets in constraining the magnitude of processes such as N_2-fixation and denitrification.

Our current knowledge of the isotopic systematics of marine systems is largely based on analysis of bulk samples of organic and inorganic nitrogen. Measurements of the carbon isotopic composition ($\delta^{13}C$) of specific biomarker molecules has been very important in paleoceanographic and carbon cycle studies, but the relatively low abundance of nitrogen relative to carbon and the analytical challenges inherent in isolating and analyzing nitrogenous compounds have both slowed the use of this biomarker approach in nitrogen cycle studies. In recent years, methodological advances have made it feasible to measure the $\delta^{15}N$ of a spectrum of amino acids isolated from relatively small samples of organic matter (Macko and Uhle, 1997; Metges *et al.,* 1996; Metges and Petzke, 1997). Lab and field studies with marine zooplankton have shown that the $\delta^{15}N$ of individual amino acids varies systematically within animals with a much larger dynamic range than is typically seen for bulk organic mattter (McClelland *et al.,* 2003; McClelland and Montoya, 2002). Interestingly, some amino acids (e.g., phenylalanine) provide a record of the $\delta^{15}N$ of the primary producers at the base of the food web, while others (e.g., glutamic acid) show a strong trophic effect (McClelland and Montoya, 2002). This means that the tissues of an animal contain isotopic information on both the sources of nitrogen supporting biological production and the overall trophic distance (or nitrogen transfer efficiency) between the primary producers and the animal sampled. McCarthy *et al.* have extended this approach to sedimenting organic matter and have found that the variance in $\delta^{15}N$ among different amino acids appears to provide additional information on the type of heterotroph responsible for consuming and reworking sinking organic matter (McCarthy *et al.,* 2007). Sample preparation for compound-specific isotope analysis is still quite complex, as is the gas chromatography/mass spectrometry analysis itself, but this biomarker approach shows great promise for extending the range of processes and rates that can be assessed with stable isotope measurements.

5.3. Conclusions

Stable isotope natural abundance measurements have the great advantage of providing information on nitrogen cycle processes with little or no manipulation of the system, in contrast to tracer-based rate measurements (see Lipschultz, Chapter 31, this volume). The natural abundance and tracer approaches are strongly complementary, providing insight into the nitrogen cycle on very different spatial and temporal scales. Nonetheless, a number of important caveats must be considered in any application of stable isotope natural abundance measurements:

1. Stable isotope measurements are useful in resolving the contribution of isotopically distinct sources of nitrogen entering a system, but both spatial and temporal variation in the isotopic composition of those sources must be considered and factored into the study design.
2. The magnitude of processes that have distinctive isotopic fractionation patterns can potentially be quantified if the fractionations are known accurately. There is a significant ongoing need for careful measurement of isotopic fractionation patterns under controlled laboratory conditions as well as under field conditions.
3. The openness of the system and the nature of its exchanges with the outside world must be known in order to interpret isotopic distributions and trends and to construct meaningful isotopic budgets.

With these caveats in mind, natural abundance measurements can provide an inherently integrative measure of nitrogen cycle processes while effectively sampling the ocean on a time scale defined by the turnover time of the pool of interest. The increased availability of the necessary instrumentation coupled with reductions in the size of sample required for analysis now make it feasible to include nitrogen stable isotope measurements in virtually any field program. Recent advances in compound specific nitrogen isotope analyses show great promise for adding an additional level of detail to our knowledge of the nitrogen cycle.

At this point, we have a reasonably good general idea of the characteristic spatial and temporal patterns of variation in the $\delta^{15}N$ of the major oceanic pools of nitrogen, but we still lack a complete theoretical framework for interpreting stable isotope measurements. There is a fundamental need for basic laboratory studies focused on the pathways and processes that generate the clear patterns we see in the $\delta^{15}N$ of marine nitrogen.

The growing set of $\delta^{15}N$ measurements make it increasingly feasible and interesting to incorporate isotopic constraints into ecosystem and biogeochemical models of nitrogen in the ocean. This is both a sign of maturity in the field and a reason to take stock of our sampling and analytical practices. Potential differences among labs clearly need to be considered when combining data sets for inclusion in basin or global scale models, but I am not aware of any systematic effort to intercalibrate measurements made by different groups working on the isotope biogeochemistry of oceanic nitrogen. In a similar vein, our current knowledge of the $\delta^{15}N$ of marine nitrogen is strongly biased toward bulk particulate organic matter collected in the North Atlantic, at HOT, and in a few other regions of the ocean (e.g., the Eastern

Tropical North Pacific and the Arabian Sea). A robust isotope budget for the ocean will require extension of these sampling efforts to other waters.

Time series of measurements from a variety of locations will also greatly enhance the utility of nitrogen isotope measurements, particularly in quantifying the flux of nitrogen through the biota during blooms and other transient events. These are effectively natural tracer experiments created by isotopic fractionation during phytoplankton consumption of inorganic nitrogen and provide an ecosystem-level analog to the short-term tracer experiments typically carried out in small volumes aboard ship. Complementing nitrogen stable isotope measurements with focused rate measurements may ultimately provide the best strategy for studying the dynamics of the nitrogen cycle on both short and long temporal and spatial scales.
